CHAPTER 4 - REACTOR

4.0 INTRODUCTION

This chapter was prepared using topical report, "General Electric Standard Application for Reactor Fuel" (GESTAR-II) including the "United States Supplement," NEDE-24011-P-A-32 and NEDE-24011-P-A-32-US. Applicable sections of this report are referenced as noted in Sections 4.1 through 4.4.

4.1 SUMMARY DESCRIPTION

The reactor assembly consists of the reactor vessel, its internal components of the core, steam separator and dryer assemblies, and jet pumps. Also included in this assembly are the control rods, CRD housings, and the CRDs. Figure 3.9-4 shows the arrangement of reactor assembly components. A summary of the important design and performance characteristics is given in Section 1.3. Loading conditions for reactor assembly components are discussed in Section 3.9.

4.1.1 REACTOR VESSEL

The reactor vessel design and description is discussed in Section 5.3.

4.1.2 REACTOR INTERNAL COMPONENTS

The major reactor internal components are the core (fuel, channels, control blades, and incore instrumentation), core support structure (including the shroud, top guide, and core plate), shroud head and steam separator assembly, steam dryer assembly, feedwater spargers, core spray spargers, and jet pumps. Except for the Zircaloy in the reactor core, these reactor internals are made of stainless steel or other corrosion-resistant alloys. Of the preceding components, the fuel assemblies (including fuel rods and channel), control blades, incore instrumentation, shroud head and steam separator assembly, steam dryers and jet pump subassemblies are removable when the reactor vessel is open.

4.1.2.1 Reactor Core

4.1.2.1.1 General

The design of the BWR core (including fuel) is based on the proper combination of many design variables and operating experience. This contributes to the achievement of high reliability.

Important features of the reactor core arrangement are as follows:

a. The bottom-entry control blades are cruciform-shaped and consist of stainless steel clad neutron absorbing material as described in Section 4.2. The neutron-absorbing material is surrounded by a stainless steel sheath in the conventional designs. In the newer designs, (e.g., GE Marathon Series) the absorber tube and sheath arrangement is replaced with an array of welded square tubes containing the neutron absorbing material.

b. Fixed incore fission chambers provide continuous power range neutron flux monitoring. A guide tube in each incore assembly provides for a traversing ion chamber for calibration and axial detail. Source and intermediate range detectors are located incore and are axially retractable. The incore location of the startup and source range instruments provides coverage of the large reactor core and provides an acceptable signal-to-noise ratio and neutron-to-gamma ratio. All incore instrument leads enter from the bottom. Source and intermediate range instruments are in service during refueling. Incore instrumentation is further discussed in Section 7.6 and 7.7.

c. Experience has shown that the operator, utilizing the incore flux monitoring system, can maintain the desired power distribution within a large core by proper control rod positioning.

d. The reusable channels provide a fixed flow path for the boiling coolant, serve as a guiding surface for the control rods, and protect the fuel during handling operations.

e. Mechanical reactivity control permits criticality checks during refueling and provides maximum plant safety. The core is designed to be subcritical at any time in its operating history, with any one control rod fully withdrawn.

f. The selected control rod pitch represents a practical value of individual control rod reactivity worth, and allows adequate clearance below the pressure vessel, between CRDMs, for ease of maintenance and removal.

4.1.2.1.2 Core Configuration

The reactor core is arranged as an upright circular cylinder containing a large number of fuel cells, and is located within the reactor vessel. The coolant flows upward through the core. The core arrangement (plan view) and the lattice configuration are given in Section 4.3.2.

4.1.2.1.3 Fuel Assembly Description

Descriptions of the fuel assembly and the fuel rods are given in Section 4.2.

4.1.2.1.4 Fuel Assembly Support and Control Rod Location

Twenty four peripheral fuel assemblies and their individual peripheral fuel support pieces are supported by the core plate. Otherwise, individual fuel assemblies in the core rest on fuel support pieces mounted on top of the control rod guide tubes. Each guide tube, with its fuel support piece, bears the weight of four assemblies, and is supported by a CRD penetration nozzle in the bottom head of the reactor vessel. The core plate provides lateral support and guidance at the top of each control rod guide tube.

The top guide, mounted inside the shroud, provides lateral support and guidance for each fuel assembly. The reactivity of the core is controlled by cruciform-shaped control rods (Section 4.2.2) and their associated mechanical-hydraulic drive system. The control rods occupy alternate spaces between fuel assemblies. Each independent CRD enters the core from the bottom, accurately positions its associated control rod during normal operation, and yet exerts approximately ten times the force of gravity to insert the control rod during the scram mode of operation. Bottom-entry allows optimum power shaping in the core, ease of refueling, and convenient CRD maintenance.

4.1.2.2 Shroud

Information on the shroud is contained in Section 3.9.5.

4.1.2.3 Shroud Head and Steam Separator Assembly

Information on the shroud head and steam separators is contained in Section 3.9.5.

4.1.2.4 Steam Dryer Assembly

Information on the steam dryer assembly is contained in Section 3.9.5.

4.1.3 REACTIVITY CONTROL SYSTEMS

4.1.3.1 Operation

The control rods perform dual functions of power distribution shaping and reactivity control. Power distribution in the core is controlled during operation of the reactor by manipulation of selected patterns of rods. The rods, which enter from the bottom of the near-cylindrical reactor core, are positioned to counterbalance steam voids in the top of the core and effect significant power flattening. These groups of control elements, used for power flattening, experience a somewhat higher duty cycle and neutron exposure than the other rods in the control system.

The reactivity control function requires that all rods be designed for both reactor scram and reactivity regulation. Because of this, the control elements are mechanically designed to withstand the dynamic forces resulting from a scram. They are connected to bottom-mounted, hydraulically actuated drive mechanisms which allow either axial positioning for reactivity regulation, or rapid scram insertion. The design of the rod-to-drive connection permits each blade to be attached or detached from its drive, without disturbing the remainder of the control system. The bottom-mounted drives permit the entire control system to be left intact and operable for tests with the reactor vessel open.

4.1.3.2 Description of Control Rods

A description of the control rods is given in Section 4.2.2.1.

4.1.3.3 Supplementary Reactivity Control

The initial and reload core control requirements are met by use of the combined effects of the movable control rods, supplementary burnable poison, and the variation of reactor coolant flow. A description of the supplementary burnable poison is given in Section 4.2.2.

4.1.4 ANALYSIS TECHNIQUES

4.1.4.1 Reactor Internal Components

Computer codes used for the analysis of the internal components are:

a. MASS

b. SNAP (MULTISHELL)

c. GASP

d. NOHEAT

e. FINITE

f. DYSEA

g. SHELL 5

h. HEATER

i. FAP 71

j. CREEP PLAST

k. ANSYS

Detailed descriptions of these programs are given below:

4.1.4.1.1 MASS (Mechanical Analysis of Space Structure)

4.1.4.1.1.1 Program Description

This program, proprietary to GE, is an outgrowth of the PAPA (Plate and Panel Analysis) program originally developed by L. Beitch in the early 1960s. The program is based on the principle of the finite-element method. Governing matrix equations are formed in terms of joint displacements using a "stiffness-influence coefficient" concept originally proposed by L. Beitch (Reference 4.1-2). The program can analyze curved beam, plate, and shell elements. It can accommodate mechanical and thermal loads in a static analysis, and can predict natural frequencies and mode shapes in a dynamic analysis.

4.1.4.1.1.2 Program Version and Computer

GE's Nuclear Energy Division used revision "0" of MASS. The program operated on a Honeywell 6000 computer.

4.1.4.1.1.3 History of Use

Since its development in the early 1960s, the program has been successfully applied to a wide variety of jet engine structural problems, many of which involve extremely complex geometries. The use of the program by GE's Nuclear Energy Division began shortly after its development.

4.1.4.1.1.4 Extent of Application

Besides the Jet Engine and Nuclear Energy Divisions, GE's Missile and Space Division, the Appliance Division, and the Turbine Division have also applied the program to a wide range of engineering problems. The Nuclear Energy Division uses it mainly for piping and reactor internals analyses.

4.1.4.1.2 SNAP (MULTISHELL)

4.1.4.1.2.1 Program Description

The SNAP program, which is also called MULTISHELL, is the GE code which determines the loads, deformations, and stresses of axisymmetric shells of revolution (cylinders, cones, discs, toroids, and rings) for axisymmetric thermal boundary and surface load conditions. Thin-shell theory is inherent in the solution of E. Peissner's differential equations for each shell's influence coefficients. Surface loading capability includes pressure, average temperature, and linear

through-wall gradients; the latter two may be linearly varied over the shell meridian. The theoretical limitations of this program are the same as those of classical theory.

4.1.4.1.2.2 Program Version and Computer

The version used for the Limerick design, was maintained by GE's Jet Engine Division at Evandale, Ohio, and was used on the Honeywell 6000 computer by the Nuclear Energy Division.

4.1.4.1.2.3 History of Use

The initial version of the Shell Analysis Program was completed by the Jet Engine Division in 1961. Since then, a considerable amount of modification and addition has been made to accommodate its broadening area of application. Its application by the Nuclear Energy Division has a history longer than ten years.

4.1.4.1.2.4 Extent of Application

The program has been used to analyze jet engine, space vehicle, and nuclear reactor components. It has been one of the main shell analysis programs in GE's Nuclear Energy Division, because of its efficiency, economy, and reliability.

4.1.4.1.3 GASP

4.1.4.1.3.1 Program Description

GASP is a finite-element program for the stress analysis of axisymmetric, or plane two-dimensional geometries. The element representations can be either quadrilateral or triangular. Axisymmetric or plane structural load inputs can be made at nodal points. Displacements, temperatures, pressure loads, and axial inertia can be accommodated. Effective plastic stress and strain distributions can be calculated using a bilinear stress-strain relationship, by means of an iterative convergence procedure.

4.1.4.1.3.2 Program Version and Computer

The GE version, originally obtained from the developer, Professor E.L. Wilson, operated on the Honeywell 6000 computer.

4.1.4.1.3.3 History of Use

The program was developed in 1965 (Reference 4.1-3). The present version used by GE's Nuclear Energy Division has been in operation since 1967.

4.1.4.1.3.4 Extent of Application

The application of GASP by the Nuclear Energy Division is mainly for elastic analysis of axisymmetric and plane structures, such as the jet pump riser brace, under thermal and pressure loads. The GE version has been extensively tested and used by GE engineers.

4.1.4.1.4 NOHEAT

4.1.4.1.4.1 Program Description

The NOHEAT program is a two-dimensional and axisymmetric transient nonlinear, temperature analysis program. An unconditionally stable numerical integration scheme is combined with an iteration procedure to compute temperature distribution within a body subjected to arbitrary time and temperature-dependent boundary conditions.

This program utilizes the finite-element method. Included in the analysis are the three basic forms of heat transfer (conduction, radiation, and convection) as well as internal heat generation. In addition, cooling pipe boundary conditions are also treated. The output includes the temperature of all the nodal points for the time instants required by the user. The program can accommodate multitransient temperature input.

4.1.4.1.4.2 Program Version and Computer

The version of the program used for the Limerick design was an improvement of the program originally developed by I. Farhoomand and Professor E.L. Wilson (Reference 4.1-4). The program operated on the Honeywell 6000 computer.

4.1.4.1.4.3 History of Use

The program was developed in 1971 and installed in GE's Honeywell computer by one of its original developers, I. Farhoomand, in 1972. A number of heat transfer problems related to the reactor pedestal have been satisfactorily solved using the program.

4.1.4.1.4.4 Extent of Application

The program using finite-element formulation is compatible with the finite-element stress analysis computer program GASP discussed above. Such compatibility simplifies the connection of the two analyses and minimizes error.

4.1.4.1.5 FINITE

4.1.4.1.5.1 Program Description

FINITE is a general purpose finite-element computer program for elastic stress analysis of two-dimensional structural problems including plane stress, plane strain, and axisymmetric structures. It has provision for thermal, mechanical, and body force loads. The materials of the structure may be homogeneous, or nonhomogeneous and isotropic, or orthotropic. The development of the FINITE program is based on the GASP program discussed above.

4.1.4.1.5.2 Program Version and Computer

The present version of the program used for the Limerick design at GE's Nuclear Energy Division was obtained from the developer, J.E. McConnelee of GE's Gas Turbine Department, in 1969 (Reference 4.1-5). The Nuclear Energy Division version operated on the Honeywell 6000 computer.

4.1.4.1.5.3 History of Use

Since its completion in 1969, the program has been widely used in GE's Gas Turbine and Jet Engine Departments for turbine component analysis.

4.1.4.1.5.4 Extent of Usage

The program is used at GE's Nuclear Energy Division in the analysis of axisymmetric, or nearly axisymmetric, BWR internals.

4.1.4.1.6 DYSEA

4.1.4.1.6.1 Program Description

The DYSEA (Dynamic and Seismic Analysis) program is a GE proprietary program developed specifically for seismic and dynamic analysis of RPV/internals and building system. It calculates the dynamic response of linear structural systems by either temporal modal superposition or response spectrum method. The fluid-structure interaction effect in the RPV is taken into account by way of hydrodynamic mass.

DYSEA is based on program SAPIV with added capability to handle the hydrodynamic mass effect. Structural stiffness and mass matrices are formulated similarly to SAPIV. Solution is obtained in time domain by calculating the dynamic response mode by mode. Time integration is performed by using Newmark's Beta method. Response spectrum solution is also available as an option.

4.1.4.1.6.2 Program Version and Computer

The DYSEA version used for the Limerick design on the Honeywell 6000 computer was developed at GE by modifying the SAPIV program. Capability was added to handle the hydrodynamic mass effect due to fluid-structure interaction in the reactor. It could accommodate three-dimensional dynamic problems with beam, trusses, and springs. Both acceleration time histories and response spectra could be used as input.

4.1.4.1.6.3 History of Use

The DYSEA program was developed in 1976. Adopted as a standard production program in 1977, it has been used extensively in all dynamic and seismic analysis of the RPV/internals and building system.

4.1.4.1.6.4 Extent of Application

The current version of DYSEA has been used in all dynamic and seismic analysis since its development. Results from test problems were found to be in close agreement with those obtained from either verified programs or analytic solutions.

4.1.4.1.7 SHELL 5

4.1.4.1.7.1 Program Description

SHELL 5 is a finite-shell-element program used to analyze smoothly curved thin-shell structures with any distribution of elastic material properties, boundary constraints, and mechanical-thermal and displacement loading conditions. The basic element is triangular, whose membrane displacement fields are linear polynomial functions, and whose bending displacement field is a cubic polynomial function (Reference 4.1-6). Five degrees of freedom (three displacements and

two bending rotations) are obtained at each nodal point. Output displacements and stresses are in a local (tangent) surface coordinate system.

Due to the approximation of element membrane displacements by linear functions, the inplane rotation about the surface normal is neglected. Therefore, the only rotations considered are due to bending of the shell cross-section, and application of the method is not recommended for shell intersection (or discontinuous surface) problems where inplane rotation can be significant.

4.1.4.1.7.2 Program Version and Computer

A copy of the source deck of SHELL 5 is retained in GE's Nuclear Energy Division. SHELL 5 was used on the UNIVAC 1108 computer.

4.1.4.1.7.3 History of Use

SHELL 5 is a program developed by Gulf General Atomic Incorporated (Reference 4.1-7) in 1969. The program has been in production status at Gulf General Atomic, GE, and at other major computer operating systems since 1970.

4.1.4.1.7.4 Extent of Application

SHELL 5 has been used at GE to analyze reactor shroud support and torus. Satisfactory results were obtained.

4.1.4.1.8 HEATER

4.1.4.1.8.1 Program Description

HEATER is used in the hydraulic design of feedwater spargers, and their associated delivery header and piping. The program utilizes test data obtained by GE using full-scale mockups of feedwater spargers, combined with a series of models which represent the complex mixing processes obtained in the upper plenum, downcomer, and lower plenum. Mass and energy balances throughout the nuclear steam supply system are modeled in detail (Reference 4.1-8).

4.1.4.1.8.2 Program Version and Computer

This program was developed at GE's Nuclear Energy Division in FORTRAN IV for the Honeywell 6000 computer.

4.1.4.1.8.3 History of Use

The program was developed in the Nuclear Energy Division beginning in 1970. The version used for the Limerick design was in operation since January 1972.

4.1.4.1.8.4 Extent of Application

The program is used in the hydraulic design of the feedwater spargers for each BWR plant, in the evaluation of design modifications, and in the evaluation of unusual operational conditions.

4.1.4.1.9 FAP-71 (Fatigue Analysis Program)

4.1.4.1.9.1 Program Description

The FAP-71 computer code, or Fatigue Analysis Program, is a stress analysis tool used to aid in performing ASME Section III structural design calculations. Specifically, FAP-71 is used in determining the primary plus secondary stress range, and the number of allowable fatigue cycles at points of interest. For structural locations at which the 3 S_m (P+Q) ASME Code limit is exceeded, the program can perform either (or both) of two elastic-plastic fatigue life evaluations: 1) the method reported in ASME Paper 68-PVP-3, 2) the method of paragraph NB-3228.3 of the ASME Section III, 1971 edition. The program can accommodate up to 25 transient stress states of as many as 20 structural locations.

4.1.4.1.9.2 Program Version and Computer

The version of FAP-71 used for the Limerick design was completed by L. Young of GE's Nuclear Energy Division in 1971 (Reference 4.1-9). The program was used on the Honeywell 6000 computer.

4.1.4.1.9.3 History of Use

Since its completion in 1971, the program has been applied to several design analyses of GE BWR vessels.

4.1.4.1.9.4 Extent of Use

The program is used in conjunction with several shell analysis programs in determining the fatigue life of BWR mechanical components subject to thermal transients.

4.1.4.1.10 CREEP/PLAST

4.1.4.1.10.1 Program Description

This finite-element program is used for the analysis of two-dimensional (plane and axisymmetric) problems under the conditions of creep and plasticity. The creep formulation is based on the memory theory of creep in which the constitutive relations are cast in the form of hereditary integrals. The material creep properties are built into the program, and they represent annealed

304 stainless steel. Any other creep properties can be included if required. The plasticity treatment is based on kinematic hardening and von Mises yield criterion. The hardening modulus can be constant or be a function of strain.

4.1.4.1.10.2 Program Version and Computer

The program was developed for elastic-plastic analysis with or without the presence of creep. It was also designed for creep analysis without the presence of instantaneous plasticity. A detailed description of theory is given in Reference 4.1-11. The program was used on the UNIVAC 1108 computer .

4.1.4.1.10.3 History of Use

This program was developed by Y.R. Rashid (Reference 4.1-11) in 1971. It underwent extensive program testing before it was put on production status.

4.1.4.1.10.4 Extent of Application

The program is used at GE's Nuclear Energy Division in the channel cross-section mechanical analysis.

4.1.4.1.11 ANSYS

4.1.4.1.11.1 Program Description

ANSYS is a general purpose finite-element computer program designed to solve a variety of problems in engineering analysis. The ANSYS program features the following capabilities:

a. Structural analysis including the following analyses:

   1. Static Elastic

   2. Plastic and Creep

   3. Dynamic

   4. Seismic and Dynamic Plastic

   5. Large Deflection

   6. Stability

b. One-dimensional fluid flow analyses

c. Transient heat transfer analysis including conduction, convection, and radiation with direct input to thermal-stress analyses

d. An extensive finite-element library, including gaps, friction interfaces, springs, cables (tension only), direct interfaces (compression only), curved elbows, etc. Many of the elements contain complete plastic, creep, and swelling capabilities.

e. Geometry plotting available for all elements in the ANSYS library, including isometric and perspective views of three-dimensional structures

f. Restart Capability - The ANSYS program has restart capability for several types of analyses. An option is also available for saving the stiffness matrix once it is calculated for the structure, and for using it for other loading conditions.

4.1.4.1.11.2 Program Version & Computer

The program used in the Limerick design was maintained current by Swanson Analysis Systems, Inc. of Pittsburgh, Pennsylvania, and was supplied to GE for use on the Honeywell 6000.

4.1.4.1.11.3 History of Use

The ANSYS program has been used for productive analyses since 1970. Users now include nuclear, pressure vessel, piping, mining, structures, bridge, chemical, and automotive industries, as well as many consulting firms.

4.1.4.1.11.4 Extent of Application

ANSYS is used extensively by GE's Nuclear Energy Division for elastic and elastic-plastic analysis of the RPV, core support structures, and reactor internals.

4.1.4.2 Fuel Rod Thermal Analysis

Fuel rod thermal design analyses are referenced in sections A.4.2.1 and A.4.2.3 of GESTAR II (Reference 4.1-1).

4.1.4.3 Reactor Systems Dynamics

The analysis techniques and computer codes used in reactor systems dynamics are described in section 4 of Reference 4.1-10. Section 4.4.4.6 of Reference 4.1-10 also provides a complete stability analysis for the RCS.

4.1.4.4 Nuclear Engineering Analysis

The analysis techniques are described and referenced in section 3 of GESTAR II (Reference 4.1-1).

4.1.4.5 Neutron Fluence Calculations

The original vessel neutron fluence calculations were carried out using a one-dimensional discrete ordinates (S_n) transport code with general anisotropic scattering.

This code is a modification of a widely used discrete ordinates code which solves a wide variety of radiation transport problems. The program solves both fixed source and multiplication problems. Slab, cylinder, and spherical geometry are allowed with various boundary conditions. The fluence calculations were done as a fixed source problem in cylindrical geometry. The fixed source was developed from neutron fission distribution data prepared as a part of the core physics data. Anisotropic scattering was considered for all regions. The cross-sections were prepared with a l/E flux weighted and (P) matrices for anisotropic scattering, but did not include resonance self-shielding factors. Fast neutron fluxes at locations other than the core midplane were calculated using a two-dimensional discrete ordinate code. The two-dimension code is an extension of the one-dimensional code.

This calculational procedure was also used on PBAPS Units 2 and 3. These units are similar in design, and are of the same core size and power rating as the LGS units. The neutron flux at

these units has been measured using a threshold foil technique on the wire samples contained in the vessel surveillance samples. Flux greater than 1 MeV was determined to be $1.3x10^9$ n/cm^2-sec for Unit 2, and $9.8x10^8$ n/cm^2-sec for Unit 3. This is equivalent to a fluence over 40 years of $1.3x10^{18}$ nvt and $9.8x10^{17}$ nvt. The calculated value using these methods is $1.4x10^{18}$ nvt.

Following the original fluence calculations, the NRC issued Regulatory Guide (RG) 1.190, which provides state of the art calculation and measurement procedures that are acceptable to the NRC for determining Reactor Pressure Vessel (RPV) neutron fluence. LGS RPV fluence has been evaluated using a method in accordance with the recommendations of RG 1.190. Future evaluations of RPV fluence will be completed using a method in accordance with the recommendations of RG 1.190 (as noted in Reference 5.3-14).

As part of the plant's extension to 60 years, a fluence calculation has been completed to extend the plant life to 57 EFPY of reactor operation.

The fast neutron fluence was determined in accordance with the guidelines and requirements presented in U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide 1.190, "Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Effluence." Fluence is determined for the 0T, 1/4T and 3/4T depths in the reactor pressure vessel (RPV) plates, welds, and nozzles throughout the RPV extended beltline region determined at 60 years of reactor operation. The damage fluence determined at the 1/4T and 3/4T depths in the RPV wall were determined using the displacements-per-atom (dpa) attenuation method prescribed in U.S. NRC Regulatory Guide 1.99, "Radiation Embrittlement of Reactor Vessel Materials."

The fluence evaluations (Reference 4.1-17 and 4.1-18) are performed based on the RAMA Fluence Methodology (Reference 4.1-14). Under funding from Electric Power Research Institute, Inc. (EPRI) and the Boiling Water Reactor Vessel and Internals Project (BWRVIP), the RAMA Fluence Methodology was developed by TransWare Enterprises Inc. for the purpose of calculating fast neutron fluence in nuclear reactor pressure vessels and reactor vessel internal components. The RAMA Fluence Methodology (hereafter referred to as "RAMA") has received generic approval (Reference 4.1-15) from the U.S. NRC for determining fast neutron fluence in BWRs and PWRs in accordance with the requirements of Regulatory Guide 1.190. Additionally, the U.S. NRC has given conditional approval of the RAMA methodology for determining fast neutron fluence in reactor internals, specifically stating that the staff will "accept RAMA calculated fluence values for BWR core shrouds and top guide for licensing actions provided that the calculation results are supported by sufficient justification that the proposed values are conservative for the intended application." (Reference 4.1-16)

4.1.4.6 Thermal-Hydraulic Calculations

A description of the thermal-hydraulic models is given in section 4 of GESTAR II (Reference 4.1-1).

4.2 FUEL SYSTEM DESIGN

The format of this section corresponds to SRP Section 4.2 in NUREG-0800. Most of the information is presented by reference to GESTAR II (Reference 4.1-1).

4.2.1 DESIGN BASES

References to design bases are given in subsection A.4.2.1 of GESTAR II (Reference 4.1-1).

4.2.2 DESCRIPTION AND DESIGN DRAWINGS

References to the fuel system description and design drawings are given in subsections A.1.2.2.3.1 and A.4.2.2 of GESTAR II (Reference 4.1-1). Details of General Electric fuel assembly designs are provided in Reference 4.2-5. For the advanced Nuclear Fuels Corp. 9X9-9, the ABB Atom Inc. SVEA-96, and the General Electric GE11 Qualification Fuel Bundles first used in Limerick 2, Cycle 2, the fuel design description can be found in Reference 4.2-6.

4.2.2.1 Reactivity Control Assembly (Control Rods)

The Unit 1 and Unit 2 cores contain a mix of control rod designs including the standard boron carbide and the advanced long-life hafnium rods. The long-life control rods are inserted in subsequent cycles as the standard rods are depleted. A description of the standard rods is given in subsection 2.2.4 and is shown in figures 2.6a, 2.6b, and 2.7 of NEDE-20944-P-1 (Reference 4.2-1). The advanced long-life control rods are described in subsection 2.1 and shown in figures 2.2 and 2.3 of NEDE-22290-A, Supplement 2 (Reference 4.2-3) and subsection 2.0 and Figures 2-1 and 2-2 of NEDE-31758P-A (Reference 4.2-7).

4.2.2.2 Reactivity Control Assembly Evaluation

The standard boron carbide control rod and the advanced long-life hafnium control rod differ primarily in the type of neutron- absorbing materials. Other minor design differences are described in NEDE-22290-A, Supplement 2 (Reference 4.2-3). The evaluation of the standard control rod is given in subsection 2.3.3 of NEDE-20944-P-1 (Reference 4.2-1). The advanced long-life control rod assemblies are directly interchangeable with the standard assemblies and are compatible with existing hardware.

4.2.3 DESIGN EVALUATION

Compliance with the design bases is discussed in subsection A.4.2.3 of GESTAR II (Reference 4.1-1), with the exceptions as provided below.

4.2.3.1 Exceptions to GESTAR II

PARAGRAPH 4.2.3.2.9 - MECHANICAL FRACTURING EVALUATION

Mechanical adequacy of the fuel assembly is demonstrated by the mechanical design analyses described in section 2.0 of Reference 4.2-4. Corrosion, oxidation, and hydriding effects are specifically addressed in subsection 2.2.1.4 of Reference 4.2-4.

All mechanical breaking under normal operation and abnormal operational transients is bounded by the analysis for LOCA plus SSE given in Section 3.9.1.4.10 and Table 3.9-6(x).

PARAGRAPH 4.2.3.3.5 - STRUCTURAL DEFORMATION EVALUATION

Results of the LGS specific SSE plus LOCA analysis are documented in Section 3.9.1.4.10.

4.2.4 TESTING, INSPECTION, AND SURVEILLANCE PLANS

Descriptions of fuel assembly testing, inspection, and surveillance are referenced in subsection A.4.2.4 of GESTAR II (Reference 4.1-1), with the exception that the following postirradiation fuel surveillance program is intended to conform with the objectives of Regulatory Guide 1.70.

Routine visual inspection of representative (usually discharged) fuel will be performed in accordance with the GE Postirradiation Fuel Surveillance Program (Reference 4.2-2).

4.3 NUCLEAR DESIGN

Most of the information of Section 4.3 is provided in the licensing topical report, GESTAR II (Reference 4.1-1). The subsection numbers in Section 4.3 directly correspond to the subsection numbers of Appendix A of GESTAR II. Any additions or differences are given below for each applicable subsection.

4.3.1 DESIGN BASES

4.3.2 DESCRIPTION

4.3.2.1 Nuclear Design Description

The nuclear design description in GESTAR II is referenced in subsection A.4.3.2.1 of GESTAR II (Reference 4.1-1). The reference loading pattern for the initial core for Limerick 1 and 2 is shown in Figure 4.3-3. The reference loading pattern for subsequent cycle of Limerick 1 and Limerick 2 can be found in the unit and cycle specific Supplemental Reload Licensing Report. The actual as loaded core may be different than the reference loading pattern. The as loaded core can be found in the unit and cycle specific Core Loading Plan.

4.3.2.2 Power Distribution

Power distribution is referenced in subsection A.4.3.2.2 of GESTAR II (Reference 4.1-1).

4.3.2.3 Reactivity Coefficient

Directly corresponds to information in Appendix A of GESTAR II (Reference 4.1-1).

4.3.2.4 Control Requirements

Directly corresponds to information in Appendix A of GESTAR II (Reference 4.1-1).

4.3.2.4.1 Shutdown Reactivity

Information on shutdown reactivity is referenced in subsection A.4.3.2.4.1 of GESTAR II (Reference 4.1-1), except for the cold shutdown margin for the reference initial core loading pattern, which is given in Table 4.3-3.

4.3.2.4.2 Reactivity Variations

Information on reactivity variations is referenced in subsection A.4.3.2.4.2 of GESTAR II (Reference 4.1-1). The combined effects of the individual constituents of reactivity are accounted for in each K_{eff} in Table 4.3-3.

4.3.2.5 Control Rod Patterns and Reactivity Worths

Control rod patterns and reactivity worths are discussed in section 3.2.5 of NEDE-20944-P-1 (Reference 4.2-1). Typical control rod patterns and the associated power distributions are presented in appendix A of NEDE-20944-P-1 (Reference 4.2-1). These control rod patterns are calculated with the BWR Core Simulator. Qualification for this model is discussed and referenced in section 3.1 of GESTAR II (Reference 4.1-1)

4.3.2.5.1 Scram Reactivity

Scram reactivity is calculated as described in section S.2 of GESTAR II (Reference 4.1-1) and is discussed in section 3.2.5.3 of NEDE-20944-P-1 (Reference 4.2-1).

4.3.2.6 Criticality of Reactor During Refueling

Directly corresponds to information in Appendix A of GESTAR II (Reference 4.1-1).

4.3.2.7 Stability

General Design Criterion 12 of 10CFR50 Appendix A states that the reactor core and associated coolant control and protection systems shall be designed to assure power oscillations that can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed. That requirement is met as described in GESTAR II (Reference 4.1-1) and this section.

4.3.2.7.1 Xenon Transients

As documented in GESTAR II (Reference 4.1-1), Xenon transients do not cause instability in BWR reactors.

4.3.2.7.2 Thermal-Hydraulic Stability

LGS has implemented the BWROG Long Term Stability Solution Option III with GEH Simplified Stability Solution (GS3). An OPRM Upscale Function is incorporated into each APRM channel to reliably detect power oscillations in the operating ranges where thermal-hydraulic instability has been determined to be credible. Upon detection of power oscillations, the OPRM Upscale Function generates a trip signal to RPS, which results in an automatic scram to suppress the oscillation before the $MCPR_{99.9\%}$ Safety Limit is reached. The OPRM Upscale Function is described in References 7.6-1 through 7.6-4, Reference 7.6-6, and in Reference 4.3-1.

Stability-based MCPR Operating Limits are calculated for each operating cycle. These calculated values validate the selected OPRM setpoints for a given core configuration. Thus, the core design combined with the OPRM Upscale Function and selected system setpoints for detection and suppression of thermal-hydraulic power oscillation conform to the requirements of General Design Criterion 12 of 10CFR50, Appendix A.

4.3.2.8 Vessel Irradiations

The neutron fluxes at the vessel were originally calculated using the one-dimensional discrete ordinates transport code described in Section 4.1.4.5. The discrete ordinates code was used in a distributed source mode with cylindrical geometry. The geometry described six regions from the center of the core to a point beyond the vessel. The core region was modeled as a single homogenized cylindrical region. The coolant water region between the fuel channel and the shroud was described as containing saturated water at 550°F and 1050 psi. The material compositions for the stainless steel in the shroud and the carbon steel in the vessel contain the mixtures by weight, as specified in the material specifications for ASME SA240, 304L, and ASME SA533 Grade B. In the region between the shroud and the vessel (for conservatism), the presence

of the jet pumps was ignored. A simple diagram showing the regions, dimensions, and weight fractions is shown in Figure 4.3-1.

The distributed source used for this analysis was obtained from the gross radial power description. The distributed source at any point in the core is the product of the power from the power description and the neutron yield from fission. By using the neutron energy spectrum, the distributed source is obtained for position and energy. The integral over position and energy is normalized to the total number of neutrons in the core region. The core region is defined as a 1 cm thick disc with no transverse leakage. The power in this core region is set equal to the maximum power in the axial direction. The radial power distribution is shown in Figure 4.3-2

The neutron fluence is determined from the calculated flux by assuming that the plant is operated 90% of the time at 90% power level for 40 years, or equivalent to $1x10^9$ full power seconds. The calculated fluxes and fluence are shown in Table 4.3-1. The calculated neutron flux leaving the cylindrical core is shown in Table 4.3-2

Following the original fluence calculations, the NRC issued Regulatory Guide (RG) 1.190, which provides state of the art calculation and measurement procedures that are acceptable to the NRC for determining Reactor Pressure Vessel (RPV) neutron fluence. LGS RPV fluence has been evaluated using a method in accordance with the recommendations of RG 1.190. Future evaluations of RPV fluence will be completed using a method in accordance with the recommendations of RG 1.190 (as noted in Reference 5.3-14).

As part of the plant's extension to 60 years, a fluence calculation has been completed to extend the plant life to 57 EFPY of reactor operation.

The fast neutron fluence was determined in accordance with the guidelines and requirements presented in U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide 1.190, "Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Effluence." Fluence is determined for the 0T, 1/4T and 3/4T depths in the reactor pressure vessel (RPV) plates, welds, and nozzles throughout the RPV extended beltline region determined at 60 years of reactor operation. The damage fluence determined at the 1/4T and 3/4T depths in the RPV wall were determined using the displacements-per-atom (dpa) attenuation method prescribed in U.S. NRC Regulatory Guide 1.99, "Radiation Embrittlement of Reactor Vessel Materials."

The fluence evaluations (Reference 4.1-17 and 4.1-18) are performed based on the RAMA Fluence Methodology (Reference 4.1-14). Under funding from Electric Power Research Institute, Inc. (EPRI) and the Boiling Water Reactor Vessel and Internals Project (BWRVIP), the RAMA Fluence Methodology was developed by TransWare Enterprises Inc. for the purpose of calculating fast neutron fluence in nuclear reactor pressure vessels and reactor vessel internal components. The RAMA Fluence Methodology (hereafter referred to as "RAMA") has received generic approval (Reference 4.1-15) from the U.S. NRC for determining fast neutron fluence in BWRs and PWRs in accordance with the requirements of Regulatory Guide 1.190. Additionally, the U.S. NRC has given conditional approval of the RAMA methodology for determining fast neutron fluence in reactor internals, specifically stating that the staff will "accept RAMA calculated fluence values for BWR core shrouds and top guide for licensing actions provided that the calculation results are supported by sufficient justification that the proposed values are conservative for the intended application." (Reference 4.1-16)

4.3.3 ANALYTICAL METHODS

Analytical methods are referenced in section A.4.3.3 of GESTAR II (Reference 4.1-1).

4.3.4 CHANGES

Changes are referenced in section A.4.3.4 of GESTAR II (Reference 4.1-1).

4.3.5 REFERENCES

Table 4.3-1
(Historical)

CALCULATED NEUTRON FLUXES
(USED TO EVALUATE VESSEL IRRADIATION)[1]

NEUTRON ENERGY Mev	AVERAGE FLUX IN THE CORE (n/cm^2-sec)	FLUX AT THE CORE BOUNDARY (n/cm^2-sec)	FLUX AT THE INSIDE SURFACE VESSEL (n/cm^2-sec)
>3.0	1.5×10^{13}	5.4×10^{12}	3.3×10^{8}
1.0 - 3.0	3.3×10^{13}	1.2×10^{13}	2.8×10^{8}
0.1 - 1.0	5.3×10^{13}	1.7×10^{13}	4.9×10^{8}
Maximum Fluence[2]	>1.0 MeV = 1.4×10^{18} n/cm^2		

(1) The calculated flux is a maximum in the axial direction, but is an average over the azimuthal angle.

(2) The maximum fluence is calculated using the flux and a capacity factor of 80% or 1×10^{9} full power seconds. The fluence includes an azimuthal peaking factor and a factor to cover analytical uncertainties.

4.4 THERMAL AND HYDRAULIC DESIGN

Most of the information of Section 4.4 is provided in the licensing topic report GESTAR II (Reference 4.1-1). The subsection numbers in Section 4.4 directly correspond to the subsection numbers of Appendix A of GESTAR II. The differences are discussed below.

4.4.1 DESIGN BASIS

The thermal and hydraulic design bases are referenced in GESTAR II (Reference 4.1-1).

The design steady-state initial operating cycle limit for the MCPR and the LHGR are given in Table 4.4-1. The MCPR and LHGR operating limits for subsequent cycles can be found in the unit and cycle specific Core Operating Limits Report.

4.4.2 Description Of Thermal-Hydraulic Design Of The Reactor Core

A description of the thermal-hydraulic design of the reactor core is referenced in GESTAR II (Reference 4.1-1). An evaluation of plant performance from a thermal and hydraulic standpoint is provided in Section 4.4.3.

4.4.2.1 Summary Comparison

A summary comparison of the thermal and hydraulic design parameters of the reactor with reactors of similar design is provided in Table 4.4-1.

4.4.2.2 Critical Power Ratio

Critical power ratio is referenced in GESTAR II (Reference 4.1-1).

4.4.2.3 Linear Heat Generation Rate

LHGR models are referenced in GESTAR II (Reference 4.1-1).

4.4.2.4 Void Fraction Distribution

The core average and maximum exit void fractions in the core at rated condition are given in Table 4.4-1.

4.4.2.5 Core Coolant Flow Distribution and Orificing Pattern

The core coolant flow distribution and orificing pattern are referenced in GESTAR II (Reference 4.1-1).

4.4.2.6 Core Pressure Drop and Hydraulic Loads

Core pressure drop and hydraulic loads are referenced in GESTAR II (Reference 4.1-1).

4.4.2.7 Correlation and Physical Data

GE has obtained substantial amounts of physical data in support of the pressure drop and thermal-hydraulic loads. This information is given in appendix US-B of GESTAR II (Reference 4.1-1) where responses are provided to NRC questions on section 4 of GESTAR II.

4.4.2.8 Thermal Effects of Operational Transients

The evaluation of the core's capability to withstand the thermal effects resulting from anticipated operational transients is covered in Chapter 15.

4.4.2.9 Uncertainties in Estimates

Ultrasonic flow meters have been installed to reduce the uncertainty in the feedwater flow measurements to 0.35%.

The uncertainties in thermal-hydraulic parameters are referenced in GESTAR II (Reference 4.1-1) and NEDC-32601P-A (Reference 4.1-13). The licensing basis power uncertainty for U.S. BWRs is 2.0% as documented in GESTAR II. This power uncertainty is based, in part, on an assumed 1.80% uncertainty in feedwater flow measurement. Feedwater flow uncertainty input to the cycle-specific Safety Limit $MCPR_{99.9\%}$ calculation is 1.80%.

4.4.2.10 Flux Tilt Considerations

The inherent design characteristics of the BWR are particularly well suited to handle perturbations due to flux tilt. The stabilizing nature of the moderator void coefficient effectively damps oscillations in the power distribution. In addition to this damping, the incore instrumentation system and the associated on-line computer provide the operator with prompt and reliable power distribution information. Thus, the operator can readily use control rods or other means to effectively limit the undesirable effects of flux tilting. Because of these features and capabilities, it is not necessary, to allocate a specific peaking factor margin to account for flux tilt. If for some reason the power distribution could not be maintained within normal limits using control rods, then the operating power limits would have to be reduced as prescribed in the Technical Specifications.

4.4.3 DESCRIPTION OF THE THERMAL AND HYDRAULIC DESIGN OF THE REACTOR COOLANT SYSTEM

The thermal and hydraulic design of the RCS is described in this section.

4.4.3.1 Plant Configuration Data

4.4.3.1.1 Reactor Coolant System Configuration

The RCS is described in Section 5.4 and shown in isometric perspective in Figure 5.4-1. The piping sizes, fittings, and valves are listed in Table 5.4-1.

4.4.3.1.2 Reactor Coolant System Thermal-Hydraulic Data

The steady-state distribution of temperature, pressure, and flow rate for each flow path in the RCS is shown in Figure 5.1-1.

4.4.3.1.3 Reactor Coolant System Geometric Data

The volumes of regions and components within the reactor vessel are shown in Figure 5.1-2.

Table 4.4-2 provides the flow path length, height, liquid level, minimum elevations, and minimum flow areas for each major flow path volume within the reactor vessel and recirculation loops of the RCS.

Table 4.4-7 provides the lengths and sizes of all safety injection lines to the RCS.

4.4.3.2 Operating Restrictions on Pumps

Expected recirculation pump performance curves are shown in Figure 5.4-3. These curves are valid for all conditions with a normal operating range varying from approximately 20% to 115% of rated pump flow.

The pump characteristics, including considerations of NPSH requirements, are the same for the conditions of two-pump and one-pump operation as described in Section 5.4.1. Section 4.4.3.3 gives the operating limits imposed on the recirculation pumps by cavitation, pump loads, bearing design flow starvation, and pump speed.

4.4.3.3 Power-Flow Operating Map

4.4.3.3.1 Limits for Normal Operation

A BWR must operate with certain restrictions because of pump NPSH, overall plant control characteristics, core thermal power limits, etc. The general power-flow map characteristics for the power range of operation is shown in Figure 4.4-1. The LGS specific power flow map is discussed in Chapter 15. The nuclear system equipment, nuclear instrumentation, and the RPS, in conjunction with operating procedures, maintain operations within the area of this map for normal operating conditions. The boundaries on this map are as follows:

a. Natural circulation line A: The operating state of the reactor moves along this line for the normal control rod withdrawal sequence in the absence of recirculation pump operation.

b. 20% Recirculation pump constant speed line B: Startup operations of the plant are normally carried out with the recirculation pumps operating at approximately 20% speed. The operating state for the reactor follows this line for the normal control rod withdrawal sequence.

c. Rated flow control line: The rated flow control line (100% rod line) passes through 100% power at 100% flow. The operating state for the reactor follows this line for recirculation flow changes with a fixed control rod pattern. The line is based on constant xenon concentration.

d. Cavitation protection line: This line (minimum power line) results from the recirculation pump and jet pump NPSH requirements. The recirculation pumps are automatically switched to 28% speed when the feedwater flow drops below a preset value.

4.4.3.3.1.1 Performance Characteristics

Other performance characteristics shown on the power-flow operating map are as follows:

a. Recirculation pump constant speed Line C: This line shows the change in flow associated with power changes while maintaining constant recirculation pump speed.

b. Constant rod line: These lines show the change in power associated with flow changes while maintaining constant control rod position, e.g., 50% rod line, etc.

4.4.3.3.2 Regions of the Power-Flow Map

For normal operating conditions, the nuclear system equipment, nuclear instrumentation, and the RPS, in conjunction with operating procedures, maintain operation outside the exclusion areas of the power-flow map. Main regions of the map are discussed below to clarify operational capabilities:

a. Region I: This is the transition region between natural circulation operation and 20% pump speed operation. Steady-state conditions cannot exist in this area because the Adjustable Speed Drive (ASD) has been programmed to limit operator manipulation of pump speed to a minimum of 28%. However, the ASD speed output may drop below 28% momentarily upon a power cell bypass or speed controller swap-over to backup controller but will maintain speed above 20% at all times. Normal startup is along the 20% pump speed boundary of this region.

b. Region II: This region represents the normal operating zone of the map where power changes can be made, either by control rod movement or by core flow changes, by changing recirculation pump drive speed.

c. Region III: This is the low power area of the map where cavitation can be expected in the recirculation pumps and in the jet pumps. Operation within this region is precluded by system interlocks that trip the recirculation pumps to 28% speed whenever feedwater flow is less than a preset value (typically 20% of rated).

4.4.3.4 Temperature-Power Operating Map (PWR)

This section is not applicable to LGS.

4.4.3.5 Load-Following Characteristics

The following simple description of BWR operation with recirculation flow control summarizes the principal modes of normal power range operation. Assuming the plant to be initially hot with the reactor critical, full power operation can be approached following the sequence shown as points 1 to 7 in Figure 4.4-1. The first part of the sequence (1 to 3) is achieved with control rod withdrawal and manual, individual recirculation pump control. Individual pump startup procedures are provided that achieve 28% of full pump speed in each loop. Power, steam flow, and feedwater flow are increased as control rods are manually withdrawn until the feedwater flow has reached approximately 20%. An interlock prevents low power/high recirculation flow combinations that create recirculation pump and jet pump NPSH problems.

Reactor power increases as the operating state moves from point 2 to 3 due to the inherent flow control characteristics of the BWR. Once the feedwater interlock is cleared, the operator can manually increase recirculation flow in each loop until the operating state reaches point 3, the lower limit of the flow control range. At point 3, the operator can switch to simultaneous recirculation pump control. Thermal output can then be increased by either control rod withdrawal or recirculation flow increase. For example, the operator can reach 50% power in the ways indicated by points 4 or 5. With a slight rod withdrawal and an increase of recirculation flow to rated flow, point 4 can be achieved. If, however, it is desired to maintain lowest recirculation flow, 50% power can be reached by withdrawing control rods until point 5 is reached. The operating map, Figure 4.4-1, shows the expected flow control range.

The curve labeled "rated flow control line" represents a typical steady-state power-flow characteristic for a fixed rod pattern. It is slightly affected by xenon, core leakage flow assumptions, and reactor vessel pressure variations; however, for this example, these effects have been neglected.

Normal power range operation is along or below the "rated flow control line." If load-following response is desired in either direction, plant operation near 90% power provides the most capability. If maximum load pickup capability is desired, the nuclear system can be operated near point 6, with fast load response available all the way up to point 7, rated power.

The large negative operating reactivity and power coefficients, which are inherent in the BWR, provide important advantages as follows:

a. Good load-following with well-damped behavior and little undershoot or overshoot in the heat transfer response

b. Load-following with recirculation flow control

c. Strong damping of spatial power disturbances

The reactor power level can be controlled over approximately 45% of the power level on the rated rod line by varying the recirculation flow to the reactor. This method of power level control takes advantage of the reactor negative void coefficient. To increase reactor power, it is necessary to increase the recirculation flow rate that sweeps some of the voids from the moderator, causing an increase in core reactivity. As the reactor power increases, more steam is formed and the reactor stabilizes at a new power level with the transient excess reactivity balanced by the new void formation. No control rods are moved to accomplish this power level change. Conversely, when a power reduction is required, it is necessary only to reduce the recirculation flow rate. When this is done, more voids in the moderator will cause a decrease in the reactor power level to a level commensurate with the new recirculation flow rate. Again, no control rods are moved to accomplish the power reduction.

Varying the recirculation flow rate (flow control) is more advantageous, relative to load-following, than using control rod positioning. Flow variations perturb the reactor uniformly in the horizontal planes and ensure a flatter power distribution and reduced transient allowances. As flow is varied, the power and void distributions remain approximately constant at the steady-state end points for a wide range of flow variations. After adjusting the power distribution by positioning the control rods at a reduced power and flow, the operator can then bring the reactor to rated conditions by increasing flow, with the assurance that the power distribution will remain approximately constant. Section 7.7 describes how recirculation flow is varied.

4.4.3.6 Thermal and Hydraulic Characteristics Summary Table

The thermal-hydraulic characteristics are provided in Table 4.4-1 for the core and in tables of Section 5.4 for other portions of the RCS.

4.4.4 EVALUATION

Refer to GESTAR II (Reference 4.1-1). The results of the cycle-1 stability analysis are given in Table 4.4-8 and Figures 4.4-2 through 4.4-6.

4.4.5 TESTING AND VERIFICATION

The testing and verification techniques to be used to assure that the planned thermal and hydraulic design characteristics of the core have been provided, and will remain within required limits throughout core lifetime, are discussed in Chapter 14 (Initial Test Program).

4.4.6 INSTRUMENTATION REQUIREMENTS

The reactor vessel instrumentation monitors the key reactor vessel operating parameters during planned operations. This ensures sufficient control of the parameters. The reactor vessel sensors are discussed in Sections 7.6 and 7.7.

4.5 REACTOR MATERIALS

4.5.1 CONTROL ROD SYSTEM STRUCTURAL MATERIALS

4.5.1.1 Material Specifications

4.5.1.1.1 Material List

The following material listing applies to the CRDM supplied for this application. The position indicator and minor nonstructural items are omitted.

a. Cylinder, tube, and flange assembly:

Flange	ASME SA182 Grade F304
Plugs	ASME SA182 Grade F304
Cylinder	ASTM A269 Grade TP 304
Outer Tube	ASTM A269 Grade TP 304
Tube	ASTM A269 Grade TP 304
Spacer	ASTM A269 Grade TP 304 or ASTM A511 Grade MT 304

b. Piston tube assembly:

Piston Tube	ASTM A269 Grade TP 304
Stud	ASTM A276 Type 304
Head	ASME SA182 Grade F304
Ind. Tube	ASME SA312 Type 316
Cap	ASME SA182 Grade F304

c. Drive line assembly:

Coupling Spud	Inconel X-750
Index Tube	ASTM A269 Grade TP 304
Piston Head	ARMCO 17-4 PH
Coupling	ASME SA312 Grade TP 304 or ASTM A511 Grade MT 304
Magnet Housing	ASME SA312 Grade TP 304 or ASTM A511 Grade MT 304

d. Collet assembly:

Collet piston	ASTM A269 Grade TP 304 or ASME SA312 Grade TP 304
Finger	Inconel X-750
Retainer	ASTM A269 Grade TP 304 or ASTM A511 Grade MT 304
Guide cap	ASTM A269 Grade TP 304
Collet piston Rings	Haynes 25 Alloy

e. Miscellaneous parts:

Stop piston	ASTM A276 Type 304
Connector	ASTM A276 Type 304
O-Ring spacer	ASME SA240 Type 304
Nut	ASME SA193 Grade B8
Barrel	ASTM A269 Grade TP 304 or ASME SA312 Grade TP 304 or ASME SA240 Type 304
O-Ring seals	Ethylene Propylene
Collet spring	Inconel X-750
Ring flange	ASME SA182 Grade F304
Ball check valve	Haynes, Deloro, or Equivalent Stellite Cobalt-Base Alloy

The materials listed under an ASTM specification number are all in the annealed condition (with the exception of the outer tube in the cylinder, tube, and flange assembly), and their properties are readily available. The outer tube is approximately 1/8 hard and has a tensile strength of 90,000/ 125,000 psi, yield strength of 50,000/85,000 psi, and minimum elongation of 25%.

The coupling spud, collet fingers, and collet spring are fabricated from Inconel X-750 in the annealed or equalized condition and are aged 20 hours at 1300°F to produce a tensile strength of 165,000 psi minimum, yield of 105,000 psi minimum, and elongation of 20% minimum. The piston head is ARMCO 17-4 PH in condition H-1100 (aged 4 hours at 1100°F), with a tensile of 140,000 psi minimum, yield of 115,000 psi minimum, and elongation of 15% minimum.

These are widely used materials whose properties are well-known. The parts are readily accessible for inspection and replacement if necessary.

All materials have been successfully used for the past 10 to 15 years in similar drive mechanisms.

4.5.1.1.2 Special Materials

No cold-worked austenitic stainless steels with a yield strength greater than 90,000 psi are employed in the CRD system. Hardenable martensitic stainless steels are not used. ARMCO 17-4 PH (precipitation-hardened stainless steel) is used for the piston head. This material is aged to the H-1100 condition to produce resistance to stress-corrosion cracking in the BWR environments. ARMCO 17-4 PH (H-1100) has been successfully used for the past 10 to 15 years in BWR drive mechanisms.

4.5.1.2 Austenitic Stainless Steel Components: Processes, Inspections, and Tests

All austenitic stainless steel used in the CRD system is solution annealed material with one exception, the outer tube in the cylinder, tube, and flange assembly (Section 4.5.1.1). Proper solution annealing is verified by testing in accordance with ASTM A262, "Recommended Practices for Detecting Susceptibility to Intergranular Attack in Stainless Steels".

Two special processes are employed that subject selected components to temperatures in the sensitization range.

a. The cylinder (cylinder, tube, and flange assembly) and the retainer (collet assembly) are hard-surfaced with Colmonoy-6.

b. The following components are nitrided to provide a wear-resistant surface:

    1. Tube (cylinder, tube, and flange assembly)

    2. Piston tube (piston tube assembly)

    3. Index tube (drive line assembly)

    4. Collet piston and guide cap (collet assembly)

Colmonoy hard-surfacing is applied by the flame spray process. Parts are preheated to 550°F-800°F and then sprayed with Colmonoy. The sprayed coating is fused at about 2000°F using an oxyacetylene torch followed by air cooling.

Nitriding is accomplished using a proprietary process called New Malcomizing. Components are exposed to a temperature of about 1080°F for about 20 hours during the nitriding cycle.

Colmonoy hard-surfaced components have performed successfully for the past 10 to 15 years in drive mechanisms. Nitrided components have been used in BWR CRDs since 1967. It is normal practice to remove some CRDs at each refueling outage. At this time, both the Colmonoy hard-surfaced parts and nitrided surfaces are accessible for visual examination. In addition, dye penetrant examinations have been performed on nitrided surfaces of the longest service drives. This inspection program is adequate to detect any incipient defects before they can become serious enough to cause operating problems.

Pickling is prohibited on stainless steel components that have been exposed to temperatures in the sensitization range during nitriding or hard-surfacing operations. Pickling of welded stainless steel

is also prohibited unless the welded material has been solution annealed subsequent to all welding operations.

Welding is performed in accordance with ASME Section IX. Heat input for stainless steel welds is restricted to a maximum of 50,000 Joules/in and interpass temperature to 350°F. Heating above 800°F (except for welding) is prohibited unless the welds are subsequently solution annealed. These controls are employed to avoid severe sensitization and comply with the intent of Regulatory Guide 1.44.

Control of Delta Ferrite Content

All type 308 and 308L weld metal is purchased to a specification that requires a minimum of 5% delta ferrite. This amount of ferrite is adequate to prevent any microfissuring (hot-cracking) in austenitic stainless steel welds.

An extensive test program performed by GE, with the concurrence of the regulatory staff, has demonstrated that controlling weld filler metal ferrite at 5% minimum produces production welds that meet the requirements of Regulatory Guide 1.31, "Control of Stainless Steel Welding." A total of approximately 400 production welds in five BWR plants was measured, and all welds met the requirements of BTP MTEB 5-1, "Interim Regulatory Position on Regulatory Guide 1.31".

4.5.1.3 Other Materials

These are discussed in Section 4.5.1.1.2.

4.5.1.4 Cleaning and Cleanliness Control

4.5.1.4.1 Protection of Materials During Fabrication, Shipping, and Storage

All the CRD parts listed above (Section 4.5.1.1) are fabricated under a process specification that limits contaminants in cutting, grinding, and tapping coolants and lubricants. It also restricts all other processing materials (marking inks, tape, etc) to those that are completely removable by the applied cleaning process. All contaminants are then required to be removed by the appropriate cleaning process before any of the following:

a. Any processing that increases part temperature above 200°F

b. Assembly that results in a decrease of accessibility for cleaning

c. Release of parts for shipment

The specification for packaging and shipping the CRD provides the following:

The drive is rinsed in hot deionized water and dried in preparation for shipment. The ends of the drive are then covered with a vapor-tight barrier with desiccant. Packaging is designed to protect the drive and prevent damage to the vapor barrier. The planned storage period considered in the design of the container and packaging is two years. This packaging has been qualified and in use for a number of years. Periodic audits have indicated satisfactory protection.

The degree of surface cleanliness obtained by these procedures meets the requirements of Regulatory Guide 1.37 (Rev 0).

Site or warehouse storage specifications require inside heated storage comparable to level B of ANSI N45.2.2. After the second year, a yearly inspection 2% of the units themselves, or a semi-annual examination of the humidity indicators, where provided, associated with 10% of the units is required to verify that the units are dry and in satisfactory condition. Position indicator probes are not subject to this inspection.

4.5.2 REACTOR INTERNAL MATERIALS

4.5.2.1 Material Specifications

Materials used for the core support structure are as follows:

a. Shroud support: SB168

b. Shroud, core plate, and top guide: ASME SA240, SA193, SA194, SA182, SA479, SA312; ASTM A276, A249, A213, (Types 304L or 304)

c. Peripheral fuel supports: ASTM A269 Grade TP 304, ASTM A312 Grade TP 304, ASTM A511, S1 and S2 Grade MT 304

d. Core plate, studs, and nuts: (all type 304), ASTM A479, ASTM A193 Grade B8A, ASTM A194 Grade 8A

e. CRD housing: ASME SA312 Type 304, SA182 Type 304

f. Control rod guide tube: ASTM A358 Class 2; or ASTM A376 Grade TP 304; or ASTM A312 Grade TP 304; ASTM A351 Grade CF8; ASTM A358 Class 2; or ASTM A213 TP 304; or ASTM A249 TP 304

g. Orificed fuel support: ASME A351 Grade CF8

Materials employed in other reactor internal structures are as follows:

a. Steam separator and steam dryer:

All materials are Type 304 stainless steel:

Plate, Sheet, and Strip	ASTM A240 Type 304
Forgings	ASTM A182 Grade F304 ASTM A182 Grade FXM-19 (Slip-fit joint clamps)
Bars	ASTM A276 Type 304
Pipe	ASTM A312 Grade TP 304
Tube	ASTM A269 Grade TP 304

Castings	ASTM A351 Grade CF8

b. Jet pump assemblies:

The components in the jet pump assemblies are a riser, inlet-mixer, diffuser, adaptor, and riser brace. Materials used for these components are to the following specifications:

Castings	ASTM A351 Grade CF8
Bars	ASTM A276 Type 304
Bolts	ASTM A193 Grade B8 or B8M
Nut	ASTM A194 Grade B8
Sheet and Plate	ASTM A240 Type 304 and 304L
Tubing	ASTM A269 Grade TP 304
Pipe	ASTM A358 Type 304 and ASTM A312 Grade TP 304
Weld Coupling	ASTM A403 Grade WP304
Forgings	ASTM A182 Grade F304 ASTM A182 Grade FXM-19 (slip-fit joint clamps)
Inconel Forgings	ASTM B166

Materials in the jet pump assemblies that are not Type 304 stainless steel are:

1. The inlet-mixer adaptor casting, the wedge casting, bracket casting adjusting screw, and the diffuser collar casting are Type 304 hard-surfaced with Stellite-6 for slip-fit joints. The auxiliary spring wedge assembly and the improved inlet-mixer wedge assembly are made of Iconel X-750, ASTM B-637. The wedge is given a high temperature anneal followed by an aging heat treatment.

2. The adaptor is a bimetallic component made by welding a Type 304 forged ring to a forged Inconel-600 ring, made to Specification ASTM B166.

3. The inlet-mixer contains a pin, insert, and beam made of Inconel X-750 to Specification ASTM A637 Grade 688. The beam is given a high temperature anneal after forging.

4. The jet pump beam bolt is SS316L conforming to ASME SA479.

5. The inlet-mixer to diffuser slip-fit joint clamp, if installed, contains small parts made of precipitation-hardened, heat treated Nickel Alloy to Specification ASTM B-637 (UNS N07750 Type 3).

6. Anti-Vibration Solution (AVS) are made of the following: wedge and spring pad are Nitronic 60, spring components and dowel pin components are X-750, and associated hardware, frame, and body are XM-19.

c. Core spray spargers and core spray lines:

Materials used for these components are as follows: ASME SA240, SA182, SA312, SA351, SA479, SA193, SA194, or ASTM A276, A249, A213, A269, A403, Types 304, 304L, 316, 316L, CF3 or CF8.

d. Feedwater Sparger:

Materials used in this component are: 304, 304L, and 316L.

All core support structures are fabricated from ASME and ASTM specified materials and are designed using ASME Section III as a guide. The other reactor internals are noncoded and are fabricated from ASTM or ASME specification materials. Material requirements in the ASTM specifications are identical to requirements in corresponding ASME material specifications.

4.5.2.2 Controls on Welding

The requirements of the ASME Section IX are followed in fabrication of core support structures and other internals.

4.5.2.3 Nondestructive Examination of Wrought Seamless Tubular Products

Core support structures and other internals for LGS were noncoded because they were fabricated before the issuance of subsection NG of ASME Section III. The only coded tubular parts are the CRD housings and incore housings, which are welded to the reactor vessel. These coded tubular parts were examined by radiographic and/or ultrasonic methods in accordance with the requirements of paragraph NB 2550 of the applicable ASME Section III issue that was in effect at that time.

Other noncoded tubular products were supplied in accordance with the applicable ASTM/ASME material specifications. These specifications require a hydrostatic test on each length of tubing.

4.5.2.4 Regulatory Guide Conformance for Fabrication and Processing of Austenitic Stainless Steel

a. Regulatory Guide 1.31, "Control of Stainless Steel Welding"

Cold-worked stainless steels are not used in the reactor internals. All austenitic stainless steel weld filler materials were supplied with a minimum of 5% delta ferrite. This amount of ferrite is considered adequate to prevent microfissuring in austenitic stainless steel welds.

An extensive test program performed by GE, with the concurrence of the regulatory staff, has demonstrated that controlling the weld filler metal ferrite at 5% minimum produces production welds that meet the requirements of Regulatory Guide 1.31. A total of approximately 400 production welds in five BWR plants was measured, and all welds met the requirements of BTP MTEB 5-1, "Interim Regulatory Position on Regulatory Guide 1.31".

b. Regulatory Guide 1.37, "Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water-Cooled Nuclear Power Plants"

Exposure to contaminants is avoided by carefully controlling all cleaning and processing materials that contact stainless steel during manufacture and construction. Any inadvertent surface contamination is removed to avoid potential detrimental effects.

Special care is exercised to ensure removal of surface contaminants before any heating operation. Water quality for rinsing, flushing, and testing is controlled and monitored. The water quality meets or exceeds the requirements of ANSI N45.2.1.

The degree of cleanliness obtained by these procedures meets the requirements of Regulatory Guide 1.37.

c. Regulatory Guide 1.44, "Control of the Use of Sensitized Steel"

All wrought austenitic stainless steel was purchased in the solution heat treated condition. Heating above 800°F

was prohibited (except for welding) unless the stainless steel was subsequently solution annealed. For 304 steel with carbon content in excess of 0.035% carbon, purchase specifications restricted the maximum weld heat input to 110,000 Joules/in and the weld interpass temperature to 350°F maximum. Welding was performed in accordance with ASME Section IX. These controls were employed to avoid severe sensitization and comply with the intent of Regulatory Guide 1.44.

d. Regulatory Guide 1.71, "Welder Qualification for Areas of Limited Accessibility"

Welder performance qualification tests are made in accordance with the requirements of ASME Section IX. Performance qualifications require testing of welders under simulated access conditions when the access to nonvolumetrically examined production welds is less than 12 inches in any direction and allow welding from one access only. Requalification is required when significantly more restricted access conditions occur or when any essential welding variable is changed.

4.5.2.5 Other Materials

Hardenable martensitic stainless steels and precipitation hardening stainless steels are not used in the reactor internals.

Materials, other than Type 300 stainless steel, employed in vessel internals are: SB166, 167, and 168 Nickel-Chrome-Iron (Inconel 600); SA637 Grade 688 Inconel X-750.

Inconel 600 tubing, plate, and sheet are used in the annealed condition. Bar may be in the annealed or cold-drawn condition.

Inconel X-750 components are fabricated in the annealed or equalized condition and aged 20 hours at 1300°F.

Stellite 6 hard-surfacing is applied to austenitic stainless steel castings using the gas tungsten arc welding or plasma arc surfacing processes.

All materials have been successfully used for the past 10 to 15 years in BWR applications.

4.5.3 CONTROL ROD DRIVE HOUSING SUPPORTS

All CRD housing support subassemblies are fabricated of ASTM A36 structural steel, except for the following items:

ITEM	MATERIAL
Grid	ASTM A441
Disc springs	Schnorr, Type BS-125-71-8
Hex bolts and nuts	STM A307
6"x4"x3/8" tubes	STM A500 Grade B

For further CRD housing support information, see Section 4.6.1.2.

4.6 FUNCTIONAL DESIGN OF REACTIVITY CONTROL SYSTEMS

The reactivity control systems consist of control rods and the CRD system, supplementary reactivity control for the initial core (Section 4.1.3), and the SLCS (Section 9.3).

4.6.1 CONTROL ROD DRIVE SYSTEM

4.6.1.1 Design

4.6.1.1.1 Safety Design Bases

The CRD mechanical system meets the following safety design bases:

a. The design provides for a sufficiently rapid control rod insertion so that no fuel damage results from any abnormal operating transient.

b. The design includes positioning devices, each of which individually supports and positions a control rod.

c. Each positioning device:

1. Prevents its control rod from initiating withdrawal as a result of a single malfunction,

2. Is individually operated so that a failure in one positioning device does not affect the operation of any other positioning device, and

3. Is individually energized when rapid control rod insertion (scram) is signaled, so that failure of power sources external to the positioning device does not prevent other positioning devices' control rods from being inserted.

4.6.1.1.2 Power Generation Design Basis

The CRD design provides for positioning the control rods to control power generation in the core.

4.6.1.2 Description

The CRD system controls gross changes in core reactivity by incrementally positioning neutron-absorbing control rods within the

reactor core, in response to manual control signals. It is also designed to quickly shut down the reactor (scram) in emergency situations by rapidly inserting withdrawn control rods into the core in response to a manual or automatic signal. The CRD system consists of locking piston CRDMs, and the CRD hydraulic system (including power supply and regulation, HCUs, interconnecting piping, instrumentation, and electrical controls).

4.6.1.2.1 Control Rod Drive Mechanisms

The CRDM (drive) used for positioning the control rod in the reactor core is a double-acting, mechanically latched, hydraulic cylinder using demineralized water as its operating fluid (Figures

4.6-1, 4.6-2, 4.6-3, and 4.6-4). The individual drives are mounted on the bottom head of the RPV. The drives do not interfere with refueling and are operative even when the head is removed from the reactor vessel.

The drives are also readily accessible for inspection and servicing. The bottom location makes maximum utilization of the water in the reactor as a neutron shield, and gives the least possible neutron exposure to the drive components. The use of water from the condensate treatment system, and/or the CST as the operating fluid, eliminates the need for a special hydraulic fluid. The drives utilize simple piston seals whose leakage provides cooling for the CRDMs. This leakage does not contaminate the reactor water.

The drives are capable of inserting or withdrawing a control rod at a slow, controlled rate, in addition to providing rapid insertion when required. A mechanism, on the drive, locks the control rod at 6 inch increments of stroke over the length of the core.

A coupling spud at the top end of the drive index tube (piston rod) engages and locks into a mating socket at the base of the control rod. The weight of the control rod is sufficient to engage and lock this coupling. Once locked, the drive and rod form an integral unit that must be manually unlocked by specific procedures before the components can be separated.

The drive holds its control rod in distinct latch positions until the hydraulic system actuates movement to a new position. Withdrawal of each rod is limited by the seating of the rod in its guide tube. Withdrawal of the drive beyond this position to the overtravel limit can be accomplished only if the rod and drive are uncoupled. Withdrawal to the overtravel limit is annunciated by an alarm.

Individual rod position indicators, grouped in one control panel display, correspond to relative rod locations in the core. A separate, smaller display, located just below the large display presents the positions of the control rod selected for movement and of the other rods in the affected rod group.

For display purposes, the control rods are considered in groups of four adjacent rods centered around a common core volume. Each group is monitored by four LPRM strings (Section 7.6.1.4). Rod groups at the periphery of the core may have less than four rods. The small display shows the positions, in digital form, of the rods in the group to which the selected rod belongs. Backlighting indicates which of the four rods is the one selected for movement.

4.6.1.2.2 Drive Components

Figure 4.6-2 illustrates the operating principle of a CRD. Figures 4.6-3 and 4.6-4 illustrate the drive in more detail. The main components of the drive and their functions are described below.

4.6.1.2.2.1 Drive Piston

The drive piston is mounted at the lower end of the index tube. The function of the index tube is similar to that of a piston rod in a conventional hydraulic cylinder. The drive piston and index tube make up the main moving assembly in the drive. The drive piston operates between positive end stops, with a hydraulic cushion provided at the upper end only. The piston has both inside and outside seal-rings, and operates in an annular space between an inner cylinder (fixed piston tube) and an outer cylinder (drive cylinder). Because the type of inner seal used is effective in only one direction, the lower sets of seal-rings are mounted with one set sealing in each direction.

A pair of nonmetallic bushings prevent metal-to-metal contact between the piston assembly and the inner cylinder surface. The outer piston rings are segmented, step-cut seals with expander springs holding the segments against the cylinder wall. A pair of split bushings on the outside of the piston prevents piston contact with the cylinder wall. The effective piston area for downtravel, or withdrawal, is approximately 1.2 in^2 versus approximately 4.1 in^2 for uptravel, or insertion. This difference in driving area tends to balance the control rod weight and ensures a higher force for insertion than for withdrawal.

4.6.1.2.2.2 Index Tube

The index tube is a long hollow shaft made of nitrided stainless steel. Circumferential locking grooves, spaced every 6 inches along the outer surface, transmit the weight of the control rod to the collet assembly.

4.6.1.2.2.3 Collet Assembly

The collet assembly serves as the index tube locking mechanism. It is located in the upper part of the drive unit. This assembly prevents the index tube from accidentally moving downward. The assembly consists of the collet fingers, a return spring, a guide cap, a collet housing (part of the cylinder, tube, and flange), and the collet piston.

Locking is accomplished by fingers mounted on the collet piston at the top of the drive cylinder. In the locked or latched position, the fingers engage a locking groove in the index tube.

The collet piston is normally held in the latched position by a force of approximately 150 pounds supplied by a spring. Metal piston rings are used to seal the collet piston from reactor vessel pressure. The collet assembly does not unlatch until the collet fingers are unloaded by a short, automatically sequenced drive-in signal. A pressure, approximately 180 psi above reactor vessel pressure, must then be applied to the collet piston to overcome spring force, slide the collet up against the conical surface in the guide cap, and spread the fingers out so they do not engage a locking groove.

A guide cap is fixed in the upper end of the drive assembly. This member provides the unlocking cam surface for the collet fingers and serves as the upper bushing for the index tube.

If reactor water is used during a scram to supplement accumulator pressure, it is drawn through a filter on the guide cap.

4.6.1.2.2.4 Piston Tube

The piston tube is an inner cylinder, or column, extending upward inside the drive piston and index tube. The piston tube is fixed to the bottom flange of the drive and remains stationary. Water is brought to the upper side of the drive piston through this tube. A series of orifices at the top of the tube provides progressive water shutoff to cushion the drive piston at the end of its scram stroke.

4.6.1.2.2.5 Stop Piston

A stationary piston, called the stop piston, is mounted on the upper end of the piston tube. This piston provides the seal between reactor vessel pressure and the space above the drive piston. It also functions as a positive end stop at the upper limit of control rod travel. A stack of spring washers just below the stop piston helps absorb the final mechanical shock at the end of control

rod travel. The piston rings are similar to the drive piston outer rings. A bleed-off passage to the center of the piston tube is located between the two pairs of rings. This arrangement allows seal leakage from the reactor vessel (during a scram) to be bled directly to the discharge line. The lower pair of seals is used only during the cushioning of the drive piston at the upper end of the stroke.

The center tube of the drive mechanism forms a well to contain the position indicator probe. The probe is an aluminum extrusion attached to a cast aluminum housing. Mounted on the extrusion are hermetically sealed, magnetically operated reed switches. The entire probe assembly is protected by a thin-walled stainless steel tube. The switches are actuated by a ring magnet located at the bottom of the drive piston.

The drive piston, piston tube, and indicator tube are all of nonmagnetic stainless steel, allowing the individual switches to be operated by the magnet as the piston passes. One switch is located at each position corresponding to an index tube groove, thus allowing indication at each latching point. An additional switch is located at each midpoint between latching points to indicate the intermediate positions during drive motion. Thus, indication is provided for each 3 inches of travel. Duplicate switches are provided for the full-in and full-out positions. One additional switch (an overtravel switch), is located at a position below the normal full-out position. Because the limit of downtravel is normally provided by the control rod itself as it reaches the back-seat position, the drive can pass this position and actuate the overtravel switch only if it is uncoupled from its control rod. A convenient means is thus provided to verify that the drive and control rod are coupled after installation of a drive and at any time during plant operation.

4.6.1.2.2.6 Flange and Cylinder Assembly

A flange and cylinder assembly is made up of a heavy flange welded to the drive cylinder. A sealing surface on the upper face of this flange forms the seal to the drive housing flange. The seals contain reactor pressure and the two hydraulic control pressures. Teflon-coated, stainless steel rings are used for these seals.

The drive flange contains the integral ball, or two-way check (ball-shuttle) valve. This valve directs either the reactor vessel pressure or the driving pressure, whichever is higher, to the underside of the drive piston. Reactor vessel pressure is admitted to this valve from the annular space between the drive and drive housing through passages in the flange.

Water used to operate the collet piston passes between the inner and outer tubes of the drive cylinder. The inside of the cylinder tube is honed to provide the surface required for the drive piston seals.

Both the cylinder tube and outer tube are welded to the drive flange. The upper ends of these tubes have a sliding fit to allow for differential expansion.

The upper end of the index tube is threaded to receive a coupling spud. The coupling (Figure 4.6-1) accommodates a small amount of angular misalignment between the drive and the control rod. Six spring fingers allow the coupling spud to enter the mating socket on the control rod. A lock plug then enters the spud and prevents uncoupling.

4.6.1.2.2.7 Lock Plug

Two means of uncoupling are provided. With the reactor vessel head removed, the lock plug can be raised against the spring force of approximately 50 pounds by a rod extending up through the center of the control rod to an unlocking handle located above the control rod velocity limiter. The control rod, with the lock plug raised, is then lifted from the drive.

If it is desired to uncouple a drive without removing the reactor vessel head for access, the lock plug can also be pushed up from below. In this case, the piston tube assembly is pushed up against the uncoupling rod assembly, which raises the lock plug and allows the coupling spud to disengage the socket as the drive piston and index tube are driven down.

The control rod is heavy enough to force the spud fingers to enter the socket and push the lock plug up, allowing the spud to enter the socket completely, and the lock plug to snap back into place. Therefore, the drive is coupled to the control rod using only the weight of the control rod.

4.6.1.2.3 Materials of Construction

Factors that determine the choice of construction materials are discussed in the following sections.

4.6.1.2.3.1 Index Tube

The index tube must withstand the locking and unlocking action of the collet fingers. A compatible bearing combination must be provided that is able to withstand moderate misalignment forces. The reactor environment limits the choice of materials suitable for corrosion resistance. The column and tensile loads can be satisfied by an annealed, 300-series stainless steel. The wear and bearing requirements are provided by Malcomizing the completed tube. To obtain suitable corrosion resistance, a carefully controlled process of surface preparation is employed.

4.6.1.2.3.2 Coupling Spud

The coupling spud is made of Inconel X-750 that is aged for maximum physical strength and for the required corrosion resistance. Because misalignment tends to cause chafing in the semispherical contact area, this component is protected by a thin chromium plating (electrolyzed). This plating also prevents galling of the threads attaching the coupling spud to the index tube.

4.6.1.2.3.3 Collet Fingers

Inconel X-750 is used for the collet fingers, which must function as leaf springs when cammed open to the unlocked position. Colmonoy-6 hard-facing provides a long-wearing surface, adequate for design life, for the area contacting the index tube and unlocking the cam surface of the guide cap.

4.6.1.2.3.4 Seals and Bushings

Graphitar-3030 is selected for seals and bushings on the drive piston and stop piston. The material is inert and has a low friction coefficient when water-lubricated. Because some loss of Graphitar-3030 strength is experienced at higher temperatures, the drive is supplied with cooling water to hold temperatures below 250°F. The Graphitar-3030 is relatively soft, which is advantageous when an occasional particle of foreign matter reaches a seal. The resulting

scratches in the seal reduce sealing efficiency until worn smooth, but the drive design can tolerate considerable water leakage past the seals into the reactor vessel.

4.6.1.2.3.5 Summary

All drive components exposed to reactor vessel water are made of austenitic stainless steel except the following:

a. Seals and bushings on the drive piston and stop piston are Graphitar-3030.

b. All springs and members requiring spring action (collet fingers, coupling spud, and spring washers) are made of Inconel X-750.

c. The ball check valve is a Haynes Stellite cobalt-base alloy.

d. Elastomeric O-ring seals are ethylene propylene.

e. Metal piston rings are Haynes-25 alloy.

f. Certain wear surfaces are hard-faced with Colmonoy-6.

g. Nitriding by a proprietary new Malcomizing process and chromium plating are used in certain areas where resistance to abrasion is necessary.

h. The drive piston head is made of ARMCO 17-4PH.

Pressure-containing portions of the drives are designed and fabricated in accordance with requirements of ASME Section III.

4.6.1.2.4 Control Rod Drive Hydraulic System

The CRD hydraulic system supplies and controls the pressure and flow to and from the drives through HCUs. The water discharged from the drives during a scram flows through the HCUs to the scram discharge volume. The water discharged from a drive during a normal control rod positioning operation flows through the HCU, the exhaust header, and is returned to the reactor vessel via the HCUs of nonmoving drives. There are as many HCUs as the number of CRDs. The design criterion for the LGS CRD hydraulic system requires that no single failure of a component, structure, or service function shall prevent a reactor shutdown. Each CRD acts somewhat independently, and reactor shutdown can be achieved assuming failure of a single rod to insert. In addition, the CRD scram hydraulic system is designed to be fail-safe (i.e., to scram on loss of electrical or pneumatic power.)

4.6.1.2.4.1 Hydraulic Requirements

The CRD hydraulic system piping and instrumentation diagram is shown in drawings M-46 and M-47, and the process diagrams are shown in drawings C11-1020-G-004, C11-1020-G-005, C11-1020-G-006, and C11-1020-G-007. The hydraulic requirements, identified by the function they perform, are as follows:

a. An accumulator hydraulic charging pressure of approximately 1400-1500 psig is required. Flow to the accumulators is required only during scram reset or system startup.

b. Drive pressure of 260 psi (minimum) above reactor vessel pressure is required. A flow rate of approximately 4 gpm to insert a control rod and 2 gpm to withdraw a control rod is required.

c. Cooling water to the drives is required at approximately 15 psi above reactor vessel pressure and at a flow rate of approximately 0.2-0.34 gpm per drive unit.

d. The scram discharge volume is sized to receive, and contain, all the water discharged by the drives during a scram; a minimum volume of 3.34 gallons per drive is required (excluding the instrument volume).

4.6.1.2.4.2 System Description

The CRD hydraulic system provides the required functions with the pumps, filters, strainers, valves, instrumentation, and piping shown in drawings M-46 and M-47, listed in Table 4.6-1, and described in the following paragraphs.

Duplicate components are included, where necessary, to ensure continuous system operation if an inservice component requires maintenance. The scram system design for LGS provides numerous indications and alarms in the control room to inform the operator of the condition of vital components, including the following:

1. SDV water level
2. Low scram accumulator pressure alarm
3. Scram accumulator H_2O leakage alarm
4. Scram air header supply low/high pressure alarm
5. SDV vent and drain valve position indication.

4.6.1.2.4.2.1 Supply Pump

One supply pump pressurizes the system with water from the condensate treatment system and/or CST. One spare pump is provided for standby. A discharge check valve prevents backflow through the nonoperating pump. During normal operation, a portion of the pump discharge flow is diverted through a minimum flow bypass line to the CST. This flow is controlled by an orifice and is sufficient to prevent pump damage if the pump discharge is inadvertently closed. An alternative alignment allows pump operation with the minimum flow bypass line closed for the purpose of CRD hydraulic system maintenance, testing or trouble shooting.

Condensate water is processed by two filters. The pump suction filter is a disposable element-type with a 25 micron absolute rating. A differential pressure indicator and control room alarm monitor the filter element as it collects foreign material. A 250 micron strainer, downstream of the suction filter at each pump suction protects the pumps when the suction filter is being serviced. The drive water filter downstream of the pump is a cleanable-element-type with a maximum 50 micron absolute rating. One spare drive water filter is provided for standby service. A 250 micron strainer in each drive water filter/discharge line guards the hydraulic system if there is a filter element failure.

4.6.1.2.4.2.2 Accumulator Charging Pressure

Accumulator charging pressure is established by precharging the nitrogen accumulator to a precisely controlled pressure at known temperature. During a scram, the scram inlet (and outlet) valves open and permit the stored energy in the accumulators to discharge into the drives. The resulting pressure decrease in the charging water header allows the CRD supply pump to "run-out" (i.e., flow rate to increase substantially) into the CRDs via the charging water header. The flow element, upstream of the accumulator charging water header, senses high flow and provides a signal to the manual auto-flow control station, which in turn closes the system flow control valve. This action maintains increased flow through the charging water header, while avoiding prolonged pump operation at run-out conditions.

Pressure in the charging water header is monitored in the control room with a pressure indicator and a low pressure alarm.

During normal operation, the flow control valve maintains a constant system flow rate. This flow is used for drive flow and drive cooling.

4.6.1.2.4.2.3 Drive Water Pressure

Drive water pressure required in the drive water header is maintained by the drive/cooling pressure control valve, which is manually adjusted from the control room. A flow rate of approximately 6 gpm (the sum of the flow rate required to insert and withdraw a control rod) normally passes from the drive water header through two solenoid-operated stabilizing valves (arranged in parallel) into the cooling water header. The flow through one stabilizing valve equals the drive insert flow; that through the other stabilizing valve equals the drive withdrawal flow. When operating a drive, the required flow is diverted to that drive by closing the appropriate stabilizing valve, and at the same time opening the drive and exhaust directional control solenoid valves. Thus, flow through the drive pressure control valve is always constant.

Flow indicators in the drive water header and in the line downstream from the stabilizing valves allow the flow rate through the stabilizing valves to be adjusted when necessary. Differential pressure between the reactor vessel and the drive header is indicated in the control room.

On Unit 2, a permanent CRD friction test facility is connected to the drive water header and to a reactor vessel pressure instrument line. The device measures the friction of the control rods during rod movement. This facility eliminates the need for repetitive instrumentation setups while testing the CRDs during startup testing, refueling outages, and power plant operation. The friction test facility will be isolated from the CRD hydraulic system except when it is being used for friction testing or diagnostics.

4.6.1.2.4.2.4 Cooling Water Header

The cooling water header is located downstream from the drive/cooling pressure valve. The drive/cooling pressure control valve is manually adjusted from the control room to produce the required drive water/cooling water pressure balance.

The flow through the flow control valve is virtually constant. Therefore, once adjusted, the drive/cooling pressure control valve maintains the required drive pressure and cooling water pressure, independent of reactor vessel pressure. Changes in setting of the pressure control valves are required only to adjust for changes in the cooling requirements of the drives, as the drive

seal characteristics change with time. A flow indicator in the control room monitors cooling water flow. A differential pressure indicator in the control room indicates the difference between reactor vessel pressure and drive cooling water pressure. Although the drives can function without cooling water, seal life is shortened by long-term exposure to reactor temperatures. The temperature of each drive is indicated and recorded, and excessive temperatures are annunciated in the control room.

4.6.1.2.4.2.5 Exhaust Water Header

The exhaust water header connects to each HCU and provides a low pressure plenum and discharge path for the fluid expelled from the drives during control rod insert and withdraw operations. The fluid injected into the exhaust water header during rod movements is discharged back up to the RPV via reverse flow through the insert exhaust directional solenoid valves of adjoining HCUs. The pressure in the exhaust water header is, therefore, maintained at essentially reactor pressure. To ensure that the pressure in the exhaust water header is maintained near reactor pressure during the period of vessel pressurization, redundant pressure equalizing valves connect the exhaust water header to the cooling water header.

4.6.1.2.4.2.6 Scram Discharge Volume

The SDV consists of header piping which connects to each HCU and drains into an instrument volume. The header piping is sized to receive and contain all the water discharged by the drives during a scram, independent of the instrument volume. A minimum SDV of 3.34 gallons per drive is specified through the system design specifications. This minimum SDV is based on conservative assumptions such that scram performance is not adversely affected.

The LGS CRD scram discharge header is connected to the instrument volume by piping of the same diameter as the SDV and is sloped towards the instrument volume, which monitors any water accumulation in the header. As the instrument volume starts to fill, the instrumentation triggers an alarm and initiates a scram when the instrument volume is full, but before the scram header begins to fill. This ensures that the scram header is able to accept the scram discharge water. The instrumentation for the instrument volume is located on the vertical instrument volume, and not on connecting piping.

There are two sets of headers, each with its own directly connected SDIV attached to the low point of the header piping. The large diameter pipe of the instrument volume thus serves as a vertical extension of the SDV that monitors water accumulation in the header piping. There is no reduction in the pipe size of the header piping going from the HCUs to the scram discharge instrument volume. This volume in turn is directly connected to the SDV without restriction.

The LGS design provides for redundant and diverse level sensing instrumentation. Two float switches and differential pressure (level) transmitters with level indicating switches provide high water level input to RPS from each SDIV. (There are two SDIVs which are hydraulically coupled via the common drain line). Each device provides an input to one channel. The devices are arranged so that no single failure prevents a reactor scram caused by high water level. These level instruments are connected to the instrument volume and trigger alarms in the control room on SDV High Level Trip.

In addition to the redundant and diverse devices which input to the RPS, there are two level switches for the instrument volume to provide operator warning. At the lowest level, a level switch actuates to indicate that the volume is not completely empty during postscram draining, or to indicate that the volume starts to fill through leakage accumulation at other times during reactor

operation. At the second level, a level switch produces a rod withdrawal block to prevent further withdrawal of any control rod when leakage accumulates to half the capacity of the instrument volume.

The instrumentation on the LGS instrument volume is designed so that no more than half of the scram trip level instruments shall be of the same manufacture, design, and operating principle to minimize the potential for common mode failure.

The SDV level instruments are located on the large diameter SDIV piping to minimize hydrodynamic forces associated with water flow following a scram.

During normal plant operation, the SDV is empty and vented to the atmosphere through its open vent and drain valves. When a scram occurs, upon a signal from the RPS, these vent and drain valves are closed to conserve reactor water. The position of the SDV vent and drain valves is continuously monitored. Lights in the control room indicate the position of these valves.

Redundant scram discharge system vent and drain valves are provided on LGS to ensure that no single failure can result in an uncontrolled loss of reactor coolant. Redundant solenoid-operated pilot valves control the vent and drain valves. The vent and drain system is therefore sufficiently redundant to avoid a failure to isolate the SDV single active failures. In addition, the solenoid-operated pilot valves are fail-safe (i.e., SDV isolates) on loss of electric or pneumatic power. The SDV drain line discharges to the equipment drain collection tank, and the vent line discharges to dirty radwaste. Vent lines are protected by vacuum breakers. The redundant isolation valves on the vent and drain lines are normally open during power operation and would not prevent draining of those lines in the nonscrammed condition. The position of these valves is indicated in the control room. Neither the vent and drain functions would be adversely affected by other system interfaces. Because of the redundant vent and drain valves, repair operations on any one valve will not prevent isolation of the vent and drain lines when scramming.

The operation of the scram discharge system is either automatic or remote manual, thus minimizing the time in which an operator would be in close contact with system components. The instrument volumes and level instruments are installed in corner locations to take advantage of shielding provided by concrete structures and to permit the installation of about two feet of temporary shielding for personnel protection. The scram discharge volume drain valves are located one floor below the instrument volumes which minimize the need for temporary shielding.

The SDV and associated vent and drain piping are classified as important to safety and required to meet the ASME Section III, Class 2 and seismic Category I requirements. Design parameters such as temperature, pressure, and frequency for limiting modes of operation provide a design basis for supply of equipment as well as the interfacing piping design and analysis.

During a scram, the SDV partly fills with water discharged from above the drive pistons. After scram is completed, the CRD seal leakage from the reactor continues to flow into the SDV until the discharge volume pressure equals the reactor vessel pressure. A check valve in each HCU prevents reverse flow from the scram discharge header volume to the drive. When the initial scram signal is cleared from the RPS, the SDV signal is overridden with a key-lock override switch, and the SDV is drained and returned to atmospheric pressure.

Remote manual switches in the pilot valve solenoid circuits allow the discharge volume vent and drain valves to be tested without disturbing the RPS. Closing the SDV valves, allows the outlet scram valve seats to be leak tested by timing the accumulation of leakage into the SDV.

System operating conditions that are required for scram are continuously monitored. Four liquid level switches and two level transmitters, connected to each instrument volume, monitor the volume for abnormal water level. They are set at three different levels. They provide redundant and diverse inputs to the RPS scram function, control room annunciation function, and control rod withdrawal block function (drawing M-47). At the lowest level, a level switch actuates to indicate that the volume is not completely empty during postscram draining, or to indicate that the volume starts to fill through leakage accumulation at other times during reactor operation. At the second level, a level switch produces a rod withdrawal block to prevent further withdrawal of any control rod when leakage accumulates to half the capacity of the instrument volume. The remaining two switches and two transmitters are interconnected with the trip channels of the RPS, and initiate a reactor scram on high water level in the SDIV. Electronic switches are actuated by level transmitters to provide diversity of signals to the RPS.

The SDIV scram level instrumentation arrangement and trip logic allows instrument adjustment or surveillance without bypassing the scram function or directly causing a scram. Each level instrument can be individually isolated without bypassing the scram function. For the repair or replacement of scram level instrumentation the "one-out-of-two-twice" logic could be temporarily modified to "one-out-of-two". Thus, the single failure criterion would not be violated and the scram function is available when needed. Provisions are included in the system design for functional testing and calibration of SDIV level instrumentation.

The SDV piping system leak rates, loading conditions and material properties are bounded by the limiting value for these parameters identified in the BWROG letter of May 10, 1984 (BWROG-8420) and accepted by the NRC in Generic Letter 86-01 (January 3, 1986). Leak tests and inspections are performed per the criterion for Class 2 piping contained in ASME Section XI. Also, the CRD Scram Discharge System is in the Leakage Reduction Program described in UFSAR Section 6.2.8

The LGS EOP for secondary containment control, which is based on the BWROG EPGs, includes an entry condition for secondary containment sump water level being above the normal operating level. In the event of a break in the scram discharge piping system, the normal plant procedures call for a reset of the scram. If, however, the affected system cannot be isolated or the isolation proves ineffective in mitigating temperature or radiation increases, rapid depressurization of the reactor is required per the EOP if the condition causes a widespread problem in the reactor enclosure. Rapid depressurization of the reactor is accomplished by safety valve discharge into the suppression pool. This reduces the leakage into the reactor building. The EOP also specifies the operator actions for achieving isolation and reactor depressurization should they be needed to mitigate leak consequences.

4.6.1.2.4.3 Hydraulic Control Units

Each HCU furnishes pressurized water, on signal, to a drive unit. The drive then positions its control rod as required. Operation of the electrical system that supplies scram and normal control rod positioning signals to the HCU is described in Section 7.7.1.2.

The basic components in each HCU are manual, pneumatic, and electrical valves; an accumulator; related piping; electrical connections; filters; and instrumentation (drawings M-46, M-47, and Figure 4.6-8). The components and their functions are described in the following paragraphs.

4.6.1.2.4.3.1 Insert Drive Valve

The insert drive valve is solenoid-operated and opens on an insert signal. The valve supplies drive water to the bottom side of the main drive piston.

4.6.1.2.4.3.2 Insert Exhaust Valve

The insert exhaust solenoid valve also opens on an insert signal. The valve discharges water from above the drive piston to the exhaust water header.

4.6.1.2.4.3.3 Withdraw Drive Valve

The withdraw drive valve is solenoid-operated and opens on a withdraw signal. The valve supplies drive water to the top of the drive piston.

4.6.1.2.4.3.4 Withdraw Exhaust Valve

The solenoid-operated withdraw exhaust valve opens on a withdraw signal, and discharges water from below the main drive piston to the exhaust header. It also serves as the settle valve which opens, following any normal drive movement (insert or withdraw), to allow the control rod and its drive to settle back into the nearest latch position.

4.6.1.2.4.3.5 Speed Control Units

The insert drive valve and withdraw exhaust valve have a speed control unit. The speed control unit regulates the control rod insertion and withdrawal rates during normal operation. The manually adjustable flow control unit is used to regulate the water flow to and from the volume beneath the main drive piston. A correctly adjusted unit does not require readjustment except to compensate for changes in drive seal leakage.

4.6.1.2.4.3.6 Scram Pilot Valve

The scram pilot valve is operated from the RPS. The single scram pilot valve with two solenoids, controls both the scram inlet valve and the scram exhaust valve. The valve is solenoid-operated and normally energized. On loss of electrical signal to the solenoids, such as the loss of external ac power, the inlet port closes and the exhaust port opens. The scram pilot valve is designed so that the trip system signal must be removed from both solenoids before air pressure can be discharged from the scram valve operators. This prevents inadvertent scram of a single drive if one of the scram pilot valve solenoids fails.

4.6.1.2.4.3.7 Scram Inlet Valve

The scram inlet valve opens to supply pressurized water to the bottom of the drive piston. This quick-opening globe valve is operated by an internal spring and system pressure. It is closed by air pressure applied to the top of its diaphragm operator. A position indicator switch on this valve and on the scram exhaust valve energizes a light in the control room as soon as the valve starts to open.

4.6.1.2.4.3.8 Scram Exhaust Valve

The scram exhaust valve opens slightly before the scram inlet valve, exhausting water from above the drive piston. The exhaust valve opens faster than the inlet valve because of the higher air pressure spring setting in the valve operator.

4.6.1.2.4.3.9 Scram Accumulator

The scram accumulator stores sufficient energy to fully insert a control rod at lower vessel pressures. At higher vessel pressures the accumulator pressure is assisted or supplanted by reactor vessel pressure. The accumulator is a hydraulic cylinder with a free-floating piston. The piston separates the water on top from the nitrogen below. A check valve in the accumulator charging line prevents loss of water pressure if supply pressure is lost.

During normal plant operation, the accumulator piston is seated at the bottom of its cylinder. Loss of nitrogen decreases the nitrogen pressure which actuates a pressure switch which sounds an alarm and actuates an indicating light in the control room.

To ensure that the accumulator is able to produce a scram, it is monitored for water leakage. A float-type level switch actuates an alarm and an indicating light in the control room if water leaks past the piston barrier and collects in the accumulator instrumentation block.

4.6.1.2.5 Control Rod Drive System Operation

The CRD system performs rod insertion, rod withdrawal, and scram. These operational functions are described below.

4.6.1.2.5.1 Rod Insertion

Rod insertion is initiated by a signal from the operator to the insert valve solenoids. This signal causes both insert valves to open. The insert drive valve applies reactor pressure plus approximately 90 psi to the bottom of the drive piston. The insert exhaust valve allows water from above the drive piston to discharge to the exhaust header.

As is illustrated in Figure 4.6-3, the locking mechanism is a ratchet-type device and does not interfere with rod insertion. The speed at which the drive moves is determined by the flow through the insert speed control valve, which is set for approximately 4 gpm for a shim speed (nonscram operation) of 3 in/sec. During normal insertion, the pressure on the downstream side of the speed control valve is 90-100 psi above reactor vessel pressure. However, if the drive slows for any reason, the flow through and the pressure drop across the insert speed control valve decreases; the full differential pressure (260 psi) is then available to cause continued insertion. With 260 psi differential pressure acting on the drive piston, the piston exerts an upward force of 1040 pounds.

4.6.1.2.5.2 Rod Withdrawal

Rod withdrawal is, by design, more involved than insertion. The collet fingers (latch) must be raised to reach the unlocked position (Figure 4.6-3). The notches in the index tube and the collet fingers are shaped so that the downward force on the index tube holds the collet fingers in place. The index tube must be lifted before the collet fingers can be released. This is done by opening the drive insert valves (in the manner described in the preceding paragraph) for approximately one second. The withdraw valves are then opened, applying driving pressure above the drive piston,

and opening the area below the piston to the exhaust header. Pressure is simultaneously applied to the collet piston. As the piston raises, the collet fingers are cammed outward, away from the index tube, by the guide cap.

The pressure required to release the latch is set and maintained at a level high enough to overcome the force of the latch return spring, plus the force of reactor pressure opposing movement of the collet piston. When this occurs, the index tube is unlatched and free to move in the withdraw direction. Water displaced by the drive piston flows out through the withdraw speed control valve, which is set to give a rod shim speed of approxiately 3 in/sec. The entire valving sequence is automatically controlled, and is initiated by a single operation of the rod withdraw switch.

Rod withdrawal will not occur without permissive operator action. Following a deliberate operator withdrawal action, a rod drift could occur due to failure of its collet assembly to return to the locked position. The operator can interrupt this withdrawal with a scram or an insert signal. No single failure can of itself initiate a rod withdrawal.

4.6.1.2.5.3 Scram

During a scram, the scram pilot valves and scram valves are operated as previously described. With the scram valves open, accumulator pressure is admitted under the drive piston, and the area over the drive piston is vented to the SDV.

The large differential pressure (approximately 1500 psi initially, and always several hundred psi, depending on reactor vessel pressure) produces a large upward force on the index tube and control rod. This force gives the rod a high initial acceleration and provides a large margin of force to overcome friction. After the initial acceleration is achieved, the drive continues at a nearly constant velocity. This characteristic provides a high initial rod insertion rate. As the drive piston nears the top of its stroke, the piston seals close off the large passage (buffer orifices) in the stop piston tube, providing a hydraulic cushion at the end of travel.

Prior to a scram signal, the accumulator in the HCU has approximately 1450-1510 psig on the water-side and 1050-1150 psig on the nitrogen side. As the inlet scram valve opens, the full water-side pressure is available at the CRD acting on a 4.1 in^2 area. As CRD motion begins, this pressure drops to the gas-side pressure, less line losses between the accumulator and the CRD. At low vessel pressures, the accumulator completely discharges with a resulting gas-side pressure of approximately 575 psi. The CRD accumulators are required to scram the control rods when the reactor pressure is low, and the accumulators retain sufficient stored energy to ensure the complete insertion of the control rods in the required time.

The ball check valve in the drive flange allows reactor pressure to supply the scram force whenever reactor pressure exceeds the supply pressure at the drive. This occurs, due to accumulator pressure decay and inlet line losses, during all scrams at higher vessel pressures. When the reactor is close to, or at, full operating pressure, reactor pressure alone inserts the control rod in the required time, although the accumulator does provide additional margin at the beginning of the stroke.

The CRD system, with accumulators, provides the following scram performances at full power operation, in terms of average elapsed time after the opening of the RPS trip actuator (scram signal) for the drives to attain the scram strokes listed (See Figure 15.0-2):

% of full stroke	5	20	50	90
Stroke, in	7.2	28.8	72.0	129.6
Average time, sec	0.375	0.90	2.0	3.5

4.6.1.2.5.4 Alternate Rod Insertion

The ARI feature of the RRCS is designed to increase the reliability of the CRD system. ARI provides for rod insertion by actuating valves that are redundant and diverse from the RPS scram pilot valves.

The RRCS signal to insert control rods results in energizing the eight ARI dc solenoid valves shown in drawings M-46, M-47, C11-1020-G-004, C11-1020-G-005, C11-1020-G-006, and C11-1020-G-007. Two of these valves, in series with the backup scram valves, also have parallel functioning check valves to ensure venting of air from the air supply line in the event that an ARI valve fails. Four ARI valves provide for venting of the HCU scram valve pilot air headers to atmosphere. Depressurizing the headers actuates rod insertion. The remaining two ARI valves vent the scram air header that supplies the air pressure to keep the vent and drain lines open, thereby resulting in isolation of the SDV.

4.6.1.2.6 Instrumentation

The instrumentation, for both the CRDMs and HCUs, is defined by that given for the RMCS. The objective of the RMCS is to provide the operator with the means to make changes in nuclear reactivity so that reactor power level and power distribution can be controlled. The system allows the operator to manipulate control rods.

The design bases and further discussion are discussed in Chapter 7. Section 7.6 lists the leak detection systems provided. Operator action is relied on to determine possible break locations based on these and plant system observations as discussed in GE report NEDO-24342 for CRD system breaks.

The licensee participated in the development of NEDO-22209, which was transmitted to the NRC by the BWROG on August 23, 1982. The results of NEDO-22209 show a probability of failure of the SDV too small to warrant exclusive monitoring devices.

4.6.1.3 Control Rod Drive Housing Supports

4.6.1.3.1 Safety Objective

The CRD housing supports prevent any significant nuclear transient from occurring if a drive housing breaks or separates from the bottom of the reactor vessel.

4.6.1.3.2 Safety Design Bases

The CRD housing supports meet the following safety design bases:

a. Following a postulated CRD housing failure, control rod downward motion is limited, so that any resulting nuclear transient could not be sufficient to cause fuel damage.

b. The clearance between the CRD housings and the supports is sufficient to prevent vertical contact stresses caused by thermal expansion during plant operation.

4.6.1.3.3 Description

The CRD housing supports are shown in Figure 4.6-9. Horizontal beams are installed immediately below the bottom head of the reactor vessel, between the rows of CRD housings. The beams are welded to brackets which are welded to the steel form liner of the drive room in the reactor support pedestal.

Hanger rods, approximately 10 feet long and 1¾ inches in diameter, are supported from the beams on stacks of disc springs. These springs compress approximately 2 inches under the design load.

The support bars are bolted between the bottom ends of the hanger rods. The spring pivots at the top, and the beveled, loose-fitting ends on the support bars prevent substantial bending moment in the hanger rods if the support bars are overloaded.

Individual grids rest on the support bars between adjacent beams. Because a single-piece grid would be difficult to handle in the limited work space and because it is necessary that CRDs, position indicators, and incore instrumentation components be accessible for inspection and maintenance, each grid is designed for in-place assembly or disassembly. Each grid assembly is made from two grid plates, a clamp, and a bolt. The top part of the clamp guides the grid to its correct position, directly below the respective CRD housing that it would support in the postulated accident.

When the support bars and grids are installed, a gap of approximately l inch at room temperature (approximately 70°F) is provided between the grid and the bottom contact surface of the CRD flange. During system heatup, this gap is reduced by a net downward expansion of the housings with respect to the supports. In the hot operating condition, the gap is approximately ¾ inch.

In the postulated CRD housing failure, the CRD housing supports are loaded when the lower contact surface of the CRD flange contacts the grid. The resulting load is then carried by two grid plates, two support bars, four hanger rods, their disc springs, and two adjacent beams.

The AISC Manual of Steel Construction, "Specification for the Design, Fabrication and Erection of Structural Steel for Buildings" is used in designing the CRD housing support system. However, to provide a structure that absorbs as much energy as practical without yielding, the allowable tension and bending stresses used are 90% of yield, and the shear stress used is 60% of yield. These design stresses are 1.5 times the AISC allowable stresses (60% and 40% of yield, respectively).

For purposes of mechanical design, the postulated failure resulting in the highest forces is an instantaneous circumferential separation of the CRD housing from the reactor vessel, with the reactor at an operating pressure of 1086 psig (at the bottom of the vessel) acting on the area of the separated housing. The weight of the separated housing, CRD, and blade, plus the pressure of 1086 psig acting on the area of the separated housing, gives a force of approximately 32,000 pounds. This force is used to calculate the impact force, conservatively assuming that the housing travels through a 1 inch gap before it contacts the supports. The impact force (109,000 lb) is then

treated as a static load in design. The CRD housing supports are designed as seismic Category I equipment as discussed in Section 3.2. Loading conditions and examples of stress analysis results and limits are shown in Table 3.9-6. A safety evaluation is provided in Section 4.6.2.3.3.

4.6.2 EVALUATIONS OF THE CRD SYSTEM

4.6.2.1 Failure Mode and Effects Analysis

This subject is discussed in Section 15.9.

4.6.2.2 Protection from Common Mode Failures

This subject is discussed in Section 15.9.

4.6.2.3 Safety Evaluation

Safety evaluation of the control rods, CRDs, and CRD housing supports is described below. Further description of control rods is contained in Section 4.2.

4.6.2.3.1 Control Rods

4.6.2.3.1.1 Materials Adequacy Throughout Design Lifetime

The adequacy of the materials throughout the design life is evaluated in the mechanical design of the control rods. The primary materials, boron carbide (B_4C) powder, solid hafnium, and 304 austenitic stainless steel, have been found suitable in meeting the demands of the BWR environment.

4.6.2.3.1.2 Dimensional and Tolerance Analysis

Layout studies are done to ensure that, given the worst combination of part tolerance ranges at assembly, no interference exists that will restrict the passage of control rods. In addition, preoperational verification is made on each control blade system to show that the acceptable levels of operational performance are met.

4.6.2.3.1.3 Thermal Analysis of the Tendency to Warp

The various parts of the control rod assembly remain at approximately the same temperature during reactor operation, negating the problem of distortion or warpage. What little differential thermal growth that could exist is allowed for in the mechanical design. A minimum axial gap is maintained between absorber rod tubes and the control rod frame assembly for this purpose. Use of dissimilar metals (stainless steel and hafnium) is evaluated to ensure that any effects due to thermal expansion or irradiation growth are acceptable.

4.6.2.3.1.4 Forces for Expulsion

An analysis has been performed which evaluates the maximum pressure forces which could tend to eject a control rod from the core. The results of this analysis are given in Section 4.6.2.3.2.2.2. In summary, if the collet were to remain open, which is unlikely, calculations indicate that the steady-state control rod withdrawal velocity would be 2 ft/sec for a pressure-under line break, the limiting case for rod withdrawal.

4.6.2.3.1.5 Functional Failure of Critical Components

The consequences of a functional failure of critical components have been evaluated and the results are covered in Section 4.6.2.3.2.2.

4.6.2.3.1.6 Precluding Excessive Rates of Reactivity Addition

In order to preclude excessive rates of reactivity addition, analysis has been performed both on the velocity limiter device, and the effect of probable control rod failures (Section 4.6.2.3.2.2).

4.6.2.3.1.7 Effect of Fuel Rod Failure on Control Rod Channel Clearances

The CRD mechanical design ensures a sufficiently rapid insertion of control rods to preclude the occurrence of fuel rod failures, which could hinder reactor shutdown by causing significant distortions in channel clearances.

4.6.2.3.1.8 Mechanical Damage

Analysis has been performed for all areas of the control system, showing that system mechanical damage does not affect the capability to continuously provide reactivity control.

In addition to the analysis performed on the CRDs (Sections 4.6.2.3.2.2 and 4.6.2.3.2.3) and the control rod blade, the following discussion summarizes the analysis performed on the control rod guide tube.

The guide tube can be subjected to any or all of the following loads:

a. Inward load due to pressure differential

b. Lateral loads due to flow across the guide tube

c. Dead Weight

d. Seismic (Vertical and Horizontal)

e. Vibration

In all cases, the analysis considers both a recirculation line break and a steam line break. These events result in the largest hydraulic loadings on a control rod guide tube.

Two primary modes of failure are considered in the guide tube analysis; exceeding allowable stress, and excessive elastic deformation. It was found that the allowable stress limit is not exceeded, and that the elastic deformations of the guide tube are never great enough to cause the free movement of the control rod to be jeopardized.

4.6.2.3.1.9 Evaluation of Control Rod Velocity Limiter

The control rod velocity limiter limits the free fall velocity of the control rod to a value that cannot result in nuclear system process barrier damage. This velocity is evaluated in the rod-drop accident analysis in Chapter 15.

4.6.2.3.2 Control Rod Drives

4.6.2.3.2.1 Evaluation of Scram Time

The rod scram function of the CRD system provides the negative reactivity insertion required by safety design basis as stated in Section 4.6.1.1.1. The scram time shown in the description is adequate as shown by the transient analyses of Chapter 15.

4.6.2.3.2.2 Analysis of Malfunction Relating to Rod Withdrawal

There are no known single malfunctions that cause the unplanned withdrawal of even a single control rod. However, if multiple malfunctions are postulated, studies show that an unplanned rod withdrawal can occur at withdrawal speeds that vary with the combination of malfunctions postulated. In all cases the subsequent withdrawal speeds are less than that assumed in the rod-drop accident analysis as discussed in Chapter 15. Therefore, the physical and radiological consequences of such rod withdrawals are less than those analyzed in the rod-drop accident.

4.6.2.3.2.2.1 Drive Housing Failure at Attachment Weld

The bottom head of the reactor vessel has a penetration for each CRD location. A drive housing is raised into position inside each penetration and is fastened by welding. The drive is raised into the drive housing and bolted to a flange at the bottom of the housing. The housing material is seamless, Type 304 stainless steel pipe with a minimum tensile strength of 75,000 psi. The basic failure considered here is a complete circumferential crack through the housing wall at an elevation just below the J-weld.

Static loads on the housing wall include the weight of the drive and the control rod, the weight of the housing below the J-weld, and the reactor pressure acting on the 6 inch diameter cross-sectional area of the housing and the drive. Dynamic loading results from the reaction force during drive operation.

If the housing were to fail as described, the following sequence of events is foreseen:

a. The housing would separate from the reactor vessel.

b. The CRD and housing would be blown downward against the support structure, by reactor pressure acting on the cross-sectional area of the housing and the drive.

c. The downward motion of the drive and associated parts would be determined by the gap between the bottom of the drive and the support structure, and by the deflection of the support structure under the load.

    1. In the current design, maximum deflection is approximately 3 inches.

    2. If the collet remains latched, no further control rod ejection would occur (Reference 4.6-1); the housing would not drop far enough to clear the reactor vessel penetration.

d. Reactor water would leak at a rate of approximately 180 gpm, through the 0.03 inch diameter clearance between the housing OD and reactor vessel penetration ID.

If the basic housing failure were to occur while the control rod is being withdrawn (this is a small fraction of the total drive operating time) and if the collet were to stay unlatched, the following sequence of events is foreseen:

a. The housing would separate from the reactor vessel.

b. The control rod, CRD, and housing would be blown downward against the CRD housing support.

c. Calculations indicate that the steady-state rod withdrawal velocity would be 0.3 ft/sec.

d. During withdrawal, pressure under the collet piston would be approximately 250 psi greater than the pressure over it; therefore, the collet would be held in the unlatched position until driving pressure was removed from the pressure-over port.

4.6.2.3.2.2.2 Rupture of Hydraulic Line(s) to Drive Housing Flange

There are three types of possible rupture of hydraulic lines to the drive housing flange: pressure-under (insert) line break; pressure-over (withdrawn) line break; and coincident breakage of both of these lines.

4.6.2.3.2.2.2.1 Pressure-Under (Insert) Line Break

For the case of a pressure-under (insert) line break, a partial or complete circumferential opening is postulated at or near the point where the line enters the housing flange. Failure is more likely to occur after another basic failure, wherein the drive housing or housing flange separates from the reactor vessel. Failure of the housing, however, does not necessarily lead directly to failure of the hydraulic lines.

If the pressure-under (insert) line were to fail and if the collet were latched, no control rod withdrawal would occur. There would be no pressure differential across the collet piston and, therefore, no tendency to unlatch the collet. Consequently, the associated control rod could not be withdrawn, but if reactor pressure is greater than 600 psig, it will insert on a scram signal.

The ball check valve is designed to seal off a broken pressure-under line by using reactor pressure to shift the check ball to its upper seat. If the ball check valve were prevented from seating, reactor water would leak to the reactor enclosure or containment. Because of the broken line, cooling water could not be supplied to the drive involved. Loss of cooling water would cause no immediate damage to the drive. However, prolonged exposure of the drive to temperatures at or near reactor temperature could lead to deterioration of material in the seals. High temperature would be indicated to the operator by the thermocouple in the position indicator probe, by high cooling water flow, and by operation of the containment sump pump.

If the basic line failure were to occur while the control rod is being withdrawn, the hydraulic force would not be sufficient to hold the collet open, and spring force normally would cause the collet to latch and stop rod withdrawal. However, if the collet were to remain open, calculations indicate that the steady-state control rod withdrawal velocity would be 2 ft/sec.

4.6.2.3.2.2.2.2 Pressure-Over (Withdrawn) Line Break

The case of the pressure-over (withdrawn) line breakage considers the complete breakage of the line at or near the point where it enters the housing flange. If the line were to break, pressure over the drive piston would drop from reactor pressure to atmospheric pressure. Any significant reactor pressure (approximately 600 psig or greater) would act on the bottom of the drive piston and fully insert the drive. Insertion would occur regardless of the operational mode at the time of the failure. After full insertion, reactor water would leak past the stop piston

seals. This leakage would exhaust to the atmosphere through the broken pressure-over line. The leakage rate at 1000 psi reactor pressure is estimated to be 1-3 gpm; however, with the Graphitar seals of the stop piston removed, the leakage rate could be as high as 10 gpm, based on experimental measurements. If the reactor were hot, drive temperature would increase. This situation would be indicated to the reactor operator by the drift alarm, by the fully inserted drive, by a high drive temperature (annunciated in the control room), and by operation of the drywell sump pump.

4.6.2.3.2.2.2.3 Simultaneous Breakage of the Pressure-Over (Withdrawn) Pressure-Under (Insert) Lines

For the simultaneous breakage of the pressure-over (withdrawn) and pressure-under (insert) lines, pressures above and below the drive piston would drop to zero, and the ball check valve would close the broken pressure-under line. Reactor water would flow from the annulus outside the drive, through the vessel ports, and to the space below the drive piston. As in the case of pressure-over line breakage, the drive would then insert (at reactor pressure approximately 600 psi or greater) at a speed dependent on reactor pressure. Full insertion would occur regardless of the operational mode at the time of failure. Reactor water would leak past the drive seals and out the broken pressure-over line to the reactor enclosure or containment, as described above. Drive temperature would increase. Indication in the control room would include the drift alarm, the fully inserted drive, the high drive temperature annunciated in the control room, and the operation of the drywell sump pump.

4.6.2.3.2.2.3 All Drive Flange Bolts Fail in Tension

Each CRD is bolted to a flange at the bottom of a drive housing. The flange is welded to the drive housing. Bolts are made of AISI-4140 steel or AISI-4340 steel, with a minimum tensile strength of 125,000 psi. Each bolt has an allowable load capacity of at least 15,200 pounds. Capacity of the 8 bolts is at least 121,600 pounds. As a result of the reactor design pressure of 1250 psig, the major load on all 8 bolts is 30,400 pounds.

If a progressive or simultaneous failure of all bolts occurs, the drive separates from the housing. The control rod and the drive would be blown downward against the support structure. Impact velocity and support structure loading would be slightly less than that for drive housing failure, because reactor pressure would act on the drive's cross-sectional area only and the housing would remain attached to the reactor vessel. The drive would be isolated
from the cooling water supply. Reactor water would flow downward past the velocity limiter piston, through the large drive filter, and into the annular space between the thermal sleeve and the drive. For worst case leakage calculations, the large filter is assumed to be deformed or swept out of the way so it would offer no significant flow restriction. At a point near the top of the annulus, where pressure would have dropped to 350 psi, the water would flash to steam and cause choke flow conditions. Steam would flow down the annulus and out the space between the housing and the

drive flanges to the drywell. Steam formation would limit the leakage rate to approximately 840 gpm.

If the collet were latched, control rod ejection would be limited to the distance the drive can drop before coming to rest on the support structure. There would be no tendency for the collet to unlatch, because pressure below the collet piston would drop to zero. Pressure forces, in fact, exert 1435 pounds to hold the collet in the latched position.

If the bolts failed during control rod withdrawal, pressure below the collet piston would drop to zero. The collet, with 1650 pounds return force, would latch and stop rod withdrawal.

4.6.2.3.2.2.4 Weld Joining Flange-to-Housing Failure in Tension

The failure considered is a crack in or near the weld that joins the flange to the housing. This crack extends through the wall and completely around the housing. The flange material is forged, Type 304 stainless steel, with a minimum tensile strength of 75,000 psi. The housing material is seamless, Type 304 stainless steel pipe, with a minimum tensile strength of 75,000 psi. The conventional, full penetration weld of Type 308 stainless steel has a minimum tensile strength approximately the same as that for the parent metal. The design pressure and temperature are 1250 psig and 575°F. Reactor pressure acting on the cross-sectional area of the drive; the weight of the control rod, drive, and flange; and the dynamic reaction force during drive operation result in a maximum tensile stress at the weld of approximately 6000 psi.

If the basic flange-to-housing joint failure occurred, the flange and the attached drive would be blown downward against the support structure. The support structure loading would be slightly less than that for drive housing failure, because reactor pressure would act only on the drive cross-sectional area. Lack of differential pressure across the collet piston would cause the collet to remain latched and limit control rod motion to approximately 3 inches. Downward drive movement would be small; therefore, most of the drive would remain inside the housing. The pressure-under and pressure-over lines are flexible enough to withstand the small

displacement and remain attached to the flange. Reactor water would follow the same leakage path described above for the flange bolt failure, except that exit to the drywell would be through the gap between the lower end of the housing and the top of the flange. Water would flash to steam in the annulus surrounding the drive. The leakage rate would be approximately 840 gpm.

If the basic failure were to occur during control rod withdrawal (a small fraction of the total operating time) and if the collet were held unlatched, the flange would separate from the housing. The drive and flange would be blown downward against the support structure. The calculated steady-state rod withdrawal velocity would be 0.13 ft/sec. Because pressure-under and pressure-over lines remain intact, driving water pressure would continue to the drive, and the normal exhaust line restriction would exist. The pressure below the velocity limiter piston would drop below normal as a result of leakage from the gap between the housing and the flange. This differential pressure across the velocity limiter piston would result in a net downward force of approximately 70 pounds. Leakage out of the housing would greatly reduce the pressure in the annulus surrounding the drive. Thus, the net downward force on the drive piston would be less than normal. The overall effect of these events would be to reduce rod withdrawal to approximately one-half of normal speed. With a 560-psi differential across the collet piston, the collet would remain unlatched; however, it should relatch as soon as the drive signal is removed.

4.6.2.3.2.2.5 Housing Wall Ruptures

This failure is a vertical split in the drive housing wall just below the bottom head of the reactor vessel. The flow area of the hole is considered equivalent to the annular area between the drive and the thermal sleeve. Thus, flow through this annular area, rather than flow through the hole in the housing, would govern leakage flow. The housing is made of Type 304 stainless steel seamless pipe, with a minimum tensile strength of 75,000 psi. The maximum hoop stress of 11,900 psi results primarily from the reactor design pressure (1250 psig) acting on the inside of the housing.

If such a rupture were to occur, reactor water would flash to steam, and leak through the hole in the housing to the drywell at approximately 1030 gpm. Choke flow conditions would exist, as described previously for the flange bolt failure. However, leakage flow would be greater because flow resistance would be less, that is, the leaking water and steam would not have to flow down the length of the housing to reach the drywell. A critical pressure of 350 psi causes the water to flash to steam.

There would be no pressure differential acting across the collet piston to unlatch the collet; but the drive would insert as a result of loss of pressure in the drive housing causing a pressure drop in the space above the drive piston.

If this failure occurred during control rod withdrawal, drive withdrawal would stop, but the collet would remain unlatched. The drive would be stopped by a reduction of the net downward force action on the drive line. The net force reduction would occur when the leakage flow of 1030 gpm reduces the pressure in the annulus outside the drive to approximately 540 psig, thereby reducing the pressure acting on top of the drive piston to the same value. A pressure differential of approximately 710 psi would exist across the collet piston and holds the collet unlatched as long as the operator holds the withdraw signal.

4.6.2.3.2.2.6 Flange Plug Blows Out

To connect the vessel ports with the bottom of the ball check valve, a hole of 0.75 inch diameter is drilled in the drive flange of this hole is sealed with a plug of 0.812 inch diameter and 0.25 inch thickness. A full penetration, Type 308 stainless steel weld holds the plug in place. The postulated failure is a full circumferential crack in this weld and subsequent blowout of the plug.

If the weld were to fail, the plug were to blow out, and the collet remained latched, there would be no control rod motion. There would be no pressure differential acting across the collet piston to unlatch the collet. Reactor water would leak past the velocity limiter piston, down the annulus between the drive and the thermal sleeve, through the vessel ports and drilled passage, and out the open plug hole to the drywell at approximately 320 gpm. Leakage calculations assume only liquid flows from the flange. Actually, hot reactor water would flash to steam, and choke flow conditions would exist. Thus, the expected leakage rate would be lower than the calculated value. Drive temperature would increase and initiate an alarm in the control room.

If this failure were to occur during control rod withdrawal and if the collet were to stay unlatched, calculations indicate that control rod withdrawal speed would be approximately 0.24 ft/sec. Leakage from the open plug hole in the flange would cause reactor water to flow downward past the velocity limiter piston. A small differential pressure across the piston would result in an insignificant driving force of approximately 10 pounds, tending to increase withdraw velocity.

A pressure differential of 295 psi across the collet piston would hold the collet unlatched as long as the driving signal was maintained.

Flow resistance of the exhaust path from the drive would be normal because the ball check valve would be seated at the lower end of its travel by pressure under the drive piston.

4.6.2.3.2.2.7 Ball Check Valve Plug Blows Out

As a means of access for machining the ball check valve cavity, a 1.25 inch diameter hole has been drilled in the flange forging. This hole is sealed with a plug with a 1.31 inch diameter and 0.38 inch thickness. A full penetration weld, utilizing Type 308 stainless steel filler, holds the plug in place. The failure postulated is a circumferential crack in this weld leading to a blowout of the plug.

If the plug were to blow out while the drive was latched, there would be no control rod motion. No pressure differential would exist across the collet piston to unlatch the collet. As in the previous failure, reactor water would flow past the velocity limiter, down the annulus between the drive and thermal sleeve, through the vessel ports and drilled passage, through the ball check valve cage and out the open plug hole to the drywell. The leakage calculations indicate that the flow rate would be 350 gpm. This calculation assumes liquid flow, but flashing of the hot reactor water to steam would reduce this rate to a lower value. Drive temperature would rapidly increase and initiate an alarm in the control room.

If the plug failure were to occur during control rod withdrawal, (it would not be possible to unlatch the drive after such a failure) the collet would relatch at the first locking groove. If the collet were to stick, calculations indicate the control rod withdrawal speed would be 11.8 ft/sec. There would be a large retarding force exerted by the velocity limiter due to a 35 psi pressure differential across the velocity limiter piston.

4.6.2.3.2.2.8 Drive/Cooling Water Pressure Control Valve Closure (Reactor Pressure, 0 psig)

The pressure to move a drive is generated by the pressure drop of practically the full system flow through the drive/cooling water pressure control valve. This valve is either a MOV or a standby manual valve; either one is adjusted to a fixed opening. The normal pressure drop across this valve develops a pressure 260 psi in excess of reactor pressure.

If the flow through the drive/cooling water pressure control valve were to be stopped, as by a valve closure or flow blockage, the drive pressure would increase to the shutoff pressure of the supply pump. The occurrence of this condition during withdrawal of a drive at zero vessel pressure will result in a drive pressure increase from 260 psig to no more than 1750 psig. Calculations indicate that the drive accelerates from 3 in/sec to approximately 6.5 in/sec. A pressure differential of 1670 psi across the collet piston would hold the collet unlatched. Flow would be upward, past the velocity limiter piston, but retarding force would be negligible. Rod movement would stop as soon as the driving signal was removed.

4.6.2.3.2.2.9 Ball Check Valve Fails to Close Passage to Vessel Ports

Should the ball check valve sealing the passage to the vessel ports be dislodged and prevented from reseating following the insert portion of a drive withdrawal sequence, water below the drive piston would return to the reactor through the vessel ports and the annulus between the drive and the housing rather than through the speed control valve. Because the flow resistance of this return path would be lower than normal, the calculated withdrawal speed would be 2 ft/sec. During

withdrawal, differential pressure across the collet piston would be approximately 40 psi. Therefore, the collet would tend to latch and would have to stick open before continuous withdrawal at 2 ft/sec could occur. Water would flow upward past the velocity limiter piston, generating a small retarding force of approximately 120 pounds.

4.6.2.3.2.2.10 Hydraulic Control Unit Valve Failures

Various failures of the valves in the HCU can be postulated, but none could produce differential pressures approaching those described in the preceding paragraphs, and none alone could produce a high velocity withdrawal. Leakage through either one or both of the scram valves produces a pressure that tends to insert the control rod rather than to withdraw it. If the pressure in the SDV should exceed reactor pressure following a scram, a check valve in the line to the scram discharge header prevents this pressure from operating the drive mechanisms.

4.6.2.3.2.2.11 Collet Fingers Fail to Latch

The failure is presumed to occur when the drive withdraw signal is removed. If the collet fails to latch, the drive continues to withdraw at a fraction of the normal speed. This assumption is made because there is no known means for the collet fingers to become unlocked without some initiating signal. Because the collet fingers will not cam open under a load, accidental application of a down signal does not unlock them. (The drive must be given a short insert signal to unload the fingers and cam them open before the collet can be driven to the unlock position.) If the drive withdrawal valve fails to close following a rod withdrawal, the collet would remain open and the drive would continue to move at a reduced speed.

4.6.2.3.2.2.12 Withdrawal Speed Control Valve Failure

Normal withdrawal speed is determined by differential pressures in the drive and is set for a nominal value of 3 in/sec. Withdrawal speed is maintained by the pressure regulating system and is independent of reactor vessel pressure. Tests show that accidental opening of the speed control valve to the fully open position produces a velocity of approximately 6 in/sec.

The CRD system prevents unplanned rod withdrawal, and it has been shown above that only multiple failures in a drive unit and in its control unit could cause an unplanned rod withdrawal.

4.6.2.3.2.3 Scram Reliability

High scram reliability is the result of a number of features of the CRD system. For example:

a. Two reliable sources of scram energy are used to insert each control rod: individual accumulators at low reactor pressure, and the reactor vessel pressure itself at power.

b. Each drive mechanism has its own scram valves and one scram pilot valve with two pilot solenoids, so only one drive can be affected if a scram valve fails to open. Both pilot solenoids must be de-energized to initiate a scram.

c. The RPS and the HCUs are designed so that the scram signal and mode of operation override all others.

d. The collet assembly and index tube are designed so they do not restrain or prevent control rod insertion during scram.

e. The SDV is monitored for accumulated water and the reactor scrams before the volume is reduced to a point that could interfere with a scram.

4.6.2.3.2.4 Control Rod Support and Operation

As described above, each control rod is independently supported and controlled as required by safety design bases.

4.6.2.3.3 Control Rod Drive Housing Supports

Downward travel of the CRD housing and its control rod following the postulated housing failure equals the sum of these distances: the compression of the disc springs under dynamic loading, and the initial gap between the grid and the bottom contact surface of the CRD flange. If the reactor were cold and pressurized, the downward motion of the control rod would be limited to the spring compression (approximately 2 inches) plus a gap of approximately 3/4" ± 1/4". If the reactor were hot and pressurized, the gap would be approximately 1/2" ± 1/4" and the spring compression would be slightly less than in the cold condition. In either case, the control rod movement following a housing failure is substantially limited below one drive "notch" movement (6 inches). Sudden withdrawal of any control rod, through a distance of one drive notch at any position in the core, does not produce a transient sufficient to damage any radioactive material barrier.

The CRD housing supports are in place during power operation and when the nuclear system is pressurized. If a control rod is ejected during shutdown, the reactor remains subcritical because it is designed to remain subcritical with any one control rod fully withdrawn at any time.

At plant operating temperature, a gap of approximately 1/2" ± 1/4" exists between the CRD housing and the supports. At lower temperatures the gap is greater. Because the supports do not contact any of the CRD housing, except during the postulated accident condition, vertical contact stresses are prevented. Inspection and testing are discussed in Section 4.6.3.2.

4.6.2.3.4 Loss of Scram Discharge Valve Air Pressure

Slow or partial loss of air pressure to the scram discharge valves will not result in rapid filling of both the SDV and the SDIV, with consequent loss of adequate discharge volume. This is assured by the physical arrangement of this piping. This SDIV has a cross-sectional area greater than that of the SDV and is connected directly to the SDV, without restriction. In addition, the SDV piping slopes continuously toward the SDIV. Because of this arrangement, both volumes will not fill concurrently but rather the SDIV will fill, causing a reactor scram on high instrument volume level, prior to any filling of the SDV.

Likewise, a loss of reactor coolant will not occur for this event because the scram signal described above will also cause the SDV vent and drain valves to go closed.

4.6.3 TESTING AND VERIFICATION OF THE CONTROL ROD DRIVES

4.6.3.1 Control Rod Drives

4.6.3.1.1 Testing and Inspection

4.6.3.1.1.1 Development Tests

The initial development drive (prototypes of the standard locking piston design) testing included more than 5000 scrams and approximately 100,000 latching cycles. One prototype was exposed to simulated operating conditions for 5000 hours. These tests demonstrated the following:

a. The drive easily withstands the forces, pressures, and temperatures imposed.

b. Wear, abrasion, and corrosion of the nitrided stainless steel parts are negligible. Mechanical performance of the nitrided surface is superior to that of materials used in earlier operating reactors.

c. The basic scram speed of the drive has a satisfactory margin above minimum plant requirements at any reactor vessel pressure.

d. Usable seal lifetimes in excess of 1000 scram cycles can be expected.

4.6.3.1.1.2 Factory Quality Control Tests

Quality control of welding, heat treatment, dimensional tolerances, material verification, and similar factors is maintained throughout the manufacturing process to ensure reliable performance of the mechanical reactivity control components. Some of the quality control tests performed on the control rods, CRDMs, and HCUs are listed below:

a. CRDM tests:

1. Pressure welds on the drives are hydrostatically tested in accordance with ASME codes.

2. Electrical components are checked for electrical continuity and resistance to ground.

3. Drive parts that cannot be visually inspected for dirt are flushed with filtered water at high velocity. No significant foreign material is permitted in effluent water.

4. Seals are tested for leakage to demonstrate correct seal operation.

5. Each drive is tested for shim motion, latching, and control rod position indication.

6. Each drive is subjected to cold scram tests at various reactor pressures to verify correct scram performance.

b. HCU tests:

1. Hydraulic systems are hydrostatically tested in accordance with the applicable code.

2. Electrical components and systems are tested for electrical continuity and resistance to ground.

3. Correct operation of the accumulator pressure and level switches is verified.

4. The unit's ability to perform its part of a scram is demonstrated.

5. Correct operation and adjustment of the insert and withdrawal valves is demonstrated.

c. Control rod tests:

1. Absorber rods are examined by nondestructive methods to ensure correct B_4C density and weld integrity.

2. The absorber rod process control rod is inspected to ensure correct assembly.

3. The envelope of each control rod is inspected to ensure correct assembly.

4.6.3.1.1.3 Operational Tests

After installation, all control rods and drive mechanisms are tested through their full stroke for operability.

During normal operation, each time a control rod is withdrawn a notch, the operator can observe the incore monitor indications to verify that the control rod is following the drive mechanism. All control rods that are partially withdrawn from the core can be tested for rod following by inserting or withdrawing the rod one notch and returning it to its original position, while the operator observes the incore monitor indications.

To make a positive test of control rod-to-CRD coupling integrity, the operator can withdraw a control rod to the end of its travel and then attempt to withdraw the drive to the overtravel position. Failure of the drive to overtravel demonstrates rod-to-drive coupling integrity.

Hydraulic supply subsystem pressures can be observed from instrumentation in the control room. Scram accumulator pressures can be observed on the nitrogen pressure gauges.

4.6.3.1.1.4 Acceptance Tests

Criteria for acceptance of the individual CRDMs and the associated control and protection systems are incorporated in specifications and test procedures covering three distinct phases: preinstallation; after installation prior to startup; and during startup testing.

The preinstallation specification will define criteria and acceptable ranges of such characteristics as seal leakage, friction, and scram performance under fixed test conditions which must be met before the component can be shipped.

The after installation, prestartup tests (Chapter 14) include normal and scram motion, and are primarily intended to verify that piping, valves, electrical components, and instrumentation are properly installed. The test specifications will include criteria and acceptable ranges for drive

speed, timer settings, scram valve response times, and control pressures. These are tests intended more to document system condition rather than to test performance.

As fuel is placed in the reactor, the startup test procedure (Chapter 14) is followed. The tests in this procedure are intended to demonstrate that the initial operational characteristics meet the limits of the specifications over the range of primary coolant temperatures and pressures from ambient to operating. The detailed specifications and procedures follow the general pattern established for such specifications and procedures in BWRs presently under construction and in operation.

4.6.3.1.1.5 Surveillance Tests

The surveillance requirements for the CRD system are described below:

a. Sufficient control rods are withdrawn, following a refueling outage when core alterations are performed, to demonstrate with a margin of 0.25% Δk that the core can be made subcritical at any time in the subsequent fuel cycle with the most reactive operable control rod fully withdrawn and all other operable rods fully inserted.

b. Each partially or fully withdrawn control rod is exercised one notch periodically in accordance with the Technical Specifications.

   In the event that operation is continuing with three or more rods valved out of service as a result of rod or drive system problems, this test shall be performed at least once each day.

   The periodic control rod exercise test serves as a periodic check against deterioration of the control rod system, and also verifies the ability of the CRD to scram. If a rod can be moved with drive pressure, it may be expected to scram, since higher pressure is applied during scram. The frequency of exercising the control rods, under the conditions of three or more control rods valved out of service as a result of rod or drive system problems, provides even further assurance of the reliability of the remaining control rods.

c. The coupling integrity is verified for each withdrawn control rod as follows:

   1. When the rod is first withdrawn, observe discernible response of the nuclear instrumentation.

   2. When the rod is fully withdrawn the first time, observe that the drive does not go to the overtravel position.

   Observation of a response from the nuclear instrumentation during an attempt to withdraw a control rod indicates indirectly that the rod and drive are coupled. The overtravel position feature provides a positive check on the coupling integrity, for only an uncoupled drive can reach the overtravel position.

d. During operation, accumulator pressure and level at the normal operating value is verified.

Experience with CRD systems of the same type indicates that weekly verification of accumulator pressure and level is sufficient to ensure operability of the accumulator portion of the CRD system.

A channel functional test of the accumulator water leak detectors and a channel calibration of the accumulator pressure detectors, including alarm setpoint $\geq$ 955 psig on decreasing pressure is performed at least once per 24 months.

e. At the time of each major refueling outage, each operable control rod is subjected to scram time tests from the fully withdrawn position.

Experience indicates that the scram times of the control rods do not significantly change over the time interval between refueling outages. A test of the scram times at each refueling outage is sufficient to identify any significant increase in the scram times.

f. The LGS Technical Specifications require periodic testing of the vent and drain valves.

g. The LGS Technical Specifications include periodic testing and acceptance criteria to demonstrate SDV operability

The operability of the entire system as an integrated whole shall be demonstrated periodically and during each operating cycle.

4.6.3.1.1.6 Functional Tests

The functional testing program of the CRDs consists of the 5 year maintenance life and the 1.5 times design life test programs as described in Section 3.9.4.4.

There are a number of failures that can be postulated on the CRD, but it would be very difficult to test all possible failures. A partial test program with postulated accident conditions and imposed single failures is available.

The following tests with imposed single failures have been performed to evaluate the performance of the CRDs under these conditions:

a. Simulated ruptured scram line test

b. Stuck ball check valve in CRD flange

c. HCU drive down inlet flow control valve (V122) failure

d. HCU drive down outlet flow control valve (V120) failure

e. CRD scram performance with V120 malfunction

f. HCU drive up outlet control valve (V121) failure

g. HCU drive up inlet control valve (V123) failure

h. Cooling water check valve (V138) leakage

i. CRD flange check valve leakage

j. CRD stabilization circuit failure

k. HCU filter restriction

l. Air trapped in CRD hydraulic system

m. CRD collet drop test

n. Control rod qualification velocity limiter drop test

Additional postulated CRD failures are discussed in Sections 4.6.2.3.2.2.1 through 4.6.2.3.2.2.12.

4.6.3.2 Control Rod Drive Housing Supports

4.6.3.2.1 Testing and Inspection

CRD housing supports are removed for inspection and maintenance of the CRDs. The supports for one control rod can be removed during reactor shutdown, even when the reactor is pressurized, because all control rods are then inserted. When the support structure is reinstalled, it is inspected for correct assembly with particular attention to maintaining the correct gap between the CRD flange lower contact surface and the grid.

4.6.4 INFORMATION FOR COMBINED PERFORMANCE OF REACTIVITY SYSTEMS

4.6.4.1 Vulnerability to Common Mode Failures

The two reactivity control systems, CRD and SLCS, do not share any instrumentation or components. Thus, a common mode failure of the reactivity systems would be limited to an accident event which could damage essential equipment in the two independent systems.

A seismic event or the postulated accident environments (Section 3.11) are not considered potential common mode failures since the essential (scram) portions of the CRD system are designed to seismic Category I standards and to operate as required under postulated accident environmental conditions. The SLCS system is also designed to seismic Category I standards.

No common mode power failure is considered possible. The scram function of the CRD system is "fail-safe" on a loss of power and is designed to override any other CRD function. The SLCS system has three independent power supplies to its essential redundant pumps and valves. The power supplies to the SLCS system are considered vital and as such are switched to the onsite standby diesels on a loss of normal power sources.

4.6.4.2 Accidents Taking Credit for Multiple Reactivity Systems

There are no postulated accidents evaluated in Chapter 15 that take credit for two or more reactivity control systems preventing or mitigating each accident.

4.6.5 EVALUATION OF COMBINED PERFORMANCE

As indicated in Section 4.6.4.2, credit is not taken for multiple reactivity control systems for any postulated accidents in Chapter 15.

CHAPTER 5 - REACTOR COOLANT SYSTEM AND CONNECTED SYSTEMS

5.1 SUMMARY DESCRIPTION

The RCS includes those systems and components that contain or transport fluids to or from the reactor core. These systems form a major portion of the nuclear system process barrier. This chapter provides information regarding the RCS and pressure-containing appendages out to and including isolation valves. This group of components is defined as the RCPB in 10CFR50.2(v) as follows:

"Reactor coolant pressure boundary means all those pressure-containing components of boiling and pressurized water-cooled nuclear power reactors, such as pressure vessels, piping, pumps, and valves, which are:

a. Part of the reactor coolant system, or

b. Connected to the reactor coolant system, up to and including any and all of the following:

   1. The outermost containment isolation valve in system piping which penetrates primary reactor containment

   2. The second of two valves normally closed during normal reactor operation in system piping which does not penetrate primary reactor containment

   3. The reactor coolant system safety and relief valves."

Section 5.4 of this chapter also deals with various subsystems to the RCPB that are closely allied to it. These are briefly reviewed below.

The nuclear pressure relief system protects the RCPB from damage due to overpressure. To protect against overpressure, pressure-operated relief valves are provided to discharge steam from the NSSS to the suppression pool. The nuclear pressure relief system also acts to automatically depressurize the NSSS if there is a LOCA in which the HPCI system fails to maintain RPV water level. Depressurization of the NSSS allows the low pressure core cooling systems to supply enough cooling water to adequately cool the fuel.

The RCPB leak detection system, described in Section 5.2.5, detects system leakage inside the primary containment so that appropriate action can be taken before the integrity of the nuclear system process barrier is impaired.

The RPV and appurtenances are described in Section 5.3. The major safety functions of the RPV are to maintain water over the core and to act as a radioactive material barrier. The RPV meets the requirements of applicable codes and criteria. The possibility of brittle fracture is considered, and suitable design and operational limits are established that avoid conditions in which brittle fracture is possible.

The reactor recirculation system provides coolant flow through the core. Adjustment of the core coolant flow rate changes reactor power output, thus providing a means of following plant load demand without adjusting the control rods. The reactor recirculation system is designed to provide a slow coast-down of flow so that fuel thermal limits cannot be exceeded as a result of recirculation system malfunctions. The arrangement of the reactor recirculation system piping is such that a piping

failure cannot compromise the integrity of the floodable inner volume of the reactor vessel, thereby helping to ensure adequate core cooling following a LOCA.

The main steam line flow restrictors are venturi-type flow devices. One restrictor is installed in each main steam line inside the primary containment. The restrictors are designed to limit the loss of coolant resulting from a main steam line break outside the primary containment. The coolant loss is limited so that RPV water level remains above the top of the core during the time required for the MSIVs to close. This action maintains the integrity of the fuel cladding (fuel barrier).

The MSIVs automatically close to isolate the nuclear system process barrier if a pipe break occurs downstream of the isolation valves, thereby limiting the loss of coolant and the release of radioactive materials from the NSSS. Two MSIVs are installed on each main steam line, one inside and the other outside the primary containment. Closure of either of the two MSIVs acts to seal the primary containment if a main steam line break occurs inside the primary containment.

The RCIC system provides makeup water to the core during a reactor shutdown when feedwater flow is not available. The system is started either automatically on receipt of a low reactor water level signal or manually by the operator. Water is pumped to the core by a turbine-driven pump using reactor steam.

The RHR system includes a number of pumps and heat exchangers that can be used to cool the NSSS in a variety of situations. During normal shutdown and reactor servicing, the RHR system removes residual and decay heat. The RHR system allows decay heat to be removed whenever the main heat sink (main condenser) is not available (e.g., hot standby). Another operational mode of the RHR system is LPCI. LPCI operation is an ESF system for use during a postulated LOCA. This operation is described in Section 6.3. Another mode of RHR system operation allows heat to be removed from the primary containment following a LOCA.

The RWCU system functions to maintain the required quality of reactor coolant by circulating coolant through a system of filter/ demineralizers.

Design and performance characteristics of the RCS and its various components are shown in Table 5.4-1.

5.1.1 SCHEMATIC FLOW DIAGRAM

A flow diagram and process information for the reactor vessel and recirculation loops under normal steady-state full power operating conditions is presented in Figure 5.1-1. Coolant volumes in the reactor vessel and recirculation loops under full power conditions are presented in Figure 5.1-2.

5.1.2 PIPING AND INSTRUMENTATION DIAGRAMS

Piping and instrumentation diagrams covering the systems included within the RCS and connected systems are presented in the following:

a. Nuclear boiler shown in drawing M-41

b. Nuclear boiler vessel instrumentation shown in drawing M-42

c. Main steam shown in drawing M-01

d. Feedwater system shown in drawing M-06

e. Recirculation system shown in drawing M-43

f. RCIC system shown in drawing M-42 and M-50

g. RHR system shown in drawing M-51

h. RWCU system shown in drawing M-44.

5.1.3 ARRANGEMENT DRAWINGS

A section drawing of the reactor enclosure and primary containment is shown in drawings M-123 and M-138. The routing of reactor recirculation, feedwater, main steam, and RHR piping inside the primary containment is shown in Figure 5.1-5. Piping layout drawings for the reactor recirculation piping and main steam piping inside primary containment are presented in Figures 5.1-6 and 5.1-7, respectively.

5.2 INTEGRITY OF REACTOR COOLANT PRESSURE BOUNDARY

This section discusses measures employed to provide and maintain the integrity of the RCPB for the plant design lifetime.

5.2.1 COMPLIANCE WITH CODES AND CODE CASES

5.2.1.1 Compliance with 10CFR50.55a

A table that shows compliance with the rules of 10CFR50, "Codes and Standards", is included in Section 3.2. As stated in Table 3.2-1, note 7, alternative codes to those required by 10CFR50.55a were used for primary pressure boundary components.

5.2.1.2 Applicable Code Cases

The RPV and appurtenances and the RCPB piping, pumps, and valves have been designed, fabricated, and tested in accordance with the applicable edition of the ASME Code, including addenda that were mandatory at the order date for the applicable components. 10CFR50.55a requires code case approval only for Class 1 components. These code cases contain requirements or special rules that may be used for the construction of pressure-retaining components of Quality Group Classification A. The various ASME code case interpretations that were applied to components in the RCPB are listed in Table 5.2-1. The listed code cases are either in accordance with the recommendations of Regulatory Guide 1.84 and Regulatory Guide 1.85 or special written acceptance has been obtained for their use. Conformance to Regulatory Guide 1.84 and Regulatory Guide 1.85 for other than Class 1 components is discussed in Section 1.8.

5.2.2 OVERPRESSURE PROTECTION

Overpressure protection for the RCPB is provided by the nuclear pressure relief system. The nuclear pressure relief system includes 14 MSRVs, which are dual-function safety/relief valves.

5.2.2.1 Design Basis

Overpressure protection is provided in conformance with GDC 15. Preoperational and startup instructions are given in Chapter 14.

5.2.2.1.1 Safety Design Bases

The nuclear pressure relief system is designed to perform the following functions:

a. Prevent overpressurization of the nuclear system that could lead to the failure of the RCPB

b. Provide automatic depressurization for small breaks in the nuclear system occurring with misoperation of the HPCI system so that the LPCI and the core spray systems can operate to protect the fuel barrier

c. Permit verification of its operability

d. Withstand adverse combinations of loadings and forces resulting from normal, upset, emergency, or faulted conditions

5.2.2.1.2 Power Generation Design Bases

The nuclear pressure relief system MSRVs are designed to meet the following power generation bases:

a. Discharge to the containment suppression pool

b. Correctly reclose following operation so that maximum operational continuity can be obtained

5.2.2.1.3 Discussion

The ASME B&PV Code requires that each vessel designed to meet Section III be protected from overpressure under upset conditions as discussed in subsection S.2.3 of GESTAR II (Reference 4.1-1). The MSRV setpoints satisfy the ASME Code specifications for safety valves, because all valves open at less than the nuclear system design pressure of 1250 psig.

The automatic depressurization capability of the nuclear pressure relief system is evaluated in Sections 6.3 and 7.3.

The following detailed criteria are used in the selection of MSRVs:

a. Meet the requirements of ASME Section III

b. Qualify for 100% of nameplate capacity credit for the overpressure protection function

c. Meet other performance requirements such as response time, etc. as necessary to provide relief functions

The MSRV discharge piping is designed, installed, and tested in accordance with the ASME Section III, Class 3. Fatigue evaluation of the unsubmerged portion of the MSRV discharge piping and downcomers in the wetwell has been performed in accordance with ASME Section III, Class 1 fatigue rules.

5.2.2.1.4 Main Steam Safety/Relief Valve Capacity

The MSRV capacity is adequate to limit the primary system pressure, including transients, to the requirements of the ASME Section III, "Nuclear Vessels", up to and including the Summer 1969 Addenda for LGS. The essential ASME requirements that are all met by this analysis are as follows.

It is recognized that the protection of vessels in a nuclear power plant is dependent on many protective systems to relieve or terminate pressure transients. Installation of pressure-relieving devices may not independently provide complete protection. The MSRV sizing evaluation assumes credit for operation of the RPS, which may be tripped by either of two sources: a direct position switch signal or an indirect high neutron flux trip signal. The direct scram trip signal is derived from position switches mounted on the MSIVs or the turbine stop valves or from pressure switches mounted on the dump valve of the turbine control valve hydraulic actuation system. The position switches are actuated when the respective valves are closing prior to 10% travel of full stroke. The pressure switches are actuated when a fast closure of the turbine control valves is initiated. Credit is taken for the SRVs in their ASME Code qualified self-actuating mode.

The rated capacity of the pressure-relieving devices is sufficient to prevent a rise in pressure within the protected vessel of more than 110% of the design pressure (1.10 x 1250 psig = 1375 psig) for events defined in Section 15.2.

Full account is taken of the pressure drop on both the inlet and discharge sides of the valves. Each MSRV discharges into the suppression pool through a separate discharge pipe that is designed to achieve sonic flow conditions through the valve, thus providing flow independence to discharge piping losses.

Table 5.2-5 lists the systems that could initiate during the design basis overpressure event.

5.2.2.2 Design Evaluation

5.2.2.2.1 Method of Analysis

The nuclear boiler system pressure protection was designed using an analytical model representing all essential dynamic characteristics of the system. This model include the hydrodynamics of the flow loop, the reactor kinetics, the thermal characteristics of the fuel and its transfer of heat to the coolant, and all the principal controller features, such as feedwater flow, recirculation flow, reactor water level, pressure, and load demand. These are represented with all their principal nonlinear features in models that have evolved through extensive experience and favorable comparison of analysis with actual BWR test data.

Detailed descriptions of the one-dimensional kinetics model (ODYN) is and the three-dimensional kinetics model (TRACG) are documented in References 5.2-7 and 5.2-34 respectively. MSRVs are simulated in a nonlinear representation, and the models thereby allow full investigation of the various valve response times, valve capacities, and actuation setpoints that are available in applicable hardware systems.

Further descriptions of these models are given in GESTAR II (Reference 4.1-1).

5.2.2.2.2 System Design

An analysis was conducted to demonstrate that the steam flow capacity of the MSRVs is sufficient for power rerate operation.

5.2.2.2.2.1 Operating Conditions

a. Operating power = 3527 MWt

b. Vessel dome pressure P =1068 psia

c. Steam flow = 15.35×10^6 lb/hr

These conditions are the most severe because maximum stored energy exists at these conditions. At lower power conditions the transients would be less severe.

5.2.2.2.2.2 Transients

The overpressure protection system must accommodate the most severe pressurization transient. There are two major transients, the closure of all MSIVs and a turbine-generator trip with a coincident closure of the turbine steam bypass system valves, that represent the most severe abnormal operational transients resulting in a nuclear system pressure rise. The evaluation of transient behavior with final plant configuration has shown that the isolation valve closure is slightly more severe when credit is taken only for indirectly derived scrams; therefore, it is used as the overpressure protection basis event.

The setpoint values used for the overpressure analysis have been reviewed to ensure that both instrument uncertainties and drift allowance are included in the transient simulation of the highest attainable transient pressures. The Technical Specification values for reactor steam dome pressure will be established consistent with the initial dome pressure of 1068 psia used for the analysis. The effect of an ATWS recirculation pump trip on reactor pressure was simulated using an analytical trip setpoint value of 1164 psia. This trip occurs approximately 4.5 seconds after the transient is initiated.

5.2.2.2.2.3 Scram

a. Scram reactivity curve - Figure 5.2-2

b. CRD scram motion Figure 5.2-3

5.2.2.2.2.4 MSRV Transient Analysis Specifications

a. Valve groups: 3

b. Pressure setpoint (maximum safety limit):

group 1 - 1205 psig

group 2 - 1215 psig

group 3 - 1226 psig

The setpoints are assumed at a conservatively high level above the nominal setpoints as shown by Table 5.2-2. This is to account for initial setpoint errors and any instrument setpoint drift that might occur during operation. Typically the assumed setpoints in the analysis are 3% above the actual nominal setpoints. Highly conservative MSRV response characteristics are also assumed.

5.2.2.2.2.5 MSRV Capacity

Sizing of MSRV capacity is based on establishing an adequate margin from the peak vessel pressure to the vessel code limit (1375 psig) in response to the reference transients (Section 5.2.2.2.2.2).

5.2.2.2.3 Evaluation of Results

5.2.2.2.3.1 MSRV Capacity

The design pressure of the reactor vessel and reactor coolant boundary is 1250 psig, and the ASME allowable overpressure limit is 1375 psig. The Main Steam Isolation Valve Closure with Flux Scram (MSIVF) event is the design basis event to demonstrate compliance to the ASME vessel

overpressure protection criteria and is analyzed during every cycle-specific reload licensing process. The rerate analysis conservatively assumes that the position scram fails and the event terminates on a high neutron flux scram signal. The closure of all MSIVs causes an abrupt pressure increase in the RPV, which is mitigated by the actuation of the SRVs. The MSIVF event was analyzed at dome pressure of 1068 psia, 2% overpower for initial power, 110% of rated core flow and normal feedwater temperature. The MSIVF event was analyzed with all SRVs in service, 110% of rated core flow and normal feedwater temperature. The MSIVF event was analyzed with three (3) SRVs out of service (OOS) (3% setpoint tolerance), and two (2)SRVs out of service (3% setpoint tolerance).

The calculated reactor dome pressures (psig) for these cases are as follows:

three (3) SRVs OOS	1329
two (2) SRVs OOS	1318

The calculated reactor vessel bottom head pressures (psig) for these cases are as follows:

three (3) SRVs OOS	1348
two (2) SRVs OOS	1338

Since the analysis for three (3) SRVs OOS with 3% SRV setpoint tolerance exceeds the Technical Specification reactor dome pressure safety limit of 1325 psig, the number of SRVs allowed OOS by the Technical Specifications has been changed from three (3) to two (2). The reactor vessel bottom head pressures remain below the ASME overpressure limit of 1375 psig.

Under the "General Requirements for Protection Against Overpressure" as given in ASME Section III, credit can be allowed for a scram from the RPS. In addition, credit is also taken for the protective circuits that are indirectly derived when determining the required MSRV capacity. The backup reactor high neutron flux scram is conservatively applied as a design basis in determining the required capacity of the MSRVs. Application of the direct position scrams in the design basis could be used, since they qualify as acceptable pressure protection devices when determining the required SRV capacity of nuclear vessels under the provisions of the ASME Code.

5.2.2.2.3.2 Pressure Drop in Inlet and Discharge

Pressure drop on the piping from the reactor vessel to the MSRV is taken into account in calculating the maximum vessel pressures. Pressure drop in the discharge piping to the suppression pool is limited by proper discharge line sizing to prevent the back pressure on each MSRV from exceeding 40% of the valve inlet pressure, thus ensuring choked flow in the valve orifice and no reduction of valve capacity due to the discharge piping. Each MSRV has its own separate discharge line.

5.2.2.3 Piping & Instrument Diagrams

Drawing M-41 and Figure 5.2-6 show the schematic location of pressure-relieving devices for the following:

a. The RCS

b. The primary side of the auxiliary or emergency systems interconnected with the primary system

c. Any blowdown or heat dissipation system connected to the discharge side of the pressure-relieving devices

The schematic arrangement of the MSRVs is shown in Figures 5.2-6 and 5.2-7. Drawings M-41 and M-59 are the P&IDs of the nuclear boiler and PCIG systems.

5.2.2.4 Equipment and Component Description

5.2.2.4.1 Description

The nuclear pressure relief system consists of dual-function safety/relief valves (the MSRVs) located on the main steam lines between the reactor vessel and the first isolation valve within the drywell. These valves protect against overpressure of the nuclear system.

The MSRVs provide two main protection functions:

a. Overpressure safety/relief operation. The valves open to limit a pressure rise.

b. Depressurization operation. The ADS valves open automatically as part of the ECCS if HPCI fails for events involving small breaks in the nuclear system process barrier (Sections 6.3 & 7.3).

Chapter 15 discusses the events that are expected to activate the MSRVs. Chapter 15 also summarizes the number of valves expected to operate during the initial blowdown of the valves and the expected duration of this first blowdown. For several of the events, it is expected that the lowest set MSRV will reopen and reclose as generated heat drops into the decay heat characteristics. The pressure increase and relief cycle will continue with lower frequency and shorter relief discharges as the decay heat drops off and until the RHR system can dissipate this heat. Remote manual actuation of the valves from the control room is recommended to minimize the total number of these discharges, with the intent of achieving extended valve seat life.

A schematic of the MSRV is shown in Figure 5.2-8. It is opened by either of two modes of operation:

a. The safety mode of operation involves extension of the pressure sensing bellows which engages the first stage pilot disc when reactor pressure approaches the valve setpoint. Once the pilot valve starts to open, the upstream seating force is eliminated, resulting in a net increase in the force tending to open the pilot valve. Opening of the first stage pilot valve admits fluid to the operating piston of the second stage valve, causing it also to open. Opening of the second stage pilot valve vents the chamber over the main valve piston to the downstream side of the valve. This venting action creates a differential pressure across the main valve piston almost equal to the system pressure and in a direction tending to open the valve.

b. The relief, or power-actuated mode of operation uses an auxiliary actuating device that directly opens the second stage valve, which vents the chamber over the main valve piston, causing the main valve to open.

The pneumatic operator is so arranged that, if it malfunctions, it will not prevent the pilot disc from lifting if steam inlet pressure reaches the set pressure.

The MSRVs can be operated in the power-actuated mode by remote manual controls from the control room.

The MSRVs are designed to operate to the extent required for overpressure protection in the following accident environments:

a. 340°F for 3 hours at drywell pressure ≤ 45 psig

b. 320°F for an additional 3 hour period, at drywell pressure ≤ 45 psig

c. 250°F for an additional 18 hour period, at 25 psig

d. 200°F at 20 psig for an additional 24 hour period, following which the valves remain fully open or closed for the remainder of a 100 day period, provided that an air and a power supply are available. No power/air supply is required to keep the valve closed.

The ADS uses selected MSRVs for depressurization of the reactor, as described in Sections 6.3 and 7.3. Each of the MSRVs used for automatic depressurization is equipped with an air accumulator and check valve arrangement. Each ADS accumulator is sized to provide two ADS valve actuations at 70% of drywell design pressure because that is the maximum pressure for which rapid reactor depressurization through the ADS valves is required. For large breaks that result in higher drywell pressure, sufficient reactor depressurization occurs due to the break to preclude the need for ADS. One ADS actuation at 70% of drywell design pressure is sufficient to depressurize the reactor and allow inventory makeup by the low pressure ECCS. However, for conservatism, the ADS accumulators are sized to allow two ADS actuations at 70% of drywell design pressure. This design provides sufficient gas to the ADS valves to permit depressurization until the RHR shutdown cooling mode can be initiated (short-term).

An allowable leakage criteria is applied only to the short-term ADS SRV operations because backup nitrogen bottles provide a longer term supply and provision is made for an infinite long-term supply through the use of external connections. An allowable leakage criteria of 164 scc/min was established to ensure that there would be sufficient pneumatic pressure to depressurize the RPV from the HPCI/RCIC operating pressure to the RHR shutdown cooling operating pressure range using two ADS SRV actuations over a period of 6 hours. Calculations indicate that this leakage criteria will ensure ADS operability for periods in excess of 6 hours for a range of containment conditions that might accompany the need for ADS operation. This short-term duration is sufficient to ensure that the ADS valves can perform their functions as described in Chapter 15, Accident Analyses.

To account for any possible increase in leakage due to a harsh environment and/or seismic event, a surveillance test leakage limit of 78 scc/min was established to provide additional margin as compared to the allowable leakage criteria of 164 scc/min.

The pneumatic components that make up the ADS accumulator system were designed for low leakage in a harsh environment and seismic event. A safety-grade pneumatic supply of nitrogen bottles is available to provide a backup supply if the ADS accumulator system leakage rate should exceed its allowable limit. These bottles are part of the long-term ADS gas supply subsystem of the Containment Instrument Gas System described in Section 9.3.1.3.2.

It should be understood that “short-term” and “long-term” as used here to describe the gas supplies for the ADS valves are not synonymous with the same terms when used to describe ECCS functions. In the context of ADS valve gas supplies, short-term is the first 6 hours of postulated events requiring power operation of ADS valves. This is the timeframe during which the plant would typically be brought to cold shutdown conditions following postulated events. In the context of ECCS functions, short-term refers to a shorter time period of ECCS operation after postulated reactor coolant pressure boundary breaks. A coolable core geometry is assured for subsequent long term cooling. Thus, the long-term gas supply subsystem is not required to support short-term ADS valve ECCS functions nor is it, typically, required to support the first few hours of ADS valve ECCS long-term cooling functions.

Testing and/or analysis has been performed, as described below, to verify that a harsh environment and/or seismic event would not increase the leakage rate of the ADS pneumatic supply system.

The pneumatic system solenoid valves have been qualified under the qualification program for electrical equipment to remain functional under conditions simulating the environment following a postulated design basis LOCA. The pneumatic system spring-loaded, soft-seated valves have been qualified to remain leak-tight after a seismic event. A materials and design review was performed to ensure that the check valves would not experience a significant increase in leakage due to post-LOCA environmental conditions. The functional capability of the check valves was further reviewed as part of the mechanical equipment qualification program. In any event, the long-term safety-grade pneumatic supply will provide the motive force for ADS valve operation.

Each MSRV discharges steam through a discharge line to a point below the minimum water level in the suppression pool. MSRV discharge line piping from the valve to the suppression pool consists of two parts. The first part is attached at one end to the valve and at its other end to a pipe anchor. The main steam piping, including this portion of the MSRV discharge piping, is analyzed as a complete system.

The second part of the MSRV discharge piping extends from the anchor to the suppression pool. Because of the upstream anchor on this part of the line, it is physically decoupled from the main steam header and is therefore analyzed as a separate piping system.

The MSRV discharge piping is designed to limit valve outlet pressure to 40% of maximum valve inlet pressure with the valve wide open at steady-state flow. Water in the line more than a few feet above the suppression pool water level would cause excessive pressure at the valve discharge when the valve is again opened. For this reason, a vacuum relief valve is provided on each MSRV discharge line to prevent the drawing of an excessive amount of water up into the line as a result of steam condensation following termination of relief operation. The MSRVs are located on the main steam line piping, rather than on the reactor vessel top head, primarily to simplify the discharge piping to the pool and to avoid the necessity of having to remove sections of this piping when the reactor head is removed for refueling. In addition, valves located on the steam lines are more accessible during a shutdown for valve maintenance.

The nuclear pressure relief system automatically depressurizes the nuclear system sufficiently to permit the LPCI and CS systems to operate as a backup for the HPCI system. Further descriptions of the operation of the automatic depressurization feature are found in Sections 6.3 and 7.3.

MSRV's A, C and N, controlled from the RSP, are provided with accumulators and check valves, which enhance the power-actuated mode of operation of these MSRV's. The accumulators and check valves are shown in drawing M-41, Sheet 2.

5.2.2.4.2 Design Parameters

The specified operating transients for components within the RCPB are given in Table 5.2-9. See Section 3.7 for a discussion of the input criteria for design of seismic Category I structures, systems, and components.

The design requirements established to protect the principal components of the RCS against environmental effects are discussed in Section 3.11.

The complete ADS accumulator system and associated equipment and control circuitry are included in the LGS Environmental Qualification Program for electrical and mechanical equipment and are qualified to accommodate the effects of, and be compatible with, the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents as stated in GDC 2 and 4 of 10CFR50, Appendix A.

5.2.2.4.2.1 Main Steam Safety/Relief Valve

The discharge area of each MSRV is 20.63 in^2, and the coefficient of discharge K_D is equal to 0.8 ($K = 0.9\ K_D$).

The design pressure and temperature of the valve inlet and outlet are 1250 psig @ 575°F and 500 psig @ 470°F, respectively.

The valves are designed to achieve the maximum practicable number of actuations consistent with state-of-the-art technology.

See Figure 5.2-8 for a schematic cross-section of the valve.

5.2.2.5 Mounting of Main Steam Relief Valves

The MSRVs are located on the main steam piping header. The mounting consists of a special contour nozzle and an oversized flange connection. This provides a high integrity connection that withstands the thrust, bending, and torsional loadings to which the main steam pipe and MSRV discharge pipe are subjected. This includes the following:

a. The thermal expansion effects of the connecting piping

b. The dynamic effects of the piping due to an SSE

c. The reactions due to transient unbalanced wave forces exerted on the MSRVs during the first few seconds after the valve is opened and before the time when steady-state flow is established (with steady-state flow, the dynamic flow reaction forces are self-equilibrated by the valve discharge piping)

d. The dynamic effects of the piping and branch connection due to the turbine stop valve closure

In no case are allowable valve flange loads exceeded, nor does the stress at any point in the piping exceed code allowables for any specified combination of loads. The design criteria and analysis methods for considering loads due to MSRV discharge are in Section 3.9.3.3.

5.2.2.6 Applicable Codes and Classification

The vessel overpressure protection system is designed to satisfy the requirements of ASME Section III. The general requirements for protection against overpressure of ASME Section III recognize that reactor vessel overpressure protection is one function of the reactor protection systems and allows the integration of pressure relief devices with the reactor protection systems of the nuclear reactor.

Hence, credit is taken for the reactor protection system as a complementary pressure protection device. The NRC has also adopted the ASME Codes as part of its requirements in 10CFR50.55a.

5.2.2.7 Material Specification

Material specifications of pressure-retaining components of MSRVs are listed in Table 5.2-3.

5.2.2.8 Process Instrumentation

Overpressure protection process instrumentation is listed in drawing M-42.

ADS valve gas supply instrumentation is described in Sections 7.6 and 9.3.1.3.

5.2.2.9 System Reliability

The system is designed to satisfy the requirements of ASME Section III; therefore, it has high reliability. The consequences of failure are discussed in Section 15.1.4.

5.2.2.10 Inspection and Testing

The MSRVs are tested at the vendor's shop in accordance with quality control procedures to detect defects and prove operability before installation. The following tests are conducted:

a. Hydrostatic test at specified test conditions

b. Pneumatic seat leakage test at 90% of set pressure, with maximum permitted leakage of 30 bubbles per minute being emitted from a 0.250 inch diameter hole submerged ½ inch below a water surface or an equivalent test using an approved test medium

c. Set pressure test: valve pressurized with saturated steam, with the pressure rising to the valve set pressure. Valve must open at nameplate set pressure ±1%.

d. Response time test: each valve is tested to demonstrate acceptable response time

The valves are installed as received from the factory. The GE equipment specification requires certification from the valve manufacturer that design and performance requirements have been met. This includes capacity and blowdown requirements. The setpoints are adjusted, verified, and

indicated on the valves by the vendor. The specified manual and automatic actuation relief mode of each MSRV is verified during the preoperational test program.

It is not feasible to test the MSRV setpoints while the valves are in place. The valves are mounted on 1500 pound primary service rating flanges. They can be removed for maintenance or bench checks and reinstalled during normal plant shutdowns. The valves are tested to check set pressure in accordance with the requirements of the Technical Specifications. The external surface and seating of all MSRVs are 100% visually inspected when the valves are removed for maintenance or bench checks. Valve operability is verified during the preoperational test program as discussed in Chapter 14.

A surveillance test of the ADS accumulator system will be conducted every refueling cycle under the LLRT program. Although the accumulator system is not considered to be a part of the primary containment boundary, this test under the LLRT program ensures completion of the surveillance test. Two tests will be performed at 90 psig. For the first test, the isolation boundaries will be the normal supply check valve, the seismic supply check valve, and the de-energized actuation solenoid. Vents are provided on the upstream side of the isolation check valves to meet the single isolation valve criteria. For the second test, the solenoid will be energized so that the SRV actuator and the solenoid valve vent port become part of the boundaries. In both tests, the leakage criteria will be 78 scc/min. as discussed in Section 5.2.2.4.1.

ADS valves gas supply pressure is monitored periodically by Operators in accordance with ECCS Technical Specifications.

5.2.3 Reactor Coolant Pressure Boundary Materials

5.2.3.1 Material Specifications

Table 5.2-3 lists the principal pressure-retaining materials and the appropriate material specifications for the RCPB components.

5.2.3.2 Compatibility with Reactor Coolant

5.2.3.2.1 PWR Chemistry of Reactor Coolant

Not applicable to BWRs.

5.2.3.2.2 BWR Chemistry of Reactor Coolant

Materials in the primary system are primarily austenitic stainless steel and Zircaloy cladding. Reactor water chemistry limits are established to provide an environment favorable to these materials. Limits are placed on conductivity, pH, and chloride concentrations. Conductivity is limited because it can be continuously and reliably measured and gives an indication of abnormal conditions and the presence of unusual materials in the coolant. Chloride limits are specified to mitigate stress-corrosion cracking of stainless steel. Other controls and limits are implemented which would further reduce stress-cracking or decrease crack growth rates, for example: Hydrogen Water Chemistry: Noble Metals as applicable based on industry experience and optimal water chemistry guidelines for BWRs. For further information, see Reference 5.2-2.

Several investigations have shown that in neutral solutions some oxygen is required to cause stress-corrosion cracking of stainless steel, while in the absence of oxygen no cracking occurs. One of

these is the chloride-oxygen relationship of Reference 5.2-3, where it is shown that at high chloride concentration little oxygen is required to cause stress-corrosion cracking of stainless steel, and at high oxygen concentration little chloride is required to cause cracking. These measurements were determined in a wetting and drying situation using alkaline-phosphate treated boiler water and, therefore, are of limited significance to BWR conditions. They are, however, a qualitative indication of trends.

When conductivity is in its normal range, pH, chloride, and other impurities affecting conductivity may be assumed to be within their normal range. When conductivity becomes abnormal, chloride measurements are made to determine whether or not they are also out of their normal operating values. This would not necessarily be the case. Conductivity could be high due to the presence of a neutral salt that would not have an effect on pH or chloride. In such a case, high conductivity alone is not a cause for shutdown. In some types of water-cooled reactors, conductivities are high because of the purposeful use of additives. In BWRs, however, where high purity water chemistry at near-neutral pH is maintained, conductivity provides a good and prompt measure of the quality of the reactor water. Significant changes in conductivity provide a warning mechanism so the operator can investigate and remedy the condition before reactor water limits are reached. Methods available to the operator for correcting the off-standard condition include operating the RWCU system, reducing the input of impurities, and placing the reactor in the cold shutdown condition. The major benefit of cold shutdown is to reduce the temperature-dependent corrosion rates and provide time for the cleanup system to reestablish the purity of the reactor coolant.

The following is a summary and description of BWR water chemistry for various plant conditions.

a. Normal plant operation

The BWR system water chemistry is conveniently described by following the system cycle as shown in Figure 5.2-9. Reference to Table 5.2-4 is made as numbered on the diagram and correspondingly in the table.

For normal operation starting with the condenser/ hotwell, condensate water is processed through condensate cleanup system, resulting in effluent water quality represented in Table 5.2-4. As the effluent is pumped through the feedwater heater train, zinc may be injected into the feedwater stream by the Zinc Injection Passivation (PZIP) Skid to adjust feedwater chemistry. The additions to feedwater are used to adjust the final water chemistry in the reactor vessel and primary loop.

On Unit 1 the GEZIP skid is used to suspend components in demineralized water and to dilute the suspension with additional demineralized water during injection. The addition of soluble zinc oxide is used to reduce the levels of corrosion products and cobalt deposits in the primary piping and components. This reduces the radioactive contamination buildup and dose levels. Iron oxide is added to maintain feedwater iron levels within the industry recommended range of 0.5-1.5 ppb. This reduces the redistribution of radioactive cobalt crud and dose levels. Impurity limits are placed on the compounds added to the GEZIP tank to limit the impact on reactor chemistry to a maximum increase of 0.5 ppb sulfates and 0.5 ppb halogens. The chloride and oxygen levels in the demineralized water and GEZIP tank have a negligible impact on the chloride and oxygen levels in feedwater due to the small quantity injected when compared to the total feedwater flow.

The PZIP uses the pressure drop between a tap on the downstream side of the feedwater pumps and a corresponding tap upstream of the feedwater pumps to inject zinc ions into the reactor water. Actual flowrate is controlled by throttling of a skid mounted flow control valve. The injection rate is manually adjusted in order to maintain zinc concentration in the reactor and feedwater at predetermined levels.

The effluent from the condensate cleanup system is pumped through the feedwater heater train and enters the reactor vessel at an elevated temperature and typically with a chemical composition as shown in Table 5.2-4.

During normal plant operation, boiling occurs in the reactor, decomposition of water takes place due to radiolysis, and oxygen and hydrogen gas are formed. Due to steam generation, stripping of these gases from the water phase takes place, and the gases are carried with the steam through the turbine to the condenser. The oxygen level in the steam, resulting from this stripping process, is typically observed to be about 20 ppm (Table 5.2-4). Deaeration takes place at the condenser, and the gases are removed from the process by SJAEs. The deaeration is completed to a level of approximately 20 ppb (0.02 ppm) oxygen in the condensate. The capability exists for adding oxygen to condensate water to maintain oxygen at levels which protect system piping from corrosion when needed.

The dynamic equilibrium in the reactor vessel water phase, established by the steam-gas stripping and the radiolytic formation (principally) rates, corresponds to a nominal value of approximately 200 ppb (0.2 ppm) of oxygen at rated operating conditions. Slight variations around this value have been observed as a result of differences in neutron flux density, core flow, and recirculation flow rate.

The RWCU system is provided for removal of impurities in the primary system. The cleanup process consists of filtration/ demineralization and serves to maintain a high level of water purity in the reactor coolant.

Typical chemical parametric values for the reactor water are listed in Table 5.2-4 for various plant conditions.

Additional water input to the reactor vessel originates from the CRD cooling water. The CRD water is of approximately feedwater quality. Separate filtration for purification and removal of insoluble corrosion products takes place within the CRD system before the water enters the drive mechanisms and reactor vessel.

During plant conditions other than normal operation, additional inputs and mechanisms are present, some of which are outlined in the following discussion.

b. Plant conditions outside normal operation

During periods of plant conditions other than normal power production, transients take place, particularly with regard to the oxygen levels in the primary coolant. Oxygen levels in the primary coolant vary from the normal during plant startup, plant shutdown, hot standby, and when the reactor is vented and depressurized. The hotwell condensate absorbs oxygen from the air when vacuum is broken on the condenser. Before the startup and input of feedwater to the reactor, vacuum is established in the condenser and deaeration of the condensate takes place by

mechanical vacuum pump, SJAE operation, and condensate recirculation. During these plant conditions, continuous input of CRD cooling water takes place as described previously.

1. Plant depressurized and reactor vented

   During certain periods, such as refueling and maintenance outages, the reactor is vented to the condenser or to the atmosphere. Under these circumstances the reactor cools, and the oxygen concentration increases to a maximum value of 8 ppm. Equilibrium between the atmosphere above the reactor water surface, the CRD cooling water input, residual radiolytic effects, and the bulk water is established after some time .

2. Plant startup/shutdown

   During these conditions, significant changes in oxygen concentration take place.

   (a) Plant startup

   Depending on the duration of the plant shutdown before startup and whether the reactor has been vented, the oxygen concentration could be that of air-saturated water: i.e., 8 ppm oxygen.

   Following nuclear heatup initiation, the oxygen level in the reactor water decreases rapidly as a function of water temperature increase and corresponding oxygen solubility in water. The oxygen level reaches a minimum of about 20 ppb (0.02 ppm) at a coolant temperature of about 380°F, at which point an increase takes place due to significant radiolytic oxygen generation. For the elapsed process up to this point, the oxygen is degassed from the water and is displaced to the steam dome above the water surface.

   A further increase in nuclear power increases the oxygen generation as well as the temperature. The solubility of oxygen in the reactor water at the prevailing temperature controls the oxygen level in the coolant until rated temperature (540°F) is reached. Thus, gradual increase from the minimum level of 20 ppb to a maximum value of about 200 ppb oxygen takes place. At and after this point (540°F), steaming and the radiolytic process control the coolant oxygen concentration to a level of around 200 ppb.

   (b) Plant shutdown

   On plant shutdown following power operation, the radiolytic oxygen generation essentially ceases as the fission process is terminated. Because oxygen is no longer generated, while some steaming still takes place due to residual energy, the oxygen concentration in the coolant decreases to a minimum value determined by the steaming rate temperature. If venting is performed, a gradual increase to essentially oxygen saturation at coolant temperature takes place, reaching a maximum value of <8 ppm oxygen.

(c) Oxygen in piping and in parts other than the reactor vessel proper

As can be concluded from the preceding descriptions, the maximum possible oxygen concentration in the reactor coolant and any other directly related or associated parts is that of air saturation at ambient temperature. At no time or location in the water phase do oxygen levels exceed the nominal value of 8 ppm. As temperature is increased and oxygen solubility is thus decreased accordingly, the oxygen concentration is maintained at this maximum value or reduced below it, depending on available removal mechanisms: i.e., diffusion, steam stripping, flow transfer, or degassing.

Depending on the location, configuration, etc., such as dead legs or stagnant water, inventories may contain less than the maximum limitation of 8 ppm dissolved oxygen.

Conductivity of the reactor coolant is continuously monitored. These measurements provide reasonable assurance of adequate surveillance of the reactor coolant.

Grab samples may be taken from the locations shown in Table 5.2-6 for special and noncontinuous measurements such as pH, oxygen, chloride, and radiochemical measurements.

The relationship of chloride concentration to specific conductance measured at 25°C is shown in Figure 5.2-10. The values essentially bracket the values of common chloride salts or mixtures at the same chloride concentration. Surveillance requirements are based on these relationships.

In addition to this program, limits, monitoring, and sampling requirements are imposed on the condensate, condensate cleanup system, and feedwater to detect and correct off-specification conditions.

The sampling frequency when reactor water has a low specific conductance is adequate for calibration and routine audit purposes. When specific conductance increases and higher chloride concentrations are possible or when continuous conductivity monitoring is unavailable, increased sampling is provided (see plant Technical Specifications).

For the higher than normal limits of <1 μmho/cm, more frequent sampling and analyses are invoked by the coolant chemistry surveillance program.

The primary coolant conductivity monitoring instrumentation, ranges, accuracy sensor, and indicator locations are shown in Table 5.2-6.

3. Water purity during a condenser leakage

To protect against a major condenser tube leak, sufficient instrumentation and monitoring is provided so that there is adequate demineralizer capacity margin available to permit orderly shutdown of the reactor in case of a serious condenser leak. Details are discussed in Section 10.4.1.

5.2.3.2.2.1 Conformance with Regulatory Guide 1.56 (July 1978) - Maintenance of Water Purity in Boiling Water Reactors

Conformance with Regulatory Guide 1.56 of the design and associated instrumentation and operating procedures for the RWCU and condensate cleanup systems is discussed in Sections 5.4.8 and 10.4.6, respectively.

Maintenance of coolant chemistry at a level comparable to the recommendations of Regulatory Guide 1.56 is discussed in Section 10.4.1 and Technical Specifications.

5.2.3.2.3 Compatibility of Construction Materials with Reactor Coolant

The construction materials exposed to the reactor coolant consist of the following:

a. Solution annealed austenitic stainless steels (both wrought and cast) Types 304, 304L, 316, and 316L

b. Nickel base alloys - Inconel 600 and Inconel 750X

c. Carbon steel and low alloy steel

d. Some 400 series martensitic stainless steel (all tempered at a minimum of 1100°F)

e. Colmonoy and Stellite hard-facing material

General corrosion on all materials, except carbon and low alloy steel, is negligible. Conservative corrosion allowances are provided for all exposed surfaces of carbon and low alloy steels.

Contaminants in the reactor coolant are controlled to very low limits per the reactor water quality specifications. The reactor coolant monitoring and control programs are based on industry guidelines for BWR water chemistry and are designed to protect construction materials from adverse affects.

5.2.3.2.4 Compatibility of Construction Materials with External Insulation and Reactor Coolant

The construction materials exposed to external insulation are:

a. Solution annealed austenitic stainless steels, Types 304, 304L, 316, and 316L

b. Carbon and low alloy steel

Two types of external insulation are employed on BWRs. The reflective metal insulation used does not contribute to any surface contamination and has no effect on construction materials. The nonmetallic insulation used on stainless steel piping and components is in accordance with

Regulatory Guide 1.36 (February 1973) and complies with the requirements of the following industry standards:

a. ASTM C692-71, Standard Methods for Evaluating Stress- Corrosion Effects of Wicking-Type Thermal Insulation on Stainless Steel (Dana Test)

b. RDT-Ml2-1T, Test Requirements for Thermal Insulating Materials for Use on Austenitic Stainless Steel, Section 5 (KAPL Test)

Chemical analyses are required to verify that the leachable sodium, silicate, and chloride are within acceptable levels. Insulation is packaged in waterproof containers to prevent damage or contamination during shipment and storage.

These same construction materials may be exposed to external penetration seals. Those penetration seals that could contribute to surface contamination of the construction materials are in accordance with Reg. Guide 1.36 (February 1973) as discussed above, or any similar standard which is at least as stringent as Reg. Guide 1.36 (February 1973).

Because of the high purity water quality of the BWR coolant, leakage exposes materials to essentially the same effects as that of demineralized water which is negligible.

5.2.3.3 Fabrication and Processing of Ferritic Materials

5.2.3.3.1 Fracture Toughness of Ferritic Materials

The ferritic materials of the containment pressure boundary were purchased and impact-tested prior to the issuance of the Summer 1977 Addenda to ASME Section III. These materials have been reviewed and found to be acceptable within the context of GDC 51 based on the following information.

Materials for AE-supplied pipe, valves, and flued heads for systems that are part of the containment pressure boundary are approved impact quality materials as listed in ASME Section III. The impact test requirements were derived from ASME Section III, 1971 Edition, including Winter 1972 Addenda. All materials required to be tested were tested satisfactorily and documented. Records for all AE-supplied containment pressure boundary piping, valves, and flued heads are available for inspection.

The material used for the fabrication of the penetration assemblies, personnel air locks, hatches, and drywell head of the containment pressure boundary are impact quality materials conforming to ASME Section III, subsection B, article 12. All materials required to be tested in accordance with paragraph NC2311 of the Summer 1977 Addenda to ASME Section III were impact-tested satisfactorily in accordance with the requirements of ASME Section III, 1968 Edition, including Winter 1969 Addenda, or later addenda or editions. Records for tested materials of the containment pressure boundary penetration assemblies, personnel air locks, hatches, and drywell head are available for inspection.

The materials of the containment pressure boundary used for the NSSS flued head fittings, main steam piping, and MSIVs, which are also part of the RCPB, meet the GDC 51 requirements for fracture toughness as demonstrated by their conformance to 10CFR50, Appendix G, which is discussed below.

The materials used for the NSSS flued head fittings and main steam piping were satisfactorily impact-tested at 0°F and 70°F, respectively, in accordance with ASME Section III, 1971 Edition with Summer 1972 Addenda. The materials used for the NSSS MSIVs were exempted from toughness testing, but have been reviewed against the criteria of 10CFR50, Appendix G and are considered to be acceptable based on the information provided in Section 5.2.3.3.1.4 below.

5.2.3.3.1.1 Piping

Toughness testing of the main steam piping is in compliance with 10CFR50, Appendix G, since it was tested at +70°F in accordance with ASME Section III, 1971 edition with Summer 1972 Addenda.

5.2.3.3.1.2 Safety/Relief Valves

The SRVs are exempted by the ASME Code from toughness testing because of their 6 inch size. This is consistent with 10CFR50, Appendix G.

5.2.3.3.1.3 Flued Head Fittings

Testing of the flued head fittings is in compliance with 10CFR50, Appendix G. These materials were impact-tested in accordance with ASME Section III, 1971 Edition with Summer 1972 Addenda. The test temperature was 0°F.

5.2.3.3.1.4 Main Steam Isolation Valves

The MSIVs were procured to meet the requirements of the 1968 ASME Nuclear Draft for Pumps and Valves Code, which did not require toughness testing for the subject valve materials. These were exempted because they are subjected to less than 20% of design pressure at temperatures less than 250°F.

The LGS Units 1 and 2 MSIV body materials are A216 Grade WCB carbon steel castings. Table 5.2-12 shows the typical chemical composition and heat treatment of these castings. Although impact tests were not run, these materials are considered to have adequate toughness to meet the current code requirements (i.e., 25 mil lateral expansion). Evidence of this design adequacy is provided in Table 5.2-13 which presents similar MSIV body material data from other BWR projects identified as Projects A through F. These materials received heat treatments equivalent to those experienced in LGS Units 1 and 2.

The bonnet (i.e., cover) materials are A105 Grade 2 forgings. Table 5.2-11 lists available information for the materials used to fabricate the valve covers. These materials were normalized at 1650°F for 12 hours and air cooled. Evidence of toughness for SA105 forgings is given in the July 1978 issue of "Metal Progress", (pages 35-39). This article (Reference 5.3-1) shows charpy V-notch in excess of 25 mils lateral expansion at +40°F and NDTT values no greater than -10°F for SA105 material normalized at 1565°F for 4 hours and air cooled after forging. Similar results would be expected for the LGS MSIV bonnet materials. MSIVs modified with nose guided poppets have bonnets made from SA105 forgings which are equivalent to the original material.

Additional toughness data for SA105 forging materials obtained from fittings in another BWR plant is presented in Table 5.2-10. These materials were normalized at 1650°F for 4 hours and air cooled. The toughness data given is for longitudinally oriented specimens whereas the code requirements are for transverse specimens. However, prior GE impact test experience with carbon steel material indicates it is appropriate to approximate transverse properties at about 40% of the corresponding

longitudinal properties. On this basis, the data given in Table 5.2-10 demonstrates that the transverse properties meet the 25 mil lateral expansion code requirements.

5.2.3.3.2 Control of Welding

5.2.3.3.2.1 Regulatory Guide 1.50 (May 1973) - Control of Preheat Temperature Employed for Welding of Low Alloy Steel

This guide delineates preheat temperature control requirements and welding procedure qualifications supplementing those in ASME Sections III and IX.

For the GE scope of supply, Regulatory Guide 1.50 is not employed as a design basis for LGS. However, the procedures in use either conform with the guide or are evaluated as satisfying the guide through the use of alternate approaches.

Preheat temperatures employed for the welding of low alloy steel meet or exceed the recommendations of ASME Section III, Subsection NA. Either components were held for an extended time at preheat temperature to ensure removal of hydrogen, or preheat was maintained until postweld heat treatment. The minimum preheat and maximum interpass temperatures were specified and monitored.

All welds were nondestructively examined by radiographic methods. In addition, a supplemental ultrasonic examination was performed.

For the Bechtel scope of supply, this guide is followed except for the following alternate approaches:

a. With respect to the position in Paragraph C.1.a of the guide that the procedure qualification should require that a minimum preheat and a maximum interpass temperature be specified, there is conformance when impact testing in accordance with Subarticle 2300 of ASME Section III, Division 1, is required. The maximum interpass temperature shall be 500°F unless otherwise specified. When impact testing is not required, specification of a maximum interpass temperature in the welding procedure is not necessary to ensure that the required mechanical properties are met. The minimum preheat temperatures of ASME Section III, Appendix D are required to be met regardless of whether impact testing is required.

b. Regarding the position in Paragraph C.1.b of the guide that the procedure qualification should require that the welding procedure be qualified at the minimum preheat temperature, the welding procedure qualification requirements of ASME Sections III and IX are considered to be more than adequate.

c. Regarding the position of Paragraph C.2 of the guide that, for production welds, the preheat temperature should be maintained until a postweld heat treatment has been performed, the position is conformed with for Class 1 pressure vessels with nominal thickness greater than 1 inch. Maintenance of preheat beyond completion of welding until postweld heat treatment is not required for thinner sections since experience has indicated that delayed cracking in the weld or heat-affected zone is not a problem.

   Current usage of low alloy steel in piping, pumps and valves is minimal and normally is limited to Class 3 construction. When low alloy steel piping, pumps and valves are

used, preheat is maintained until welding is complete but not until postweld heat treatment is performed, since the conditions which cause delayed cracking in the weld or heat-affected zone are not present.

When the regulatory guide positions or above alternate approaches are not met, the weld is subject to rejection; however, the soundness of the weld may be verified by an acceptable examination procedure.

5.2.3.3.2.2 Regulatory Guide 1.34 - Control of Electroslag Weld Properties

No electroslag welding was performed on BWR components.

5.2.3.3.2.3 Regulatory Guide 1.71 - Welder Qualification for Areas of Limited Accessibility

The qualification for areas of limited accessibility is discussed in Section 5.2.3.4.2.3.

5.2.3.3.2.4 Regulatory Guide 1.43 - Control of Stainless Steel Weld Cladding of Low Alloy Steel Components

This guide applies to welding of cladding to low alloy steels made to coarse grain practice. LGS vessel plate and nozzle forgings are made to fine grain practice and a low heat input process is used. Other components are not clad. Therefore, the guide is not applicable.

5.2.3.3.3 Nondestructive Examination of Ferritic Tubular Products - Regulatory Guide 1.66 (October 1973)

This regulatory guide was withdrawn on September 28, 1977, by the NRC because the additional requirements imposed by the guide were satisfied by the ASME Code. The following discussion applies only to activities performed prior to that time.

This guide described a method of implementing requirements acceptable to the NRC regarding nondestructive examination requirements of tubular products used in the RCPB.

For the GE scope of supply, wrought tubular products were supplied in accordance with applicable ASTM/ASME material specifications. Also, the specification for the tubular product used for CRD housings specified ultrasonic examination to paragraph NB-2550 of ASME Section III.

These RCPB components met the requirements of the ASME Codes existing at the time of the placement of the order that predated Regulatory Guide 1.66. At the time of the placement of the orders, the 10CFR50, Appendix B requirements and ASME code requirements ensure adequate control of quality for the products.

For the Bechtel scope of supply, there was partial conformance with the guide in that tubular products used for Class 1, 2, and 3 components were ultrasonically examined in accordance with the requirements of ASME Section III, Division 1, 1971 Edition with Addenda through Winter 1971. In addition, the ultrasonic examination procedures were in accordance with ASTM E213-68.

5.2.3.3.4 Moisture Control for Low Hydrogen, Covered Arc Welding Electrodes

All low hydrogen covered welding electrodes are stored in controlled storage areas, and only authorized persons are permitted to release and distribute electrodes. Electrodes are received in hermetically sealed canisters. After removal from the sealed containers, electrodes which are not immediately used are placed in storage ovens which are maintained at about 250°F (generally 200°F minimum).

Electrodes are distributed from sealed containers or ovens as required. At the end of each work shift, unused electrodes are returned to the storage ovens. Electrodes which are damaged, wet, or contaminated are discarded. If any electrodes are inadvertently left out of the ovens for more than one shift, they are discarded or reconditioned in accordance with the manufacturer's instructions.

5.2.3.4 Fabrication and Processing of Austenitic Stainless Steels

5.2.3.4.1 Avoidance of Stress-Corrosion Cracking

5.2.3.4.1.1 Avoidance of Significant Sensitization - Regulatory Guide 1.44 (May 1973) - Control of the Use of Sensitized Stainless Steel

The purpose of Regulatory Guide 1.44 is to address 10CFR50, Appendix A, GDC 1 and 4, and the Appendix B requirements to control "the application and processing of stainless steel to avoid severe sensitization that could lead to stress-corrosion cracking."

This guide is not used by GE as a design basis for LGS. However, the procedures used either conform with the guides or are evaluated as satisfying the guide through the use of alternate approaches.

All austenitic stainless steel was purchased in the solution heat treated condition in accordance with applicable ASME and ASTM specifications. Cooling rates from solution heat treating temperatures were required to be rapid enough to prevent sensitization. Non-sensitization was verified using ASTM A262, Practice A or E methods.

Material changes have been made to minimize the possibility of IGSCC. Except certain valves, for which alternate means of mitigating IGSCC or inspection procedures were employed to comply with the intent of Regulatory Guide 1.44, wrought austenitic stainless steel in the RCPB was changed to low carbon (0.025% maximum) material. Piping in the following systems, from the reactor vessel to the first isolation valve, is manufactured from low carbon austenitic stainless steel (AISI 316L, maximum carbon content of 0.02%): the core spray system and the RHR system (shutdown cooling suction line, shutdown cooling return line, LPCI). The RWCU system uses 316L from the recirculation system connection through the containment penetration. The recirculation system piping is manufactured from low carbon high strength austenitic stainless steel (316K). Thus, there is no piping that is nonconforming and service sensitive, as defined in NUREG-0313 (Rev 1). 316L seamless small-bore piping and forged fittings (2 inch and smaller) are not subject to the 0.02% maximum carbon content requirement.

For manual welds with gas tungsten arc and shielded metal arc welding processes, heat input was limited by weaving and welding technique restrictions. Nonweaving (stringer bead) techniques were used where possible. Where required, weaving was controlled to meet the following bead width limits:

a. For gas tungsten arc, the lesser of 5 times the filler wire diameter or 7/8 inch

b. For shielded metal arc, the lesser of 4 times the electrode core wire diameter or 5/8 inch.

For machine, automatic, and manual welding with processes except gas tungsten arc and shielded metal arc, heat input for piping was restricted to 50,000 joules/in. Interpass temperature was restricted to 350°F for all stainless steel welds. High heat welding processes such as block welding and electroslag welding were not permitted. All weld filler metal and castings were required by specification to have a minimum of 5% ferrite.

For welding of short sections of 316L pipe to forged 316 LPCI and core spray valves adjacent to the reactor, heat was controlled by use of a demineralized water heat sink. The 316L pipe sections were welded to the valves with a gas tungsten arc root pass with argon backing. Subsequent welds were made with a demineralized water backing heat sink as a means of mitigating IGSCC.

Whenever any wrought austenitic stainless steel was heated to temperatures over 800°F by means other than welding or thermal cutting, the material was re-solution heat treated.

These controls were used to avoid severe sensitization and to conform with the intent of Regulatory Guide 1.44.

For the Bechtel scope of supply, the guide is followed except for the following alternate approaches:

a. Regarding the position in Paragraph C.3 of the guide which discusses testing for non-sensitization, there is partial conformance in that all austenitic stainless steels are furnished in accordance with applicable ASME or ASTM material specifications. Testing to determine susceptibility to intergranular attack is performed only when required by the material specification.

b. Regarding the position of Paragraph C.6 of the guide which discusses intergranular corrosion testing, welding practices are controlled to avoid severe sensitization, and heat treatment in the temperature range 800°F to 1500°F is not permitted. Since severe sensitization is avoided, testing to determine susceptibility to intergranular attack is not performed.

5.2.3.4.1.2 Process Controls to Minimize Exposure to Contaminants

Exposure to contaminants capable of causing stress-corrosion cracking of austenitic stainless steel components is avoided by carefully controlling all cleaning and processing materials that contact the stainless steel during manufacture and construction.

Special care is exercised to ensure the removal of surface contaminants before any heating operations. Water quality for cleaning, rinsing, flushing, and testing is controlled and monitored. Suitable packaging and protection is provided for components to maintain cleanliness during shipping and storage.

The degree of surface cleanliness achieved by the GE procedures meets the requirements of Regulatory Guide 1.44 and Regulatory Guide 1.37.

Regulatory Guide 1.37 and the associated ANSI N45.2.1 are not specifically applied in the Bechtel scope of work. However, the procedures in use are generally equivalent to the regulatory guide and standard.

5.2.3.4.1.3 Cold-Worked Austenitic Stainless Steels

Austenitic stainless steels with a yield strength greater than 90,000 psi are not used.

5.2.3.4.1.4 Noble Metals Chemical Addition

Noble Metals added to the wetted surfaces of the reactor vessel and internals in combination with low rates of feedwater hydrogen injection (Hydrogen Water Chemistry), provides improved mitigation of Stress Corrosion Cracking of the Noble Metals treated components and associated piping.

5.2.3.4.2 Control of Welding

5.2.3.4.2.1 Avoidance of Hot-Cracking - Regulatory Guide 1.31 - Control of Ferrite Content in Stainless Steel Weld Metal

Regulatory Guide 1.31 describes an acceptable method of implementing requirements with regard to the control of welding when fabricating and joining austenitic stainless steel components and systems.

Per the implementation section of Regulatory Guide 1.31 (Rev 3), April 1978, of the guide, the guide is not applicable to LGS. Nevertheless, for explanatory purposes, LGS procedures with reference to the guide are discussed below.

GE employs Regulatory Guide 1.31 (Rev 1), June 1973, as a design basis for LGS, with certain alternate approaches:

> Written welding procedures which are approved by GE are required for all primary pressure boundary welds. These procedures comply with the requirements of ASME Sections III and IX and applicable regulatory guides.
>
> All austenitic stainless steel weld filler materials were required by specification to have a minimum of 5% ferrite. Prediction of ferrite content was made by using the chemical composition in conjunction with the Schaeffler diagram. The use of the 5% minimum limit for ferrite content determined by the Schaeffler diagram has been shown to be adequate to prevent hot-cracking in austenitic stainless steel welds. An extensive test program performed by GE, with the concurrence of the NRC, demonstrated that controlling weld filler metal ferrite at 5% minimum (by Schaeffler diagram) resulted in production welds which met the requirements of Regulatory Guide 1.31 "Control of Stainless Steel Welding." A total of approximately 400 production welds in five BWR plants were measured and all welds met the requirements of BTP MTEB 5-1 "Interim Regulatory Position on Regulatory Guide 1.31, Control of Stainless Steel Welding."

Bechtel employs an alternate approach to the guide:

> With respect to Paragraph C.1 of the guide, the delta ferrite determination for consumable inserts, electrodes, rod or wire filler metal used with gas tungsten arc welding process and

the plasma arc welding process is predicted from a chemical analysis of as-manufactured material using the constitutional diagram in ASME Section III, figure NX-2433.1-1.

As an alternate to the magnetic method of determining the ferrite content of an undiluted weld deposit as specified in Paragraph C.1, C.2 and C.3, the chemical analysis method specified in ASME Section III, NX-2430 may be used.

5.2.3.4.2.2 Regulatory Guide 1.34 - Electroslag Welds

Electroslag welding was not employed for RCPB components.

5.2.3.4.2.3 Regulatory Guide 1.71 (December 1973) - Welder Qualification for Areas of Limited Accessibility

Regulatory Guide 1.71 recommends that weld fabrication and repair for wrought low alloy and high alloy steels, or other materials such as static and centrifugal castings and bimetallic joints, should comply with the fabrication requirements of ASME Sections III and IX. It also recommends additional performance qualifications for welding in areas of limited access.

For the GE scope of supply, Regulatory Guide 1.71 is not employed as a design basis for LGS. However, the procedures in use either conform with the guide or alternate approaches are used that are evaluated as satisfying the intent of the guide.

All ASME Section III welds were fabricated in accordance with the requirements of ASME Sections III and IX. There are few restrictive welds involved in the fabrication of BWR components. The welder qualification for welds with the most restrictive access was accomplished by mockup welding. Mockups were examined by radiography or sectioning.

For the Bechtel scope of supply, alternate approaches are employed:

Performance qualifications for personnel who weld under conditions of limited access, as defined in Regulatory Position C.1, are maintained in accordance with the applicable requirements of ASME Sections III and IX. Additionally, responsible site supervisors are required to assign only the most highly skilled welders to limit access welding. Of course, welding conducted in areas of limited access is subjected to the required nondestructive testing and no waiver or relaxation of examination methods or acceptance criteria because of the limited access is permitted.

Requalification is required when any of the essential variables of ASME Section IX are changed or when any authorized inspector questions the ability of the welder to perform satisfactorily the requirements of ASME Sections III or IX.

Production welding is monitored and welding qualifications are certified in accordance with the alternate approaches discussed above.

5.2.3.4.3 Nondestructive Examination of Tubular Products - Regulatory Guide 1.66

For GE scope of supply, wrought tubular products were supplied in accordance with applicable ASTM/ASME material specifications. The specification for the tubular product used for CRD housings requires ultrasonic examination in compliance with ASME Section III, paragraph NB-2550.

All tubular products meet the requirements of ASME Codes existing at time of placement of order which predated Regulatory Guide 1.66.

Bechtel conformance with Regulatory Guide 1.66 is discussed in Section 5.2.3.3.3.

5.2.4 PRESERVICE/INSERVICE INSPECTION, EXAMINATION AND TESTING OF THE REACTOR COOLANT PRESSURE BOUNDARY

The construction permits for LGS Units 1 and 2 were issued in June 1974. Based on this date, 10CFR50.55a requires that the preservice inspection program for the RCPB meet the examination requirements set forth in ASME Section XI, 1971 edition with addenda through Winter 1972 or, alternatively, the examination requirements of subsequent editions and addenda, subject to the limitations and modifications listed in 10CFR50.55a. The LGS preservice inspection programs follow the alternative requirement.

Specifically, the Unit 1 PSI program (with the exception of the RPV and the operability testing of safety-related pumps and valves) meets the requirements of ASME Section XI, 1974 edition with addenda through Summer 1975, as modified by Appendix III of the Winter 1975 Addenda and paragraph IWA-2232 of the Summer 1976 Addenda.

At the time the LGS PSI program commenced, the latest edition of the code permissible for use was the Summer 1975 Addenda. In an effort to take advantage of improved UT methods, Appendix III of the Winter 1975 Addenda and paragraph IWA-2232 of the Summer 1976 were used. Although these items were not specifically referenced by 10CFR50.55a, they are equivalent to the comparable portions of the Summer 1978 Addenda (which was subsequently approved by 10CFR50.55a) as long as Section XI Appendix III indications greater than 50% DAC are recorded. The LGS ISI procedures do record such indications.

Supplement 7 of Appendix III permits the use of Appendix III for austenitic piping welds with certain modifications. It is our position, consistent with the PSI/ISI industry, that Appendix III (at 50% DAC recording) is more appropriate for austenitic piping weld examination than article 5 of ASME Section V. Thus for austenitic piping welds:

a. All of the Supplement 7 modifications are being used.

b. Examination sensitivity is ensured through the calibration process.

c. Where one-sided access only occurs and penetrations cannot be confirmed, a one-sided access limitation is noted in the data package for that weld.

When using Section XI, Appendix III for either ferritic or austenitic piping welds, the following applies:

a. All indications showing signal amplitudes equal to or in excess of 20% of the reference response are evaluated to the extent that the level II or III examiner can determine their true nature.

b. The owner evaluates and takes corrective action for the disposition of any indication investigated and found to be other than geometrical or metallurgical in nature.

The Unit 1 RPV PSI program meets the requirements of ASME Section XI, 1980 edition with addenda through Winter 1980. The Unit 2 preservice inspection program and Units 1 and 2

programs for the preservice testing of safety-related pumps and valves meet the requirements of ASME Section XI, 1980 edition with addenda through Winter 1981.

For certain ASME Section XI requirements that have been determined to be impractical in the course of inspecting the components, the licensee has submitted and will submit requests for relief from the requirements to the NRC in accordance with the provisions of 10CFR50.55a.

In accordance with 10CFR50.55a, throughout the service life, RCPB components (including supports) will meet the ISI requirements, except design and access provisions and preservice examination requirements, set forth in the ASME Section XI edition and addenda that become effective, to the extent practical within the limitations of design, geometry, and materials of construction

of the components. In accordance with 10CFR50.55a, inservice examination of components, inservice tests to verify operational readiness of safety-related pumps and valves, and system pressure tests conducted during the initial 10 year inspection interval will comply with the ASME Section XI edition and addenda in effect 12 months prior to the date of issuance of the operating license. In accordance with 10CFR50.55a(g)(4)(ii), the initial 10 year inspection interval commences with commercial operation. The successive 10 year inspection intervals will comply with the ASME Section XI edition and addenda in effect 12 months prior to the start of the 10 year inspection interval.

5.2.4.1 System Boundary

LGS piping was originally designed to ANSI B31.7. For the purpose of inservice inspection, ANSI B31.7, Class I is considered equivalent to ASME Section III, Class 1. The PSI/ISI program includes figures showing the systems or portions of systems within the scope of ASME Section XI. The applicable PSI/ISI programs are described in References 5.2-8 through 5.2-18. Any necessary requests for relief are addressed in these documents.

5.2.4.2 Accessibility

The access provided for the various components and parts is in accordance with ASME Section XI, Subarticle IWA-1500.

a. Sufficient space has been provided for personnel and equipment to perform examinations of the RCPB, as follows:

    1. Piping welds - The access provided depends on whether ultrasonic, surface, or visual examinations are performed.

    2. Pumps and valves - Space has been provided to disassemble and reassemble pump and valves. For visual examination, space for lighting and access sufficient to permit examination of the inner surface has been provided. For ultrasonic examination and depending on the specific design of the weld, access to equipment has been provided.

    3. Supports - Access provisions for supports requiring examination has been made and depends on the specific type and design detail of the supports.

    4. Reactor vessel - The reactor vessel insulation has been designed to allow access for examination, by a remotely operated scanning device, of the

vessel longitudinal and circumferential welds, nozzle-to-vessel inside radiused sections, and nozzle-to-safe-end welds.

The vessel-to-flange weld and flange ligaments are accessible during refueling. The closure head-to-flange weld and closure head circumferential and meridional welds are accessible from the outside.

The vessel-to-skirt weld is accessible during refueling.

Closure studs, nuts, and washers can be removed when the vessel head is removed. This provides adequate access.

Portions of the vessel cladding and interior are accessible by removal of components. Portions of the interior attachments and core support structures are accessible by removal of components.

Only the peripheral CRD housings are accessible for volumetric examination.

b. Capability for removal and storage of structural members, shielding components, and insulation is provided.

c. Hoists and other handling machinery necessary to support inservice inspection are provided.

d. Equipment, personnel, and procedures for alternative examinations that may be required will be provided.

e. Repair and replacement procedures are provided for system components and parts, when necessary.

5.2.4.3 Examination Techniques and Procedures

a. The techniques and procedures for surface, visual, and volumetric examinations are in compliance with ASME Section XI, Subarticle IWA-2200.

b. Alternate examination methods are acceptable provided the results are equal or superior to the methods of Subarticle IWA-2220. The acceptance criteria for alternate examination methods shall be in accordance with Subarticle IWB-3100.

5.2.4.4 Inspection Intervals

Inservice inspection is performed according to the schedule outlined in Subarticle IWB-2400; all required examinations being completed within a nominal 10 year period, hereafter referred to as the inspection interval. Inspections will be scheduled to coincide with normal plant or system outages.

5.2.4.5 Examination Categories and Requirements

The PSI/ISI program provides a listing of the Class 1 components or parts, the corresponding ASME Section XI item number, examination category, the required method of examination, and the extent and frequency of examination. The applicable PSI/ISI programs are identified in References 5.2-8 through 5.2-18.

5.2.4.6 Evaluation of Examination Results

a. The standards for evaluation of examination results are in accordance with Article IWB-3000.

b. The repair procedures are in agreement with Article IWA-4000.

c. Flaw indications are characterized in accordance with the requirements of IWB-3420 and compared with the acceptance standards specified in IWB-3410.

d. The replacement procedures are in agreement with Article IWA-4000.

e. Summary reports for the RPV and piping PSI will be submitted in accordance with subarticles IWA-6000.

5.2.4.7 System Leakage and Hydrostatic Pressure Tests

The Class 1 leakage and hydrostatic pressure test program meets the requirements of ASME Section XI, Article IWB-5000, "System Leakage and Hydrostatic Pressure Tests." The Technical Specification requirements for operating limitations for heatup, cooldown, and system hydrostatic pressure testing will be met during such testing.

5.2.4.8 Augmented Inservice Inspection

Class 1 components will receive augmented inservice inspections in accordance with the documents listed below to the extent specified in the applicable PSI/ISI programs identified in References 5.2-8 through 5.2-18.

a. Regulatory Guide 1.150 (Rev 1), February 1983, with Appendix A, Alternate Method. "Ultrasonic Testing of Reactor Vessel Welds During Preservice and Inservice Examinations" and NRC Generic Letter 83-15 dated March 23, 1983.

b. NUREG-0619, November 1980, "BWR Feedwater Nozzle and Control Rod Drive Return Line Nozzle Cracking. Resolution of Generic Technical Activity A-10"

   The LGS feedwater nozzle has been modified. The new configuration is the triple-sleeve with two sister ring seals and an unclad nozzle. This ensures the longest ISI intervals in accordance with NUREG-0619.

c. IE Bulletin 80-07, April 4, 1980, "BWR Jet Pump Assembly Failure" (NUREG/CR-3052)

d. IE Bulletin 80-13, May 12, 1980, "Cracking in Core Spray Spargers"

e. NUREG-0313 (Rev 1), July 1980, "Technical Report on Material Selection and Processing Guidelines for BWR Coolant Pressure Boundary Piping. Resolution of Generic Technical Activity A-42," applicable prior to issuance of Generic Letter 88-01.

   Following issuance of Generic Letter 88-01, the criteria of NUREG-0313 (Rev 2), January 1988 become applicable for both LGS Units 1 and 2, with full implementation

effective for both units by the second refueling outage at Unit 1. The ISI program for weldments in piping shall conform with the NRC staff positions identified in Generic Letter 88-01 and BWRVIP-75-A, "BWR Vessel and Internals Project Technical Basis for Revisions to Generic Letter 88-01 Inspection Schedule," as documented in the licensee's responses to Generic Letter 88-01 (References 5.2-19,20,21,23 and 25), approved by the NRC (References 5.2-24 and 5.2-26), and required by amended Technical Specifications for Units 1 and 2 (Reference 5.2-28 and 5.2-33). Details for schedule, methods, personnel, and sample expansion shall be included as augmented inspection requirements. Correspondence relating to Generic Letter 88-01 is specified in References 5.2-19 through 5.2-28.

f. BTP MEB 3-1 (NUREG-0800) for high energy piping between containment isolation valves and first outboard restraint for which no breaks are postulated.

In addition, high energy fluid system piping between containment isolation valves will receive an augmented examination as follows:

a. Protective measures and structures are located, to the greatest extent possible, so as not to prevent access for inservice inspections.

b. High energy fluid system piping between containment isolation valves is required to be either 100% volumetrically examined (circumferential welds) during each examination interval or examined in accordance with the Risk Informed Inservice Inspection Program as applied to these welds.

c. High energy piping requiring ISI receives a baseline (preservice) examination to establish the integrity of the original condition of the welds.

d. Augmented examination for high energy piping is maintained out to outboard restraints.

e. Welds between outboard containment isolation valves and piping restraints will be included in the PSI and the ISI plans.

5.2.5 Reactor Coolant Pressure Boundary Leak Detection System

5.2.5.1 Design Bases

The leak detection system is designed to:

a. Detect the occurrence of and alert operating personnel to abnormal leakage from the RCPB.

b. Detect leakage from selected portions of systems located outside the primary containment, and not a part of the RCPB.

c. Remain functional following a SSE, except as discussed in Sections 5.2.5.2.1.4 and 5.2.5.2.1.5.

5.2.5.2 Description

The RCPB leak detection system consists of temperature, pressure, flow, and radiation sensors, and associated instrumentation and alarms. The system detects, annunciates, and, in certain cases, isolates abnormal leakage in the following systems:

a. Main steam lines

b. RWCU system

c. RHR system

d. RCIC system

e. Feedwater system

f. HPCI system

g. Reactor recirculation system

h. Core spray system

A summary of isolation and/or alarms of affected systems and the methods used appears in Table 5.2-7. The table shows those leak detection methods which detect gross leakage and initiate immediate automatic isolation. Those methods which are capable of detecting small leaks initiate an alarm in the control room, at which time the operator can either manually isolate the leaking system or take other appropriate action.

5.2.5.2.1 Detection of Abnormal Leakage Within the Primary Containment

Leaks within the primary containment are detected by continuously monitoring for:

a. Abnormally high pressure and temperature within the primary containment

b. Rapid level increase in drywell equipment and floor drain sumps

c. A decrease in the reactor vessel water level

d. High gaseous radiation level in the primary containment atmosphere

e. High containment air cooler condensate flow.

In addition to these leak detection methods, selected RCPB components within the primary containment are provided with their own leak detection devices. While some of the methods provided for detecting leakage within the primary containment are not redundant in themselves, it is not postulated that any one event could render all means of leak detection inoperable. Each of the leak detection methods are discussed below. The systems and equipment provided at LGS meet or exceed the requirements and recommendations of ANSI/ISA S67.03 (1982).

5.2.5.2.1.1 Drywell Temperature Monitoring

Drywell temperature monitoring provides an indirect method of detecting RCPB leakage.

The drywell area unit coolers circulate and cool the drywell atmosphere to maintain the drywell at its design operating temperature. Cooling water is supplied to the unit coolers by the DCWS (Section 9.2.10). A temperature rise in the drywell will indicate the presence of reactor coolant or steam leakage and is detected by the drywell temperature monitors located at various elevations and at the inlet and outlet of the air coolers. A discussion of indications and alarms for drywell temperature in accordance with Regulatory Guide 1.45 is given in Section 7.5.

5.2.5.2.1.2 Drywell Pressure Monitoring

Drywell pressure monitoring provides an indirect method of detecting RCPB leakage.

The drywell normally ranges from slightly below to slightly above atmospheric pressure during reactor operation. The pressure typically fluctuates slightly as a result of barometric pressure changes and/or outleakage. A pressure rise above the normally indicated value indicates leakage within the drywell. Drywell pressure monitoring is shown in drawings M-42 and M-57. A discussion of indications, alarms, and protective functions for drywell pressure in accordance with Regulatory Guide 1.45 is given in Sections 7.2, 7.3, 7.4, and 7.5.

5.2.5.2.1.3 Drywell Sump Level Monitoring

All leakage from RCPB components inside the drywell, with the exception of leakage from the MSRVs (Section 5.2.5.2.1.8), flows directly to either the drywell equipment drain sump or the drywell floor drain sump. There are no other reservoirs in the drywell of sufficient capacity to prevent leakage from draining directly to either of these sumps. Both drain sumps are identically sized, horizontal cylindrical tanks located inside the reactor vessel pedestal below the diaphragm slab and vented to the drywell atmosphere. The liquid radwaste collection system piping and instrumentation diagram is given in drawing M-61. These drain sumps are discussed below:

a. Drywell equipment drain sump - Certain RCPB components within the drywell are, by the nature of their design, normally subject to a limited amount of leakage. These components include pump seals, valve stem packings, and other equipment that cannot practicably be made to be completely leak-tight. These leakages are piped directly to the drywell equipment drain sump. All of the various drains are open only to the equipment they serve, thereby receiving leakage only from identified sources. Background leakage to this sump is determined during initial plant operation. Rates of leakage collection in excess of background indicates abnormal RCPB leakage.

b. Drywell floor drain sump - Leakage from RCPB components inside the primary containment which are not normally subject to leakage is collected by the drywell floor drain sump. This leakage, which may originate from any number of sources within the drywell, is transported to the sump via the floor drain network within the drywell. Thus, separation of unidentified leakage from the identifiable leakage routed to the equipment drain sump ensures that a small unidentified leakage that is of concern will not be masked by a larger, acceptable, identified leakage.

c. Each sump tank has its own level transmitter which is monitored by a dedicated processing unit. Normally closed drain valves are provided, enabling the level in each tank to increase as leakage drains into them. The processing unit calculates an average leak rate for a given measurement period by establishing the amount of increase in level that occurred during the period, and converting that value into

volumetric terms (gpm). The processing units provide an alarm in the main control room each time the average leak rate changes by a predetermined valve since the last time that alarm was reset. The setpoint is a 1 gpm change in unidentified leakage collected in the drywell floor drain sump tank, and a 2 gpm change in identified leakage collected in the drywell equipment drain tank.

Alarms are also generated in the main control room for high total average leak rate. The high total average leak rate alarm setpoints can be adjusted at the processing unit, which is located in the main control room, as the amount of acceptable identified leakage changes during operation. Indication of the leakage rates is provided in the main control room on panel-mounted indicators. Sump tank levels (in gallons) are provided on CRT displays from the ERFDS system.

An alternative method to quantify RCPB leakage in the drywell is used when the Drywell floor drain sump monitoring system in unavailable. The alternate method allows the Drywell floor drain sump to overflow, through installed piping, to the Drywell equipment drain monitoring system to verify that RCPB leakage is within allowable limits. In this condition, all input into the Drywell equipment drain sump will be considered unidentified drywell leakage.

Level switches, which are independent of the level transmitters, open the sump tank drain valves when the level increases to an upper setpoint value and keep them open until the level decreases to lower setpoint value. The level switches then close the drain valves and reset the processing units to start a new measurement period. The measurement period must be long enough to ensure that the level transmitter loop can adequately detect the increase in level that would correspond to the 1 gpm and 2 gpm changes in leak rates described above, and yet short enough to ensure that such a leak rate will be detected within an hour. The measurement period will be less than 1 hour.

The transmitters which are located in the reactor enclosure and the processing units which are located in the main control room, are accessible during normal plant operation for calibration. The transmitters can be isolated from the sump tanks by existing bypass manifolds. Zero and span adjustments can be made using portable test equipment. The processing unit functions can be calibrated by applying known input levels at the unit and observing the response.

The DSLMS is comprised of the processing units, level transmitters, control room leakage flow indicators and interconnecting raceway and cables. The DSLMS has been demonstrated to remain operational after an SSE. The DSLMS is energized by Class 1E power. The Class 1E power to the panel is provided with a Class 1E fuse and circuit breaker in series to meet separation requirements. The DSLMS is automatically shed from the Class 1E power in the event of a LOCA (the load shedding relay, however, is not qualified for Class 1E service). Drawing M-61 shows the piping and instrument diagram for this system.

In addition to the sump level monitoring system described above, the discharge from each sump is monitored by a flow element. The measured flow rate is integrated and recorded in the control room. A control room alarm is also provided to indicate excessive discharge rates. These indications and alarms are provided in accordance with Regulatory Guide 1.45.

5.2.5.2.1.4 Drywell Air Cooler Condensate Drain Flow Monitoring

The drywell air cooler condensate drain flow monitoring system consists of six flow sensors and their associated flow transmitters that provide inputs to a separate flow monitoring device. The flow sensors are mounted in the drywell air cooler drain lines located in the drywell. There are a total of eight coolers. Two flow sensors measure the flow from two air cooler drain line headers. Four additional flow sensors measure the drain flow from each of the remaining coolers which are piped separately to the drywell floor drain sump tank. The outputs from the six flow transmitters which receive their input from the flow sensors are added to provide a total continuous drain flow rate by the use of two summing units. The continuous drain flow rate is monitored by a flow switch, located in the main control room, which will alarm if the rate exceeds 1 gpm over the preset identified leak rate. The plant operator establishes the acceptable identified drain flow rate and adjusts the setpoint of this flow switch accordingly (i.e., if the identified flow rate is established at 5 gpm, the system will be set to alarm at 6 gpm). The requirement to detect a 1 gpm increase in unidentified leakage within an hour is met by monitoring the continuous flow rate. Indication of the total continuous drain flow rate is provided in the main control room on panel-mounted indicators and CRT displays from the ERFDS system.

The calibration and test interval for the flow sensors, transmitters, and processing units is in accordance with the manufacturer's recommendation.

The drywell air cooler condensate drain flow monitoring system is qualified to withstand an OBE. The system is energized by Class 1E power. Drawing M-87 shows the piping and instrument diagram for this system.

5.2.5.2.1.5 Containment Airborne Radioactivity Monitoring

The primary containment is continuously monitored for airborne gaseous radioactivity. A drywell air sample is extracted via sample line through containment penetration X-117B at el 292', area 16. Air flow through the monitoring system is assured by the suction created by a vacuum pump. The air sample is surveyed by the GM tubes in the sampling chamber for its radioactivity content. The air sample is returned to the drywell through the same containment penetration. The level of radioactivity is recorded in the main control room in counts per minute. The range is from 10 cpm to 10^6 cpm. The corresponding concentration is 10^{-6} μCi/cc to 10^{-1} μCi/cc. Particulate and iodine monitors are not provided due to the substantial limitations of their usefulness as described below.

The noble gas monitoring equipment is shown in drawing M-26. It is not designed to be operable following an SSE.

Radioactivity level indication and alarms for loss of sample flow, high radiation, and down-scale are provided locally and in the main control room. Activity level indication in the control room is provided on a strip-chart recorder to provide trend information.

The operability of the sensor and the electronic circuitry can be verified during operations from the auxiliary equipment room. A check source is supplied with the monitor. Sample connections are also provided to facilitate additional sampling for laboratory analysis.

The radiation monitor is capable of being calibrated during power operation and will be calibrated in accordance with Technical Specifications requirements (Chapter 16).

The reliability, sensitivity, and response times of radiation monitors to detect 1 gpm in 1 hour of RCPB leakage will depend on many complex factors. The major limiting factors are discussed below.

5.2.5.2.1.5.1 Source of Leakage

a. Location of Leakage - The amount of activity that would become airborne following a 1 gpm leak from the RCPB will vary depending on the leak location and the coolant temperature and pressure. For example, a feedwater pipe leak may have concentration factors of 100 to 1000 lower than a recirculation line leak. A steam line leak may be a factor of 50 to 100 lower in iodine and particulate concentrations than the recirculation line leak, but the noble gas concentrations may be comparable. An RWCU leak upstream of the demineralizers and heat exchangers may be a factor of 10 to 100 higher than downstream, except for noble gases. Differing coolant temperatures and pressures will affect the flashing fraction and partition factor for iodines and particulates. Thus, an airborne concentration cannot be directly correlated to a quantity of leakage without knowing the source of the leakage.

b. Coolant Concentrations - Variations in coolant concentrations during operation can be as much as two orders of magnitude within a time frame of several hours. These effects are mainly due to spiking during power transients or changes in the use of the RWCU system. Examples of these transients for I-131 are given in Reference 5.2-6. An increase in the coolant concentrations could give increased containment concentrations when no increase in unidentified leakage occurs.

c. Other Sources of Leakage - Because the unidentified leakage is not the sole source of activity in the containment, changes in other sources will result in changes in the containment airborne concentrations. For example, identified leakage is piped to the equipment drain tank in the drywell, but the tank is vented to the drywell atmosphere allowing the release of noble gases and some small quantities of iodines and particulates from the drain tank.

5.2.5.2.1.5.2 Drywell Conditions Affecting Monitor Performance

a. Equilibrium Activity Levels - During normal operation, the activity release from acceptable quantities of identified and unidentified leakage will build up to significant amounts in the drywell air. Due to these high equilibrium activity levels, the activity increase due to a small increase in leakage may be difficult to detect within a short period of time.

b. Purge and Pressure Release Effects - Changes in the detected activity levels have occurred during containment venting operations. These changes are of the same order of magnitude as approximately a 1 gpm leak and are sufficient to invalidate the results from iodine and particulate monitors.

c. Plateout, Mixing, Condensation, Fan Coolant Depletion - Plateout effects on measured iodine and particulate levels will vary with the distance from the coolant release point to the detector. Larger travel distances would result in more plateout. In addition, the pathway of the leakage will influence the plateout effects. For example, a leak from a pipe with insulation will have greater plateout than a leak from an uninsulated pipe. Although the drywell air will be mixed by the fan coolers, it may be possible for a leak to develop in the vicinity of the radiation detector sample lines. In addition, condensation in the coolers and sample lines will remove iodines and particulates from the air. Variations in flow, temperature, and number of coolers will

affect the plateout fractions. Plateout within the detector sample chamber will also add to the reduction of the iodine and particulate activity levels. The uncertainties in any estimate of plateout effects could be as much as one or two orders of magnitude.

5.2.5.2.1.5.3 Physical Properties and Capabilities of the Detector

a. Detector Range - The detector was chosen to ensure that the operating range covered the concentrations expected in the drywell. The operating range of the noble gas monitor is: 10^{-6} μCi/cc to 10^{-1} μCi/cc.

b. Sensitivity - In the absence of background radiation and equilibrium drywell activity levels, the detector has the following minimum sensitivity: 10^{-6} μCi/cc for Xe-133.

c. Counting Statistics and Monitor Uncertainties - In theory, this radioactivity monitor is statistically able to detect increases in concentration as small as 2 or 3 times the square root of the count rate, i.e., at $1x10^6$ cpm an increase of $2x10^3$ or 0.2% is detectable; at 100 cpm an increase of 20, or 20% is detectable. In addition, at high count rates the monitors have dead-time uncertainties and the potential for saturating the monitor or the electronics. Uncertainties in calibration (±5%), sample flow (±10%), and other instrument design parameters tend to make the uncertainty in a count rate closer to 20% to 40% of the equilibrium drywell activity.

d. Monitor Setpoints - Due to the uncertainty and extreme variability of the radioactivity concentrations to be measured in the containment, the use of tight alarm setpoints on the radioactivity monitor would not be practical or useful. The setpoint, which would be required to alarm at 1 gpm, would be well within the bounds of uncertainty of the measurements. The use of such setpoints would result in many unnecessary alarms and the frequent resetting of setpoints. The alarm setpoints for the radiation monitors are set significantly above normal readings to prevent nuisance alarms.

e. Operator Action - There is no direct correlation or known relationship between the detector count rate and the leakage rate because the coolant activity levels, source of leakage, and background radiation levels (from leakage alone) are not known and cannot be cost-effectively determined in existing reactors. There are also several other sources of containment airborne activity (e.g., SRV leakage) that further complicate the correlation.

Thus, the procedure for the control room operator is to set an alarm setpoint at 1 gpm in 1 hour on the sump level monitor (measuring water collected in the sump that may not exactly correspond to water leaking from an unidentified source). When the alarm is actuated, the operator will review all other monitors (e.g., noble gas, containment temperature and pressure, air cooler condensate flow, etc.) to determine if the leakage is from the primary coolant pressure boundary and not from an SRV or cooling water system, etc. Appropriate actions will then be taken in accordance with Technical Specifications. The review of other monitors will consist of comparisons of the increases and rates of increase in the values previously recorded. Increases in all parameters except sump level will not be correlated to a RCPB leakage rate. Instead, the increases will be compared to normal operating limits and limitations, and abnormal increases will be investigated.

Because the Technical Specification limit for leakage is allowed to be averaged over 24 hours, quick and accurate responses are not necessary unless the leakage is large and indicative of a pipe break. In this case, the containment pressure and reactor vessel water level monitors will alarm within seconds, and the sump level monitor would alarm within minutes or tens of minutes.

Radiation monitor alarms are not set to levels that are intended to correspond to the RCPB leakage levels because such correlations are not valid. Because the containment airborne activity levels vary by orders of magnitude during operation due to power transients, spiking, steam leaks, and outgassing from sumps, an appropriate alarm setpoint is determined by the operator based on experience with the specific plant. A setpoint level of 10 times the level during full power steady-state operation may be useful for alarming large leaks and pipe breaks, but it would not always alarm for 1 gpm in one hour and therefore could not be considered as any more than a qualitative indication of the presence of abnormal leakage.

Due to the sum total of the uncertainties identified in the previous paragraphs, iodine and particulate monitors are not relied upon for immediate leak detection purposes. The noble gas monitor is used to give supporting information to that supplied by the sump discharge monitoring, and it would be able to give an early warning of a major leak, especially if equilibrium containment activity levels are low. However, the uncertainties and variations in noble gas leaks and concentrations would preclude the setting of a meaningful alarm setpoint. Grab sampling and laboratory analyses of airborne particulate, noble gas, and iodine may be used to characterize leakage detected by other means.

5.2.5.2.1.6 Reactor Vessel Head Seal Leak Detection

The reactor vessel head is provided with two concentric metallic seals, with a leak-off connection between the seals to permit detection of leakage through the inner seal. The connection is piped to a local pressure indicator and pressure switch. High pressure in this leak-off connection is annunciated in the control room, alerting the operator to failure of the inner seal. This system is shown in drawing M-41.

5.2.5.2.1.7 Reactor Recirculation Pump Seal Leak Detection

Each of the reactor recirculation pumps is provided with a system for monitoring leakage through each of its two mechanical seals. Two types of monitoring are provided for each pump.

Instrumentation is provided to monitor the pressure within each of the pump seal cavities. Changes in seal cavity pressure from that normally expected alerts the operator to possible reactor recirculation pump seal damage or excessive wear.

Instrumentation is also provided to monitor the flow rate in the drain line from each seal. A limited amount of leakage is expected past each of the mechanical seals. Flow instrumentation in each seal drain line actuates an annunciator in the control room wherever the leakage flow in the line becomes excessive. The instrumentation is shown in drawing M-43.

5.2.5.2.1.8 MSRV Leak Detection

Temperature sensors connected to a multipoint recorder are provided to detect MSRV leakage during reactor operation. Using a thermo-well, temperature elements are mounted, in the MSRV discharge piping downstream of the valve body. Normally, all MSRVs are in the shut-tight condition and remain at approximately the same temperature. Steam leakage past an MSRV elevates the sensed temperature in its discharge line. High discharge line temperature is annunciated in the control room, alerting the operator to MSRV leakage. The temperature sensors are shown in drawing M-41.

5.2.5.2.1.9 RPV Water Level

Under conditions of normal reactor operation at constant power, reactor water level should remain fairly constant at its programmed level since the rate of steam mass flow leaving the boiler is matched by the feedwater mass flow rate into the reactor vessel. However, given a condition of continued steam leakage from the closed system, the CST level and the reactor water level decreases.

Reactor water level is monitored by the level indicating switches associated with the containment isolation system in addition to the normal complement of process monitoring instruments. Reactor water level falling below the predetermined minimum allowable level results in switch actuation and subsequent containment isolation. Section 7.3 gives a complete description of this isolation function. The level instrumentation is shown in drawing M-42.

5.2.5.2.2 Detection of Abnormal Leakage Outside the Primary Containment

The various methods utilized for detecting leakage from components outside the primary containment are discussed below.

5.2.5.2.2.1 Main Steam Line Leak Detection Outside Primary Containment

The main steam lines are continuously monitored for leaks by the main steam line leak detection system. Steam line leaks will cause changes in at least one of the following monitored operating parameters: air temperature adjacent to the main steam lines, main steam line flow rate, or water level in the reactor vessel. If a leak is detected, the detection system actuates an annunciator in the control room and, depending upon the activating parameter, initiates steam line isolation action. The following methods are used for monitoring the above operating parameters:

a. Air temperature of the space adjacent to the main steam lines (both inside the steam tunnel and from the steam tunnel exit to the inlet of the main turbine) is monitored by a set of temperature sensors located along the length of each main steam line (drawing M-25). The temperature sensors are located or shielded so as to be sensitive to air temperature only and not to the radiated heat from hot equipment. These temperature sensors are connected to nonindicating temperature switches which initiate an alarm in the control room on abnormally high temperature. In order to prevent excessive loss of reactor coolant and the release of significant amounts of radioactive material from the RCPB, these temperature switches initiate isolation of the following lines on abnormally high temperature in the area adjacent to the main steam lines:

    1. All 4 main steam lines

    2. Main steam line drain

In addition to the above temperature sensors and switches used for detecting gross leakage, temperature sensors are also provided to detect possible small leaks in the main steam lines by monitoring (1) the ambient temperature within the main steam line tunnel, and (2) the temperature difference between the supply and return ventilation air for the main steam line tunnel. These sensors are also located or shielded so as to be sensitive to air temperature only and not to radiated heat from hot equipment. A rise in either the ambient temperature or the ventilation air differential temperature above the values normally indicated is alarmed in the control room, alerting the operator to possible main steam line leakage.

The heat balance for the area under consideration for the temperature sensor location is established for normal load, and that area is evaluated for various leak rates. The alarm and isolation setpoints are computed and checked by this method. The alarms and isolation setpoints associated with the above temperature devices are selected to be high enough to avoid spurious alarms and isolations, yet low enough to provide timely detection and isolation of a main steam line break.

b. Main steam flow rate within each of the main steam lines is monitored by the main steam flow restrictors and their associated differential pressure transducers and indicating switches. The outputs of the differential pressure indicating switches initiate an alarm in the control room and isolation of the following lines whenever the flow in a single steam line exceeds 140% of the line rated flow:

   1. All 4 main steam lines

   2. Main steam line drain

   The main steam line high flow alarm and isolation setpoint is set to be high enough to permit the isolation of one main steam line for test at rated power without causing an automatic isolation of the rest of the steam lines, yet low enough to provide timely detection and isolation of a gross main steam line break.

c. Reactor water level monitoring is described in Section 5.2.5.2.1.8.

5.2.5.2.2.2 RWCU System Leak Detection

Leakage in the high temperature process flow of the RWCU system external to the primary containment is detected by temperature sensors located within the RWCU equipment compartments and in the supply and return ventilation air ducts for the compartments (drawing M-25). The temperature sensors are located or shielded so as to be sensitive to air temperature only and not to the radiated heat from hot equipment. These temperature sensors are connected to nonindicating temperature switches which initiate an alarm in the control room whenever the ambient temperature or the ventilation air differential temperature of an RWCU system equipment compartment exceeds the value normally indicated. In order to prevent excessive loss of reactor coolant and the release of significant amounts of radioactive material from the RCPB, these temperature switches also initiate isolation of the RWCU system. The alarm and isolation setpoints associated with the above temperature devices are selected to be high enough to avoid spurious isolation, yet low enough to provide timely detection and isolation of a break in the RWCU system.

In addition to the temperature detection method above, leakage from the RWCU system is also detected by means of a RWCU system inlet and outlet flow comparison. If the inlet flow exceeds the

outlet flow by at least 54.9 gpm for a minimum of 45 seconds, an alarm is actuated in the control room and the RWCU system is automatically isolated.

5.2.5.2.2.3 RHR System Leak Detection

RHR system leakage external to the primary containment is detected by temperature sensors in the RHR compartments (drawing M-25).

The temperature sensors are located or shielded so as to be sensitive to air temperature only and not to the radiated heat from hot equipment. These temperature sensors are connected to nonindicating temperature switches which initiate an alarm in the control room whenever the ambient temperature or the ventilation air differential temperature of a RHR system compartment exceeds the value normally expected.

5.2.5.2.2.4 RCIC and HPCI Systems Leak Detection

Leak detection components are provided for monitoring, annunciation, and, in certain cases, isolation of steam supply line leakage in the RCIC and HPCI equipment compartments and pipe-ways. Steam line leaks cause changes in air temperature adjacent to the steam lines or steam line flow rate (drawing M-25). If a leak is detected, the detection system actuates an annunciator in the control room and, depending upon the activating parameter, initiates steam line isolation action. The following methods are used for monitoring the above operating parameters:

a. As are provided for the RWCU and RHR equipment compartments, temperature sensors are located in each of the RCIC and HPCI equipment compartments and in the supply and return ventilation air ducts for the compartments. The temperature sensors are located or shielded so as to be sensitive to air temperature only and not to the radiated heat from hot equipment. These temperature sensors are connected to nonindicating temperature switches which initiate alarms in the control room whenever the ambient temperatures or the ventilation air differential temperatures of the compartments exceed the values normally indicated. In order to prevent excessive loss of reactor coolant and the release of significant amounts of radioactive material from the RCPB, the temperature switches associated with ventilation air differential temperatures of the RCIC and HPCI compartments initiate isolation of the corresponding RCIC or HPCI steam lines.

   Temperature sensors are also located along the length of the RCIC and HPCI steam lines between the primary containment and the respective equipment compartments and in the equipment compartments for monitoring air temperature adjacent to the steam lines. The temperature sensors are located or shielded so as to be sensitive to air temperature only and not to the radiated heat from hot equipment. These temperature sensors are connected to nonindicating temperature switches which initiate an alarm in the control room on abnormally high temperature. In order to prevent excessive loss of reactor coolant and the release of significant amounts of radioactive material from the RCPB, the switches also initiate isolation of the corresponding RCIC or HPCI steam lines.

   The alarms and isolation setpoints associated with the above temperature devices in the RCIC and HPCI equipment compartments and pipe-ways are selected to be high enough to avoid spurious isolation, yet low enough to provide timely detection and isolation of a RCIC or HPCI steam line break.

b. Steam flow rates in the RCIC and HPCI steam supply lines are monitored by venturi-type flow elements and their associated differential pressure transducers and indicating switches. The outputs of the differential pressure indicating switches initiate an alarm in the control room and isolation of the corresponding steam supply line whenever the flow in a single steam line exceeds 300% of the line rated flow.

The RCIC and HPCI steam supply line high flow alarm and isolation setpoints are selected to provide timely detection and isolation of an RCIC or HPCI steam supply line break. Spurious isolations due to short-term flow peaks are precluded by a predetermined time delay feature.

5.2.5.2.2.5 Other Leakage Detection Methods

Instrumentation associated with the plant drainage system (Section 9.3.3) can provide indication of leakage of systems outside containment.

The RHR, CS, HPCI, and RCIC compartments are equipped with level switches to sense and alarm in the main control room if excessive leakage or flooding occurs in the compartment.

Excessive leakage outside the containment can also be detected by observation of abnormal reactor enclosure sump pump operating times and by sump high level alarms. This instrumentation is provided in the radwaste control room.

5.2.5.2.2.6 Intersystem Leak Detection

Radiation monitors are used to detect reactor coolant leakage into the RHRSW system, ESW system, and the RECW system from the RHR heat exchangers, ESW cooled compartment and the RWCU nonregenerative heat exchangers, respectively. These radiation monitoring channels are part of the PRMS (drawing M-26), and monitor for leakage into the cooling water flows downstream of the RHR heat exchangers and the RWCU system nonregenerative heat exchangers and the ESW return flow.

High radiation levels in the monitored cooling water systems is annunciated in the control room. Associated trips and interlocks for the RHRSW system pumps and the design basis and the associated instrumentation for PRMS are discussed in Section 11.5.

5.2.5.3 Indication in Control Room

Details of the leakage detection system indications are included in Section 7.6.

5.2.5.4 Limits for Reactor Coolant Leakage Inside the Containment

The total leakage inside containment consists of all leakage, both identified and unidentified, which flows to the drywell floor and equipment drain sumps. The total leakage rate limit is well within the makeup capability of the RCIC system. This limit is 30 gpm of which a limit of 5 gpm is set for unidentified leakage, and 25 gpm is allowed for identified sources.

The unidentified leakage rate limit must be low because of the possibility that most of the unidentified leakage might emanate from a single crack in the nuclear system process barrier that could be large enough to propagate rapidly.

The unidentified leakage rate limit is established at 5 gpm to allow time for corrective action before the process barrier could be significantly compromised. This 5 gpm unidentified leakage rate is adequate since it is a small fraction of the calculated flow from a critical crack in a primary system pipe as discussed in Section 5.2.5.6. Safety limits and safety limit settings are discussed in Chapter 16.

5.2.5.5 Sensitivity and Response Time

Sensitivity, including sensitivity tests, and response times of the leak detection system components are discussed in Section 7.6. As indicated therein, the sensitivity and response time of the sump leak detection system is adequate to detect an increase in unidentified leakage inside the containment of 1 gpm in less than 1 hour. The airborne radiation monitors are capable of detecting a 1 gpm coolant leak in 1 hour in a containment atmosphere free from airborne radioactivity (zero background). However, during normal plant operation (i.e. operation within technical specification limits), the normal levels of containment airborne activity coupled with normal changes in coolant activity concentrations may mask an increase in coolant leakage to the extent that its detection, by this method alone, is not possible within 1 hour.

5.2.5.6 Crack Length and Through-Wall Flow

Experiments conducted by GE and BMI permit an analysis of critical crack length and crack opening displacement (Reference 5.2-4). This analysis relates to axially oriented through-wall cracks.

a. Critical Crack Length

Both the GE and BMI test results indicate that theoretical fracture mechanics formulas do not predict critical crack length, but that satisfactory empirical expressions may be developed to fit test results. A simple equation which fits the data in the range of normal design stresses (for carbon steel pipe) is:

$$L_c = \frac{15000\ D}{h} \qquad \text{(EQ. 5.2-1)}$$

where:

L_c = critical crack length (in)

D = mean pipe diameter (in)

h = nominal hoop stress (psi)

Data correlation for Equation (EQ. 5.2-1) is shown in Figure 5.2-13.

b. Crack Opening Displacement

The theory of elasticity predicts a crack opening displacement of:

$$W = \frac{2\ L\sigma}{E} \qquad \text{(EQ. 5.2-2)}$$

where:

W = crack opening displacement (in)

L = crack length (in)

σ = applied nominal stress (psi)

E = Young's Modulus

Measurements of crack opening displacement made by BMI show that local yielding greatly increases the crack opening displacement as the applied nominal stress (σ) approaches the failure stress (σ_f). A suitable correction factor for plasticity effects is:

$$C = \sec\left(\frac{\pi\sigma}{2\sigma_f}\right) \qquad \text{(EQ. 5.2-3)}$$

The crack opening area is given by,

$$A = \frac{C\pi WL}{4} = \frac{\pi L^2\sigma}{2E}\sec\left(\frac{\pi\sigma}{2\sigma_f}\right) \qquad \text{(EQ. 5.2-4)}$$

For a given crack length L:

σ_f = 15000 D/L

c. Leakage Flow Rate

The maximum flow rate for blowdown of saturated water at 1000 psi is 55 lb/sec-in^2, and for saturated steam the rate is 14.6 lb/sec-in^2, (Reference 5.2-5). Friction in the flow passage reduces this rate, but for cracks leaking at 5 gpm (0.7 lb/sec) the effect of friction is small. The required leak size for 5 gpm flow is:

A = 0.0126 in^2 (saturated water)
A = 0.0475 in^2 (saturated steam)

From this mathematical model, the critical crack length and the 5 gpm crack length have been calculated for representative BWR pipe size (Schedule 80) and pressure (1050 psi). Results are tabulated as follows:

Nominal Pipe Size (Sch 80) (in)	Avg. Wall Thickness (in)	5 gpm Crack Length (in)		Critical Crack Length (in)	
		Steam Line	Wtr Line	Steam Line	Wtr Line
4	0.337	7.2	4.9	9.7	9.6
12	0.687	8.5	4.8	19.7	19.8
24	1.218	8.6	4.6	34.8	34.8

The ratios of crack length (L) to the critical length (L_c) as a function of nominal pipe size are:

Nominal Pipe Size (Sch 80) (in)	Ratio/L/L	
	Steam Line	Water Line

4	0.745	0.510
12	0.432	0.243
24	0.247	0.132

It is important to recognize that the failure of ductile piping with a long, through-wall crack is characterized by large crack opening displacements which precede unstable rupture. Judging from observed crack behavior in the GE and BMI experimental programs involving both circumferential and axial cracks, it is estimated that leak rates of hundreds of gallons per minute will precede crack instability. Measured crack opening displacements for the BMI experiments were in the range of 0.1-0.2 inches at the time of incipient rupture, corresponding to leaks of the order of 1 in^2 in size for plain carbon steel piping. For austenitic stainless steel piping, ever larger leaks are expected to precede crack instability, although there is insufficient data to permit quantitative prediction.

The results given are for a longitudinally oriented flaw at normal operating hoop stress. A circumferentially oriented flaw could be subjected to stress as high as the 550°F yield stress, assuming high thermal expansion stresses exist. A good mathematical model which is supported by test data is not available for the circumferential crack. Therefore, it is assumed that the longitudinal crack, subject to a stress as high as 30,000 psi, constitutes a "worst case" with regard to leak rate versus critical size relationships. Given the same stress level, differences between the circumferential and longitudinal orientations are not expected to be significant in this comparison.

Figure 5.2-12 shows general relationships between crack length, leak rate, stress, and line size, using the mathematical model described above. The asterisks denote conditions at which the crack opening displacement is 0.1 inch, at which time instability is imminent. This provides a realistic estimate of the leak rate to be expected from a crack of critical size. In every case, the leak rate from a crack of critical size is greater than the 5 gpm unidentified leakage rate limit.

5.2.5.7 Margins of Safety

The margins of safety for a detectable flaw to reach critical size are presented in Section 5.2.5.6. Figure 5.2-12 shows general relationships between crack length, leak rate, stress, and line size using the mathematical model presented in Section 5.2.5.6.

5.2.5.8 Criteria to Evaluate the Adequacy and Margin of the Leak Detection System

For process lines that are normally open, there are at least two different methods of detecting abnormal leakage from the reactor system process barrier located in the primary containment and reactor enclosure (Table 5.2-7). The instrumentation can be set to provide alarms at established leakage rate limits and isolate an affected system when necessary. The alarm setpoints are determined

analytically or, where appropriate, based on measurements of appropriate parameters made during startup and preoperational tests.

The primary containment unidentified leakage rate limit of 5 gpm is based, with an adequate margin for contingencies, on the crack size large enough to propagate rapidly. The established limit is sufficiently low so that, even if the entire unidentified leakage rate were coming from a single crack in the nuclear system process barrier, corrective action could be taken before the integrity of the barrier would be threatened with significant compromise.

5.2.5.9 Differentiation Between Identified and Unidentified Leakage

Section 5.2.5.2 describes the systems that are monitored by the leak detection system. The ability of the leak detection system to differentiate between identified, and unidentified leakage is discussed in Section 5.2.5.2.

5.2.5.10 Sensitivity and Operability Tests

Testability of the leak detection system is discussed in Section 7.6.

5.2.5.11 Testing and Calibration

The leak detection system is preoperationally tested in accordance with the requirements of Chapter 14 and is periodically tested in accordance with the requirements of Chapter 16.

Table 5.2-7 (Cont'd)

(1) All systems within the drywell share a common leak detection system.

(2) Isolation and alarm occur on high temperature in the main steam line Outboard MSIV room. Alarm occurs on high temperature in the main steam line steam tunnel in the turbine enclosure.

(3) Alarm only.

(4) Leakage downstream of the flow element will cause isolation of the steam line.

(5) The following notations are used:

A - alarm
I - isolation
PC - primary containment
RE - reactor enclosure

(6) Plant drainage system instrumentation.

SEQUENCE OF EVENTS

(REDY, ODYN, and TRACG)

This page was intentionally left bank

Table 5.2-8 (Cont'd)

SEQUENCE OF EVENTS

(3 SRV Out-Of-Service)*

TIME-SEC	EVENT
0	Initiate closure of all MSIVs.
0.3	MSIVs reach 90% open and initiate reactor scram. However, hypothetical failure of this position scram is assumed in this analysis.
1.64	Neutron flux reaches the high APRM flux scram setpoint and initiates reactor scram.
2.35	Recirculation pump drive motors trip due to high vessel pressure.
2.75	Steam line pressure reaches the relief valve pressure setpoint and valves start to open.
3.01	All SRVs opened.
3.0	The MSIVs completely closed.
4.41	Vessel bottom pressure at its peak value.

* General Electric performed a re-analysis to increase the allowable SRV as-found setpoint tolerance to ± 3% of the SRV setpoint (ref. 3.9-26). The results of this analysis require that the number of SRVs allowed out-of-service, be limited to 2. An assessment of the data given in Table 5.2-8 indicates that the effect from the re-analysis on the time sequence is not significant. The change to ± 3% of the SRV setpoint tolerance is effective after 2R05 for Unit 2, and after 1R08 for Unit 1.

5.3 REACTOR VESSEL

5.3.1 REACTOR VESSEL MATERIALS

5.3.1.1 Materials Specifications

The materials used in the RPV and appurtenances are shown in Table 5.2-3 together with the applicable specifications.

5.3.1.2 Special Processes Used for Manufacturing and Fabrication

The RPV is primarily constructed from low alloy, high strength steel plate and forgings. Plates are ordered to ASME SA533, Grade B, Class 1, and forgings to ASME SA508, Class 2. These materials are melted to fine grain practice and are supplied in the quenched and tempered condition. Further restrictions include a requirement for vacuum degassing to lower the hydrogen level and improve the cleanliness of the low alloy steels.

Studs, nuts, and washers for the main closure flange are ordered to ASME SA540, Grade B23, or Grade B24. Welding electrodes are low hydrogen-type ordered to ASME SFA5.5.

All plate, forgings, and bolting are 100% ultrasonically tested and surface examined by magnetic particle methods or liquid penetrant methods in accordance with ASME Section III standards. Fracture toughness properties are also measured and controlled in accordance with ASME Section III requirements.

All fabrication of the RPV is performed in accordance with GE approved drawings, fabrication procedures, and test procedures. The shells and vessel heads are made from formed plates, and the flanges and nozzles from forgings. Welding performed to join these vessel components is in accordance with procedures qualified in accordance with ASME Sections III and IX requirements. Weld test samples are required for each procedure for major vessel full penetration welds. Tensile and impact tests are performed to determine the properties of the base metal, heat-affected zone, and weld metal.

Submerged arc and manual stick electrode welding processes are employed. Electroslag welding is not permitted. Preheat and interpass temperatures employed for welding of low alloy steel meet or exceed the requirements of ASME Section III. Postweld heat treatment at 1100°F minimum is applied to all low alloy steel welds.

Radiographic examination is performed on all pressure-containing welds in accordance with requirements of ASME Section III, Paragraph N-624 including Summer 1975 Addenda. In addition, all welds are given a supplemental ultrasonic examination.

The materials, fabrication procedures, and testing methods used in the construction of BWR RPVs meet or exceed requirements of ASME Section III, Class I vessels.

The Unit 2 N16D repair was performed using Machine and Manual Gas Tungsten Arc Welding with the Ambient Temperature Temper Bead weld technique in accordance with the rules of ASME Section XI Code Case N-638-4.

5.3.1.3 Special Methods for Nondestructive Examination

The materials and welds on the RPV were examined in accordance with methods prescribed, and met the acceptance requirements specified by ASME Section III. In addition, the pressure-retaining welds were ultrasonically examined using manual techniques. The ultrasonic examination method, including calibration, instrumentation, scanning sensitivity, and coverage is based on the requirements imposed by ASME Section XI, Appendix I. Acceptance standards are equivalent to, or more restrictive than, those required by ASME Section XI.

5.3.1.4 Special Controls For Ferritic and Austenitic Stainless Steels

5.3.1.4.1 Compliance With Regulatory Guides

5.3.1.4.1.1 Regulatory Guide 1.31, Control of Ferrite Content in Stainless Steel Weld Metal

Controls on stainless steel welding are discussed in Section 5.2.3.4.2.1.

5.3.1.4.1.2 Regulatory Guide 1.34, Control of Electroslag Weld Properties

Electroslag welding is not employed for the RPV fabrication.

5.3.1.4.1.3 Regulatory Guide 1.43, Control of Stainless Steel Weld Cladding of Low Alloy Steel Components

This guide applies to welding of cladding to low alloy steels made to coarse grain practice. LGS vessel plate and nozzle forgings are made to fine grain practice and a low heat input process is used. Other components are not clad. Therefore, the guide is not applicable.

5.3.1.4.1.4 Regulatory Guide 1.44, Control of the Use of Sensitized Stainless Steel

Controls to avoid severe sensitization are discussed in Section 5.2.3.4.1.1.

5.3.1.4.1.5 Regulatory Guide 1.50, Control of Preheat Temperature for Welding Low Alloy Steel

Preheat controls are discussed in Section 5.2.3.3.2.1.

5.3.1.4.1.6 Regulatory Guide 1.71, Welder Qualification for Areas of Limited Accessibility

Welder qualification for areas of limited accessibility is discussed in Section 5.2.3.4.2.3.

5.3.1.4.1.7 Regulatory Guide 1.99, Effects of Residual Elements on Predicted Radiation Damage to Reactor Pressure Vessel Materials

Predictions for changes in transition temperature and upper-shelf energy are made in accordance with the guidelines of Regulatory Guide 1.99 (Rev 2).

5.3.1.5 Fracture Toughness

This section is supplemented by Sections 5.3.1.7 and 5.3.1.8 in discussing the compliance to the intent of 10CFR50, Appendix G.

5.3.1.5.1 Assessment of 10CFR50, Appendix G

A major condition necessary for full compliance to 10CFR50, Appendix G is satisfaction of the requirements of the Summer 1972 Addenda to ASME Section III. This is not possible with components that were purchased to earlier code requirements. For the extent of compliance see Table 5.3-1.

Ferritic materials complying with 10CFR50, Appendix G must have both drop weight tests and Charpy V-notch tests with the CVN specimens oriented transverse to the maximum material working direction to establish the RT_{NDT}. The CVN tests must be evaluated against both an absorbed energy and a lateral expansion criteria. The maximum acceptable RT_{NDT} must be determined in accordance with the analytical procedures of ASME Section XI, Appendix G. 10CFR50, Appendix G, requires an initial minimum of 75 ft-lb upper-shelf CVN energy for beltline material. It also requires at least 45 ft-lb CVN energy and 25 mils lateral expansion for bolting material at the lower of the preload or lowest service temperature.

By comparison, materials for the LGS Units 1 and 2 reactor vessels are qualified by drop weight tests and/or in most cases longitudinally oriented CVN tests (both not required), confirming that the material NDTT is at least 60°F below the lowest service temperature. When the longitudinal CVN test was applied, a 30 ft-lb energy level was used in defining the NDTT. There was no upper-shelf CVN energy requirement on the LGS Units 1 and 2 beltline material. The bolting material was qualified to a 30 ft-lb CVN energy requirement at 60°F below the minimum preload temperature.

To determine operating limits in accordance with 10CFR50, Appendix G, estimates of the beltline material RT_{NDT} and the highest RT_{NDT} of all other material were made, as explained in Section 5.3.1.5.3. The method for developing these operating limits is also described therein.

5.3.1.5.2 Method of Compliance

The method of compliance is based on the last paragraph on page 19013 of the July 17, 1973 Federal Register.

The intent of the proposed special method of compliance with Appendix G for this vessel is to provide operating limitations on pressure and temperature based on fracture toughness. These operating limits ensure that a margin of safety against a nonductile failure of this vessel is very nearly the same as a vessel built to the Summer 1972 Addenda.

The specific temperature limits for all modes of plant operation when the core is critical are based on 10CFR50, Appendix G.

5.3.1.5.3 Methods of Obtaining Operating Limits Based on Fracture Toughness

Operating limits that define minimum metal temperatures versus reactor pressure during normal heatup and cooldown, and during inservice hydrostatic testing, are established using the methods of ASME Section XI, Appendix G, 2007 Edition with addenda through 2008. (Reference 5.3-11 and 5.3-12). The results are shown in Figures 5.3-4 (LGS Unit 1) and 5.3-5 (LGS Unit 2).

Estimated RT_{NDT} values and temperature limits are given in this section for the limiting locations in the reactor vessel.

All the vessel shell and head areas remote from discontinuities were evaluated and the operating limit curves are based on the limiting location. The bolt-up limits for the flange and adjacent shell regions are based on a minimum metal temperature of RT_{NDT} + 60°F. The maximum through-wall temperature gradient from continuous heating and cooling at 100°F per hour was considered. The safety factors applied were as specified in ASME Section XI, Appendix G.

For the purpose of setting these operating limits the reference temperature, RT_{NDT}, is determined from the toughness test data taken in accordance with requirements of the Code to which the vessels are designed and manufactured. These toughness test data, CVN and/or drop-weight NDT are analyzed to permit compliance with the intent of 10CFR50, Appendix G. Because all toughness testing needed for strict compliance with Appendix G was not required at the time of vessel procurement some toughness results are not available. For example, longitudinal CVNs, instead of transverse, were tested, usually at a single test temperature of +10°F or +40°F, for absorbed energy. Also, at the time, either CVN or drop-weight testing was permitted; therefore, in many cases both tests were not performed as is currently required. To substantiate the design adequacy, toughness property correlations are derived for the vessel materials to give a conservative estimate of RT_{NDT}, compliant with the intent of Appendix G criteria.

These toughness correlations vary, depending on the specific material analyzed, and are derived from the results of Bulletin 217, "Properties of Heavy Section Nuclear Reactor Steels," and from toughness data from the LGS Unit 1 and 2 vessels and other reactors. In the case of vessel plate material (SA533, Grade B, Class 1), the predicted limiting toughness property is either NDT or transverse CVN 50 ft-lb temperature minus 60°F. NDT values are available for all beltline and some other LGS 1 and 2 vessel plates. Where NDT results are missing, NDT is estimated as the longitudinal CVN 35 ft-lb transition temperature. The transverse CVN 50 ft-lb transition temperature is estimated from longitudinal CVN data in the following manner. The lowest longitudinal CVN ft-lb value is adjusted to derive a longitudinal CVN 50 ft-lb transition temperature by adding 2°F per ft-lb to the test temperature. If the actual data equals or exceeds 50 ft-lb, the test temperature is used. Once the longitudinal 50 ft-lb temperature is derived, an additional 30°F is added to account for orientation effects and to estimate the transverse CVN 50 ft-lb temperature minus 60°F, estimated in the preceding manner.

For forgings (SA508, Class 2), the predicted limiting property is the same as for vessel plates. CVN and drop-weight values are available for the vessel flange, closure head flange, and feedwater and LPCI nozzle materials for LGS Units 1 and 2. RT_{NDT} is estimated in the same way as for vessel plate.

For the vessel weld metal the predicted limiting property is the CVN 50 ft-lb transition temperature minus 60°F, as the NDT values are -50°F or lower for these materials. This temperature is derived in the same way as for the vessel plate material, except the 30°F addition for orientation effects is omitted since there is no principal working direction. When NDT values are available, they are also considered and the RT_{NDT} is taken as the higher of NDT or the 50 ft-lb temperature minus 60°F. When NDT is not available, the RT_{NDT} shall not be less than -50°F, since lower values are not supported by the correlation data.

For vessel weld heat-affected zone material the RT_{NDT} is assumed the same as for the base material, since ASME Code weld procedure qualification test requirements and postweld heat treatment indicates this assumption is valid.

Closure bolting material (SA540, Grade B24) toughness test requirements for LGS Units 1 and 2 are for 30 ft-lb at 60°F below the bolt-up temperature. Current Appendix G requirements are for 45 ft-lb

and 25 MLE at the preload or lowest service temperature, including bolt-up. All LGS Units 1 and 2 closure stud materials meet current requirements at +10°F.

Using this general approach, an initial RT_{NDT} of 20°F is established for the core beltline region for LGS Unit 1 and 40°F for LGS Unit 2.

The effect of the main closure flange discontinuity is considered by adding 60°F and 90°F to the RT_{NDT} to establish the minimum temperature for bolt-up and pressurization respectively. The minimum bolt-up temperature of 80°F for LGS Unit 1, which is shown in Figure 5.3-4 is based on an initial RT_{NDT} of +20°F for the shell plate which connects to the closure flange. The minimum bolt-up temperature of +70°F for LGS Unit 2, which is shown in Figure 5.3-5, is based on an initial RT_{NDT} of +10°F for the closure flange forgings. A flange region flaw size less than 0.24 inch critical flaw depth can be detected at the outside surface of the flange to shell and head junctions where stresses due to bolt-up are most limiting.

These values are consistent with the minimum temperature limits and minimum bolt-up temperature in the previous docketed P-T curves (Reference 5.3-18 and 5.3-19) (approved by the NRC in Reference 5.3-20 and 5.3-21). These values also bound the minimum temperature in the first set of P-T limits approved for initial operation (thereby addressing the NRC condition in Reference 5.3-17, Section 4.0).

The composite P-T curves are extended below 0 psig to -14.7 psig based on the evaluation in Reference 5.3-11 and 5.3-12, which demonstrates that the P-T curves are applicable to negative gauge pressures. A pressure of -14.7 psig bounds the maximum expected vacuum pressure as well as externally applied pressures the RPV may experience.

The reactor vessel closure studs have a minimum Charpy impact energy of 48 ft-lb and a 27 MLE at 10°F for LGS Unit 1. The studs for LGS Unit 2 have a minimum Charpy impact energy of 25 MLE and 46 ft-lb at 10°F. The lowest service temperature for bolt-up of LGS Unit 2 is 10°F. Charpy test results are discussed in Sections 5.3.1.7 and 5.3.1.8.

5.3.1.6 Material Surveillance

5.3.1.6.1 Compliance with "Reactor Vessel Material Surveillance Program Requirements"

The materials surveillance program monitors changes in the fracture toughness properties of ferritic materials in the reactor vessel beltline region resulting from their exposure to neutron irradiation and thermal environment.

Materials for the original surveillance program were selected to represent materials used in the reactor beltline region. The specimens were manufactured from a plate actually used in the beltline region, and a weld typical of those in the beltline region, and thus represent base metal, weld metal, and the transition zone between base metal and weld. The plate and weld were heat treated in a manner that simulates the actual heat treatment performed on the core region shell plates of the completed vessel.

The original surveillance program included three capsule holders per reactor vessel.

Information on the specimen arrangement is given in Table 5.3-12, referenced in Section 5.3.1.10.

A set of out-of-reactor baseline CVN specimens is provided with the surveillance test specimens.

Charpy impact specimens for the original reactor vessel surveillance programs are of the longitudinal orientation consistent with the ASME requirements prior to the issue of the 1972 Addenda and ASTM E185-73. Based on GE experience, the amount of shift measured by these irradiated longitudinal test specimens is essentially the same as the shift in an equivalent transverse specimen.

For LGS Units 1 and 2, each set of surveillance specimens is loaded in 6 small capsules rather than one large capsule. Therefore, each capsule holder which contains all 6 small capsules can be considered to be the same as one surveillance capsule as defined in 10CFR50, Appendix H. Three capsule holders are included in each reactor vessel. Since the predicted adjusted increase in reference temperature of the beltline region, estimated at the time of design, was less than 100°F at EOL and the calculated peak neutron fluence is less than $5x10^{18}$ n/cm^2, the use of three capsule holders meets the requirements of 10CFR50, Appendix H, and ASTM E185-73.

For the extent of compliance of the original surveillance program to 10CFR50, Appendix H, see Table 5.3-2.

In 2003, the NRC approved LGS participation in the BWR Vessel and Internals Project (BWRVIP) Integrated Surveillance Program (ISP) as described in BWRVIP-78 and BWRVIP-86 (Reference 5.3-13). The NRC approved the ISP for the industry in Reference 5.3-13 and approved LGS participation in Reference 5.3-14. The ISP meets the requirements of 10 CFR 50 Appendix H and provides several advantages over the original program. The surveillance materials in many plant-specific programs do not represent the best match with the limiting vessel beltline materials since some were established prior to 10 CFR 50 Appendix H requirements. Also, the ISP allows for better caparison to unirradiated material data to determine actual shifts in toughness. Finally, for many plants, ISP data will be available sooner to factor into plant operations since there are more sources of data.

The current withdrawal schedule for both units is based on the latest NRC-approved revision of BWRVIP-86 (Reference 5.3-13). Based on this schedule, LGS is not scheduled to withdrawal any additional material specimens. Per Reference 5.3-15, the schedule is not changed due to MUR power uprate.

The Unit 2 surveillance capsule and holder at Azimuth 120° was removed from the vessel during the 2M54 maintenance outage due to the failure of the holder. This surveillance capsule and holder was not reinstalled in the vessel. A letter was sent to the NRC (LG-17- 172) for notification in accordance with the Integrated Surveillance Program (ISP).

5.3.1.6.2 Neutron Flux and Fluence Calculations

A description of the methods of analysis is contained in Sections 4.1.4.5 and 4.3.2.8.

5.3.1.6.3 Predicted Irradiation Effects on Vessel Beltline Materials

Estimated maximum changes in RT_{NDT} (initial reference temperature) and upper shelf fracture energy as a function of the EOL fluence at the ¼ depth of the vessel beltline materials are provided in Section 5.3.1.7. The predicted peak EOL maximum neutron irradiation fluences for the 110% power rerate condition at the ¼ of the vessel beltline are $1.3x10^{18}$ n/cm^2 after 32 EFPY (where an EFPY is based on the rerated power level). For conservative flux calculations, 251 inches is used as the inside diameter of the beltline region with a wall thickness of 6-3/16 inches. Transition temperature changes and variations in upper-shelf energy were calculated in accordance with the rules of Regulatory Guide 1.99 (Rev 2). Reference temperatures were established in accordance with 10CFR50, Appendix G and NB-2330 of the ASME Code. Per Reference 5.3-15, the rerate fluence bounds the requirements for operation at the MUR power uprate.

As part of the license renewal, the adjusted reference temperature (ART) and upper shelf energy (USE) values are calculated for fluence values corresponding to 57 effective full power years (EFPY), representative of the end of extended operation (60 years). The ART values and predicted EOL USE reductions calculated in accordance with RG 1.99 (Rev. 2) for all LGS Unit 1 and 2 RPV beltline materials exposed to fluence greater than $1x10^{17}$ n/cm^2 for 57 EFPY. The re-evaluation demonstrates that the EOL USE values for all LGS Units 1 and 2 beltline materials are expected to satisfy the requirements of 10 CFR 50, Appendix G, through 57 EFPY.

5.3.1.6.4 Positioning of Surveillance Capsules and Method of Attachment

Surveillance specimen capsules are located at three azimuths at a common elevation in the core beltline region. The sealed capsules are not attached to the vessel but are in welded capsule holders. The capsule holders are mechanically retained by capsule holder brackets welded to the vessel cladding as shown in Figure 5.3-3. The capsule holder brackets allow the capsule holder to be removed at any desired time in the life of the plant for specimen testing. These brackets are designed, fabricated, and analyzed to the requirements of ASME Section III. A positive spring-loaded locking device is provided to retain the capsules in position throughout any anticipated event during the lifetime of the vessel.

The Unit 2 surveillance capsule and holder at Azimuth 120° was removed from the vessel during the 2M54 maintenance outage due to the failure of the holder. This surveillance capsule and holder was not reinstalled in the vessel. A letter was sent to the NRC (LG-17- 172) for notification in accordance with the Integrated Surveillance Program (ISP).

5.3.1.6.5 Dosimetry Measurements

Each surveillance capsule contains iron and copper flux wires. These wires can be used to determine the relationship between reactor power and neutron fluence.

5.3.1.7 Vessel Beltline Plates and Welds

This section supplements Section 5.3.1.5 in discussing the compliance to the intent of 10CFR50, Appendix G.

5.3.1.7.1 Test Data

Available Charpy V-notch and drop-weight impact test data are presented in Tables 5.3-3 and 5.3-4. The sample test welds are prepared in accordance with the ASME Code and do not include base material from the beltline. There are two categories of belt-line welds identified "shop" welds and "field" welds. The shop welds represent vessel vertical seams which were made prior to shipment of preassembled ring segments to the LGS Unit 1 and Unit 2 plant site. The flux material for the submerged arc weld is LINDE 124. The field welds (i.e., girth welds) were made at the plant site. However, exact identification of weld materials used in the beltline girth weld seam is not available. Therefore, a conservative assumption is made to consider all electrodes which were released for field welding the vessel shells.

Figure 5.3-7 shows the vessel beltline layouts. They give plate heat numbers and locations, as well as weld seam locations and identifications.

5.3.1.7.2 Effects of Irradiation

Copper, nickel, and phosphorus values used to estimate the effects of irradiation on toughness are presented in Table 5.3-5.

Estimated starting (i.e., unirradiated) RT_{NDT} values for the beltline plate and weld materials are presented in Table 5.3-5. These values were calculated using the data in Tables 5.3-3 and 5.3-4 in accordance with ASME Section III, NB2300.

Estimated EOL RT_{NDT} values including the influence of power rerate and MUR power uprate for (for ¼ thickness location from the vessel ID) are also given in Table 5.3-5. The EOL RT_{NDT} values are estimated in accordance with Regulatory Guide 1.99 (Rev 2).

As part of the license renewal, RT_{NDT} corresponding to 57 effective full power years (EFPY) are also given in Table 5.3-5. The EOL values have been estimated in accordance with RG 1.99 (Rev. 2) and meet the requirements of 10 CFR 50, Appendix G, through 57 EFPY.

5.3.1.7.3 Upper-Shelf Toughness Testing

Charpy V-notch upper-shelf toughness testing was not required when the LGS vessels were manufactured. 10CFR50, Appendix G requires a minimum of 75 ft-lb transverse upper-shelf CVN energy for beltline material. BTP MTEB 5-2 indicates that 70 ft-lb is adequate for fluence levels less than $1x10^{19}$ n/cm^2.

All of the LGS Units 1 and 2 beltline plates were CVN impact- tested as longitudinal specimens at only one temperature, +40°F. For Unit 1, the lowest CVN value obtained for beltline plate was 45 ft-lb with 50% shear, and the highest was 104 ft-lb with 70% shear. For Unit 2, the lowest value obtained for beltline plate was 35 ft-lb with 30% shear, and the highest was 97 ft-lb with 50% shear. The 50% and 30% shear values suggest there is a considerable margin remaining before the upper-shelf (i.e., 100% shear) level is reached.

Table 5.3-6 summarizes the test certificates for representative LGS Units 1 and 2 beltline plate. Similar data are also documented for all other plates. Supporting data from representative plate materials in other BWR plants are provided in Table 5.3-7. Compatibility of the supporting data from other BWRs, Plants A through E, with respect to LGS is based on criteria such as similarity in material, fabrication, vendor source, welding procedure, etc. All listed plate materials were produced by Luken's Steel Co. These data show that plates with as low as 36 ft-lb (Plant E, Heat No. C9570-1) of absorbed energy with 30% shear at +40°F can have longitudinal upper-shelf energies in excess of 100 ft-lb.

BTP MTEB 5-2 states that longitudinal values should be reduced to 65% of the test value to estimate transverse upper-shelf. To account for the power rerate end-of-life fluence of $1.3x10^{18}$, a further shift in upper-shelf toughness can be made using Regulatory Guide 1.99, resulting in a maximum reduction of approximately 12.5% for the highest Cu content of 0.12 wt% for Unit 1 and 15% for the highest Cu content of 0.15 wt% for Unit 2 as shown in Table 5.3-5. Using these conservative assumptions with a goal of achieving at least 50 ft-lb transverse toughness at EOL, the following equations are derived:

Unit 1: $50 = .65(L) - (.125)[.65(L)]$

Unit 2: $50 = .65(L) - (.15)[.65(L)]$

(where L is unirradiated longitudinal upper-shelf value.)

These equations predict a minimum required unirradiated longitudinal upper-shelf toughness requirement of 88 ft-lb for Unit 1 and 91 ft-lb for Unit 2. Table 5.3-7 indicates that toughness in excess of 91 ft-lb is to be expected for longitudinal upper- shelf of this material.

Although upper-shelf testing was not required for the beltline welds, Table 5.3-4 shows that the majority of the weld materials, both field and shop, meet the 75 ft-lb minimum upper-shelf requirement.

Weld materials that do not meet the 75 ft-lb minimum upper-shelf requirement were impact-tested exclusively at +10°F. The upper-shelf level (i.e., the absorbed energy corresponding with 100% shear) is not expected at this temperature. For Unit 1, Heat No. 07L857, Lot No. B101A27A evidenced the lowest toughness properties exhibiting a minimum of 28 ft-lbs and 20% shear at +10°F T_{CV}. For Unit 2, Heat No. 432A2671, Lot No. H019A27A evidenced the lowest toughness properties exhibiting a minimum of 31 ft-lbs and 30% shear at +10°F T_{CV}. Again, the 20% and 30% shear values indicate that there is considerable margin for improved properties at higher test temperatures.

For these welds where the minimum upper-shelf energy was not established, the Cu content does not exceed 0.05 wt.%. Based on power rerate EOL fluence of 1.3×10^{18} n/cm^2, Regulatory Guide 1.99 predicts a maximum decrease in upper-shelf energy of approximately 12% for weld material containing .05% Cu. With a goal of achieving at least 50 ft-lbs upper-shelf at EOL, the following equation is derived:

$$50 = (U.V.) - .12 (U.V.)$$

where:

U.V. = the unirradiated upper-shelf value for weld metal.

This equation predicts a minimum required unirradiated upper-shelf level of only 57 ft-lbs.

Further upper-shelf toughness data for representative welds, made by the same vendor as LGS Units 1 and 2, are given in Table 5.3-8. Tables 5.3-9 and 5.3-10 present the weld procedures typical for the data base in Table 5.3-8. These tables represent surveillance program weld procedures and some corresponding baseline data, along with other vessel material data which are considered representative of LGS Units 1 and 2 beltline welds. These data are in excess of 75 ft-lbs at the upper-shelf.

5.3.1.7.4 Upper Shelf Energy Equivalent Margin Analysis

10CFR50 Appendix G requires that 50 ft-lb upper shelf energy be maintained in the vessel beltline low alloy steel material throughout operation. It further requires, if 50 ft-lb USE cannot be demonstrated, that methods to show equivalent margin be provided. Since initial USE data is not available to demonstrate 50 ft-lb USE per NCR methods, an equivalent margin analysis was performed (Reference 5.3-6). This analysis has been approved by the NRC and confirms that, even in the absence of initial USE data, adequate margin of safety against fracture equivalent to 10CFR50 Appendix G requirements does exist. For the MUR power uprate, all materials that did not demonstrate 50 ft-lb USE were qualified in Reference 5.3-15 by the equivalent margin analysis methodology of Reference 5.3-6.

However, the equivalent margin analysis methodology defined in Reference 5.3-6 does not specifically identify that forging materials were included in the statistical calculations. Therefore, the LPCI nozzle forgings and the water level instrumentation (WLI) nozzles were assessed in a plant

specific evaluation (Reference 5.3-16). The evaluation concluded that the LPCI nozzle forgings in the RPV meet the margin of safety against fracture equivalent to those required by Appendix G of Section XI of the ASME code. The WLI nozzles were not evaluated further because the forging material is less than 2.5 inches thick. The evaluation for the WLI nozzle in Reference 5.3-15, based on the plate material in the shell where the nozzles are located, is appropriate.

5.3.1.8 Nonbeltline Region and Ferritic Piping and Valves

This section supplements Section 5.3.1.5 in discussing the compliance to the intent of 10CFR50, Appendix G.

Table 5.3-11 lists the estimated reference temperature (RT_{NDT}) for various components in the LGS Units 1 and 2 vessel nonbeltline region. These values were derived in accordance with the intent of ASME Section III, Paragraph NB-2300.

5.3.1.9 Assessment to Appendix G, 1983 Revision

This section addresses the latest requirements of Appendix G, 1983 Revision.

a. The 1983 revision of Appendix G has redefined the adjusted reference temperature by stating "change from the 50 ft-lb level to the 30 ft-lb level of Charpy energy at which the transition temperature shift is to be measured as an indicator of radiation damage." This change does not impact the current reference temperature RT_{NDT} shift information provided in Table 5.3-5. Those shift values were estimated in accordance with Regulatory Guide 1.99 (Rev 2). The data base to establish the procedures for shift prediction in this regulatory guide was given in terms of the 30 ft-lb level; therefore, the predicted reference temperature shifts meet the latest Appendix G requirement.

b. The 1983 revision of Appendix G requires that reactor vessel beltline materials "must maintain upper-shelf energy throughout the life of the vessel of no less than 50 ft-lbs." Section 5.3.1.7.4 describes the equivalent margin analysis which was performed to demonstrate compliance with this requirement.

c. The 1983 revision of Appendix G changes the definition of the "adjacent regions" by stating "beltline region of reactor vessel means the region of the reactor vessel (shell material including welds, heat-affected zones, and plates or forgings) that directly surrounds the effective height of the active core and adjacent regions of the reactor vessel that are predicted to experience sufficient neutron radiation damage to be considered in the selection of the most limiting material with regard to radiation damage." The active fuel region for the LGS vessels is contained by shell courses 1 and 2. The design elevation of the fuel assemblies indicates there remains approximately 36 inches of vessel steel above, and 90 inches of vessel steel below, the fuel elevation before reaching any additional girth welds/shell courses. Therefore, the "adjacent regions" of vessel shell are considered to represent material from shell courses 1 and 2 as well. For this reason, no additional considerations of beltline plates or welds are warranted. Moreover, the effect of radiation on the low pressure coolant injection nozzles and their related welds has been included in the current Appendix G analysis. No other components are near enough to the fuel to be significantly affected by radiation.

5.3.1.10 RPV Surveillance Program

This section supplements Section 5.3.1.6 in discussing the compliance to the intent of 10CFR50, Appendix H.

5.3.1.10.1 LGS Unit 1 Surveillance Program

The base-plate and weld materials used to fabricate the surveillance test plate are identified in Table 5.3-5. The base metal from a core beltline plate Heat No. C7689-1 was used for surveillance test material. With respect to initial RT_{NDT} and percent of copper by weight, this material is considered equivalent to other beltline plates and its utilization for test plate fabrication is in compliance with current recommendations for selection of surveillance materials. The test plate weld, like the core beltline vertical weld seams, was made using both SMAW and SAW welding processes. The test plate weld procedure is presented in Table 5.3-10. For each of the two welding processes, only one heat of weld material was used. The SAW material Heat/Flux No. 1P4218/3929-989, which was also used for beltline seams BE, BA, and BB (Figure 5.3-7), is considered suitable for surveillance monitoring because it represents the most limiting SAW material in terms of shift and predicted EOL RT_{NDT}. The SMAW material Heat/Lot No. 421A6811/F022A27A which was used for surveillance material was not used for production beltline welds; however, the weight percentages of copper and nickel which it contains (0.09% Cu and 0.81% Ni) are generally greater than those for actual belt-line material. Moreover, the unirradiated RT_{NDT} of this material is equivalent to the initial RT_{NDT} of the beltline weld materials. The Chicago Bridge and Iron weld procedure for test plate fabrication involves utilizing stick electrode to fuse backup bars and completing the major volume of the weld with SAW. This includes back-gouging of the backup bar to complete the back side of the weld. Therefore, the test plate weld metal is essentially SAW welded material. Table 5.3-5 indicates that all beltline materials, both plate and weld, are highly resistant to irradiated degradation of notch toughness.

5.3.1.10.2 LGS Unit 2 Surveillance Program

The base-plate and weld materials used to fabricate the surveillance test plate are identified in Table 5.3-5. The base metal used was plate from Heat No. C9569-2; this material was also used for one of the core beltline plates, and its use in RPV surveillance is consistent with the requirements at the time of vessel fabrication.

The test plate weld, like the core beltline vertical weld seams, was made using SMAW and SAW welding processes. The test plate weld procedure is presented in Table 5.3-10. The SAW material Heat No. 3P4000, Lot No. 3933 (both single and tandem wire) was also used for fabrication of beltline seams BA, BB, BC, BD, BE, and BF, and is considered suitable for surveillance monitoring.

Two heats of SMAW material were used for test plate fabrication. One weld material, Heat/Lot No. CTY538/A027A27A, was not used for production beltline welds; however, the weight percentages of Cu and Ni (0.03% Cu and 0.83% Ni) are equivalent to the concentrations of these elements for actual beltline material. The other SMAW material, Heat/Lot No. 03R728/L910A27A, was used in production beltline seam fabrication and is considered suitable for surveillance monitoring.

Table 5.3-5 indicates that all beltline materials, both plate and weld, are acceptably resistant to irradiation degradation of notch toughness.

For Units 1 and 2, Table 5.3-12 lists the actual number of specimens and their orientations in each surveillance capsule (including tensile specimens). The number and orientation of the Charpy impact specimens are consistent with the ASME requirements prior to the issuance of the Summer 1972 Addenda and ASTM 185-73.

Prior surveillance experience indicates the amount of radiation-induced shift in properties measured by longitudinally oriented specimens is applicable to equivalent transverse oriented specimens (Reference 5.3-2). Therefore, the shift when determined can be used for the transverse RT_{NDT} values for the beltline materials. Referring to Table 5.3-12, the longitudinal orientation of the base metal heat-affected zone specimens are such that they simulate beltline vertical seams in this manner.

5.3.1.11 Reactor Vessel Fasteners

The reactor vessel closure head (flange) is fastened to the reactor vessel shell flange by multiple sets of threaded studs and nuts. The lower end of each stud is installed in a threaded hole in its vessel shell flange. A nut and washer are installed on the upper end of each stud. The proper amount of preload can be applied to the studs by a sequential tensioning using hydraulic tensioners. The design and analysis of this area of the vessel is in full compliance with all ASME Section III, Class I, code requirements. The material for studs, nuts, and washers is SA540, Grade B23 or Grade B24. The maximum reported ultimate tensile stresses for the bolting material are 164,000 psi for Unit 1 and 169,000 psi for Unit 2 which are less than the 170,000 psi limitation in Regulatory Guide 1.65. Also, the Charpy impact test recommendations of paragraph IV.A.4 of 10CFR50, Appendix G were not specified in the vessel order since the order was placed prior to issuance of 10CFR50, Appendix G. However, impact data from the certified materials report shows that all bolting materials meet the Appendix G impact properties.

A phosphate coating is applied to threaded areas of studs and nuts and bearing areas of nuts and washers to act as a rust inhibitor and to assist in retaining lubricant on these surfaces.

5.3.2 PRESSURE -TEMPERATURE LIMITS

5.3.2.1 Limit Curves

The basis for setting operational limits on pressure and temperature for normal, upset, and test conditions for the RPV is described in Section 5.3.1.5.

5.3.2.1.1 Temperature Limits for Bolt-Up

A minimum temperature of 20°F is required on LGS Unit 1 and 10°F on LGS Unit 2 for the closure studs. A sufficient number of studs can be tensioned at a temperature between 20°F and 80°F for Unit 1 and 10°F and 70°F for Unit 2 to seal the closure flange O-rings for the purpose of raising reactor water level above the closure flanges in order to assist in warming them. The flanges and adjacent shell are required to be warmed to minimum temperatures of 80°F (Unit 1) and 70°F (Unit 2) before they are stressed by the full intended bolt preload (all bolts tensioned). The fully preloaded bolt-up limits are shown on Figures 5.3-4 and 5.3-5.

5.3.2.1.2 Temperature Limit for Preoperational Tests and Inservice Inspection

Based on the NRC general revision to 10CFR50, Appendix G, Document No. [7590-1], paragraph IV.A.4, the preoperational system hydrostatic test at 1563 psig prior to fuel loading was performed at a minimum temperature of 100°F for Unit 1 without fuel in the reactor, and 100°F for Unit 2. These limits were established by the 40°F maximum RT_{NDT} of the reactor vessel materials.

The fracture toughness analysis for system pressure tests with fuel in the reactor yields the curves labeled A shown in Figures 5.3-4 and 5.3-5. The curves labeled "core beltline" are based on an initial RT_{NDT} of 20°F for Unit 1 and 40°F for Unit 2. The predicted shift in the RT_{NDT} based on the power rerate neutron fluence at ¼ of the vessel wall thickness, has been added to the belt-line curve to account for the effect of fast neutrons. (References 5.3-11 and 5.3-12)

5.3.2.1.3 Operating Limits During Heatup, Cooldown, and Core Operation

The fracture toughness analysis is done for the normal heatup or cooldown rate of 100°F/hour. The temperature gradients and thermal-stress effects corresponding to this rate are included. The results of the analyses are a set of operating limits for non-nuclear heatup or cooldown shown as curves labeled B in Figures 5.3-4 and 5.3-5. Curves labeled C in these figures apply whenever the core is critical. The predicted shift in the RT_{NDT}, based on the power rerate neutron fluence at ¼ of the vessel wall thickness, has been added to the belt-line curve to account for the effect of fast neutrons. As part of the plant's extension to 60 years, a pressure temperature curve has been re-evaluated to extend the plant life to 57 EFPY of reactor operation (References 5.3-11 and 5.3-12).

5.3.2.1.4 Reactor Vessel Annealing

Inplace annealing of the reactor vessel because of radiation embrittlement is not anticipated to be necessary because the predicted value of adjusted reference temperature does not exceed 200°F (10CFR50, Appendix G), even for the power rerate condition or the MUR power condition.

5.3.2.2 Operating Procedures

By comparison of the pressure versus temperature limits in Section 5.3.2.1 with intended normal operating procedures for the most severe upset transient, it is shown that the limits are not exceeded during any foreseeable upset condition. Reactor operating procedures are established so that actual transients are not more severe than those for which the vessel design adequacy has been demonstrated. Of the design transients, the upset condition producing the most adverse temperature and pressure condition anywhere in the vessel head and/or shell areas yields a minimum fluid temperature of 250°F and a maximum power rerate pressure peak of 1233 psig. Scram automatically occurs with initiation of this event, prior to the reduction in fluid temperature, so the applicable operating limits are given by curve B in Figures 5.3-4 and 5.3-5. For a temperature of 250°F, the maximum allowable pressure exceeds 1233 psig for the intended margin against nonductile failure. The maximum transient pressure is therefore within the specified allowable limits.

5.3.3 REACTOR VESSEL INTEGRITY

The reactor vessels are fabricated for GE's Nuclear Energy Division by Chicago Bridge and Iron Company; and are subject to the requirements of GE's Quality Assurance program.

Measures are established to ensure that purchased material, equipment, and services associated with the reactor vessels and appurtenances conform to the requirements of the purchase documents. These measures include provisions, as appropriate, for source evaluation and selection, objective evidence of quality furnished, inspection at the vendor source, and examination of the completed reactor vessels.

GE provides inspection surveillance of the reactor vessel fabricator's in-process manufacturing, fabrication, and testing operations in accordance with GE's Quality Assurance program and approved inspection procedures. The reactor vessel fabricator is responsible for the first level inspection of his manufacturing, fabrication, and testing activities and GE is responsible for the first level of audit and surveillance inspection.

Adequate documentary evidence that the reactor vessel material, manufacture, testing, and inspection conform to the specified quality assurance requirements contained in the procurement specification is available at the fabricator's plant site.

5.3.3.1 Design

5.3.3.1.1 Description

5.3.3.1.1.1 Reactor Vessel

The reactor vessel shown in Figure 5.3-1 is a vertical, cylindrical pressure vessel of welded construction. The vessels for LGS are designed, fabricated, tested, inspected, and stamped in accordance with the ASME Section III, Class A including the Summer Addenda 1969. Design of the reactor vessel and its support system meets seismic Category I requirements.

The materials used in the RPV are shown in Table 5.2-3.

The cylindrical shell and bottom head sections of the reactor vessel are fabricated of low alloy steel, the interior of which is clad with stainless steel weld overlay. Nozzle and nozzle weld zones are unclad except for those mating to stainless steel piping systems.

Inplace annealing of the reactor vessel is unnecessary because shifts in transition temperature caused by irradiation during the 40 year life can be accommodated by raising the minimum pressurization temperature. Radiation embrittlement is not a problem outside of the vessel beltline region because the irradiation in those areas is less than $1x10^{18}$ nvt with neutron energies in excess of 1 MeV.

Quality control methods used during the fabrication and assembly of the reactor vessel and appurtenances ensure that design specifications are met.

The vessel top head is secured to the reactor vessel by studs and nuts. These nuts are tightened with a stud tensioner. The vessel flanges are sealed with two concentric metal seal-rings designed to permit no detectable leakage through the inner or outer seal at any operating condition, including heating to operating pressure and temperature at a maximum rate of 100°F/hr in any one hour period. To detect seal failure, a vent tap is located between the two seal-rings. A monitor line is attached to the tap to provide an indication of leakage from the inner seal-ring seal.

5.3.3.1.1.2 Shroud Support

The shroud support is a circular plate welded to the vessel wall. This support is designed to carry the weight of the shroud, shroud head, peripheral fuel elements, neutron sources, core plate, top guide, the steam separators, the jet pump diffusers, and to laterally support the fuel assemblies. Design of the shroud support also accounts for pressure differentials across the shroud

support plate, for the restraining effect of components attached to the support, and for earthquake loadings. The shroud support design is specified to meet appropriate ASME code stress limits.

5.3.3.1.1.3 Protection of Closure Studs

The BWR does not use borated water for reactivity control. This section is therefore not applicable.

5.3.3.1.2 Safety Design Basis

The design of the reactor vessel and appurtenances meets the following safety design bases:

a. The reactor vessel and appurtenance will withstand adverse combinations of loading and forces resulting from operation under abnormal and accident conditions

b. To minimize the possibility of brittle fracture of the nuclear system process barrier, the following are required:

1. Impact properties at temperatures related to vessel operation are specified for materials used in the reactor vessel

2. Expected shifts in transition temperature during design life as a result of environmental conditions, such as neutron flux, are considered in the design. Operational limitations ensure that RT_{NDT} temperature shifts are accounted for in reactor operation.

3. Operational margins to be observed with regard to the transition temperature are specified for each mode of operation.

5.3.3.1.3 Power Generation Design Basis

The design of the reactor vessel and appurtenances meets the following power generation design bases:

a. The reactor vessel has been designed for a useful life of 40 years.

b. External and internal supports that are integral parts of the reactor vessel are located and designed so that stresses in the vessel and supports that result from reactions at these supports are within ASME Code limits.

c. Design of the reactor vessel and appurtenances allows for a suitable program of inspection and surveillance.

5.3.3.1.4 Reactor Vessel Design Data

The reactor vessel design pressure is 1250 psig and the design temperature is 575°F. The maximum installed test pressure is 1656 psig (1563 psig plus the ASME Code tolerance of 6%).

5.3.3.1.4.1 Vessel Support

The reactor vessel support assembly consists of a ring girder and the various bolts and shims necessary to position and secure the assembly between the reactor vessel support skirt and the support pedestal. The concrete and steel support pedestal is constructed as an integral part of the structure-foundation. Steel anchor bolts are set in the concrete with their threads extending above the surface. The anchor bolts extend through the ring girder bottom flange. High strength bolts are used to secure the flange of the reactor vessel support skirt to the top flange of the ring girder. The ring girder is fabricated of ASTM A-36 structural steel according to AISC specifications.

5.3.3.1.4.2 Control Rod Drive Housings

The CRD housings are inserted through the CRD penetrations in the reactor vessel bottom head and are welded to the reactor vessel. Each housing transmits loads to the bottom head of the reactor. These loads include the weights of a control rod, a CRD, a control rod guide tube, a four-lobed fuel

support piece, and the four fuel assemblies that rest on the fuel support piece. The housings are fabricated of Type 304 austenitic stainless steel.

5.3.3.1.4.3 Incore Neutron Flux Monitor Housings

Each incore neutron flux monitor housing is inserted through the incore penetrations in the bottom head and is welded to the inner surface of the bottom head.

An incore flux monitor guide tube is welded to the top of each housing and either a SRM/IRM drive unit or a LPRM is bolted to the seal/ring flange at the bottom of the housing (Sections 7.6 and 7.7).

5.3.3.1.4.4 Reactor Vessel Insulation

The reactor vessel top head insulation is designed to permit complete submersion in water during shutdown without loss of insulating material, contamination of the water, or adverse effect on the insulation efficiency after draining. Most of the reactor vessel insulation is of the stainless steel, reflective type. The insulation used for many of the large reactor vessel nozzles is fiberglass-type, in blanket form. The top head insulation framework is designed to seismic Category I requirements and is used as an anchor point for reactor vessel vent piping.

The insulation above the reactor vessel stabilizer brackets is close-fitting, freestanding insulation designed to be 100% removable for inservice inspection of the reactor vessel.

The insulation below the stabilizer brackets is suspended from the brackets to allow a minimum of 8 inches annular clearance between the reactor vessel and the insulation for remote inservice inspection of the reactor vessel. Some of the suspended insulation is removable to permit access for manual inspection in locations where remote inspection may not be feasible. The suspended insulation is also equipped with removable access ports.

Reactor vessel bottom head insulation includes horizontal flat panels connected to a cylindrical shell covering the inside of the reactor support skirt. The top row of the cylindrical shell panels are removable to expose the bottom head for inservice inspection.

Quick removable insulation is provided around all reactor vessel nozzles to allow manual or remote automatic examination of nozzle-to-vessel and nozzle-to-piping welds.

5.3.3.1.4.5 Reactor Vessel Nozzles

All piping connected to the reactor vessel nozzles is designed to not exceed the allowable loads on any nozzle.

The vessel top head nozzles are provided with a flange with small groove facings. The drain nozzle is of the full penetration weld design. The recirculation inlet nozzles (located as shown in Figure 5.3-1), feedwater inlet nozzles, the RHR LPCI inlet nozzles, and the core spray inlet nozzles all have thermal sleeves.

With the exception of the Unit 2 N16D nozzle (ASME Section III, SB-167), nozzles connecting to stainless steel piping have safe ends made of stainless steel or Inconel (ASME Section III, SB-166). These safe ends are welded to the nozzles after the pressure vessel has been heat treated to avoid furnace sensitization of the stainless steel safe ends. The material used is compatible with the material of the mating pipe.

5.3.3.1.4.6 Materials and Inspections

The reactor vessel is designed and fabricated in accordance with the appropriate ASME Code as defined in Section 5.2.1. Table 5.2-3 defines the materials and specifications. Section 5.3.1.6 defines the compliance with reactor vessel material surveillance program requirements.

5.3.3.1.4.7 Reactor Vessel Schematic (BWR)

The reactor vessel schematic is contained in Figure 5.3-1. Trip system water levels are indicated as shown in Figure 5.3-2.

5.3.3.2 Materials of Construction

All materials used in the construction of the RPV conform to the requirements of ASME Section II materials. The vessel heads, shells, flanges, and nozzles are fabricated from low alloy steel plate and forgings purchased in accordance with ASME SA533, Grade B, Class 1 and ASME SA508, Class 2. Special requirements for the low alloy steel plate and forgings are discussed in Section 5.3.1.2. Cladding employed on the interior surfaces of the vessel consists of austenitic stainless steel weld overlay.

These materials are selected because they provide adequate strength, fracture toughness, fabricability, and compatibility with the BWR environment. Their suitability is demonstrated by long-term successful operating experience in reactor service.

5.3.3.3 Fabrication Methods

The RPV is a vertical, cylindrical pressure vessel of welded construction fabricated in accordance with ASME Section III, Class I requirements. All fabrication of the RPV is performed in accordance with GE approved drawings, fabrication procedures, and test procedures. The shell and vessel head are made from formed low alloy steel plates, and the flanges and nozzles from low alloy steel forgings. Welding performed to join these vessel components is in accordance with procedures qualified in ASME Sections III and IX requirements. Weld test samples are required for each procedure for major vessel full penetration welds.

Submerged arc and manual stick electrode welding processes are employed. Electroslag welding is not permitted. Preheat and interpass temperatures employed for welding of low alloy steel meet or exceed the requirements of ASME Section III, subsection NA. Postweld heat treatment of 1100°F minimum is applied to all low alloy steel welds.

All previous BWR pressure vessels employed similar fabrication methods. These vessels have operated for periods of up to 16 years and their service history is excellent.

The vessel fabricator, Chicago Bridge and Iron Co., has had extensive experience with GE reactor vessels dating back to 1966. Chicago Bridge and Iron Nuclear Co. was formed in 1972 from a merger agreement between Chicago Bridge and Iron Co. and GE and has continued as the primary supplier for GE domestic reactor vessels.

5.3.3.4 Inspection Requirements

All plate, forgings, and bolting were 100% ultrasonically tested and surface examined by magnetic particle methods or liquid penetrant methods in accordance with ASME Section III requirements. Welds on the reactor pressure vessel were examined in accordance with methods prescribed and

meet the acceptance requirements specified by ASME Section III. In addition, the pressure-retaining welds were ultrasonically examined in accordance with ASME Section XI requirements prior to shipping.

5.3.3.5 Shipment and Installation

The LGS reactor vessels were assembled at the site. Methods and procedures are discussed in the PSAR, Appendix G. Suitable measures were taken during installation to ensure that vessel integrity was maintained; for example, access controls were applied to personnel entering the vessel, weather protection was provided, and periodic cleanings were performed.

5.3.3.6 Operating Conditions

Procedural controls on plant operation are implemented to hold thermal-stresses within acceptable ranges. These restrictions on coolant temperature are:

a. The average rate of change of reactor coolant temperature during normal heatup and cooldown shall not exceed 100°F during any 1 hour period.

b. If the coolant temperature difference between the dome (inferred from PSAT) and the bottom head drain exceeds 145°F, the reactor recirculation pumps shall not be started, and neither reactor power nor recirculation pump flow shall be increased.

c. The pump in an idle reactor recirculation loop shall not be started unless the coolant temperature in that loop is within 50°F of average reactor coolant temperature.

The limit regarding the normal rate of heatup and cooldown (item a) ensures that the vessel closure, closure studs, vessel support skirt, and CRD housing and stub tube stresses and usage remain within acceptable limits. The limit regarding a vessel temperature limit on recirculation pump operation and power level increase restriction (item b) augments the item a. limit in further detail by ensuring that the vessel bottom head region is not warmed at an excessive rate caused by rapid sweep out of cold coolant in the vessel lower head region by recirculation pump operation or natural circulation (cold coolant can accumulate as a result of control drive inleakage and/or low recirculation flow rate during startup or hot standby). The item c. limit further restricts operation of the recirculation pumps to avoid high thermal-stress effects in the pumps and piping, while also minimizing thermal-stresses on the vessel nozzles.

The above operational limits are maintained to ensure that the stress limits within the reactor vessel and its components are within the thermal limits to which the vessel is designed for normal operating conditions. To maintain the integrity of the vessel if these operational limits are exceeded, the reactor vessel is also designed to withstand a limited number of transients caused by operator error. Also, for abnormal operating conditions where safety systems or controls provide an automatic temperature and pressure response in the reactor vessel, the reactor vessel integrity is maintained since the severest anticipated transients are included in the design conditions. Therefore, it is concluded that vessel integrity is maintained during the most severe postulated transients, since all such transients are evaluated in the design of the reactor vessel.

5.3.3.7 Inservice Surveillance

The vessel is examined once prior to startup to satisfy the preoperational requirements of ASME Section XI. Subsequent ISI is scheduled and performed in accordance with the requirements of 10CFR50.55a .

The materials surveillance program monitors changes in the fracture toughness properties of ferritic materials in the reactor vessel beltline region resulting from their exposure to neutron irradiation and the thermal environment. Specimens of actual reactor beltline material are exposed in the reactor vessel and periodically withdrawn for impact testing. Operating procedures are modified in accordance with test results to ensure adequate brittle fracture control.

Material surveillance programs and ISI programs are in accordance with applicable ASME code requirements, and provide assurance that brittle fracture control and pressure vessel integrity are maintained throughout the service life of the RPV.

Inservice inspection and testing of the RCPB is discussed in detail in Section 5.2.4.

APPENDIX G MATRIX FOR LGS
(Unit 1)

APPENDIX G PARA. NO.	TOPIC	COMPLY YES/NO OR N/A	ALTERNATE ACTIONS OR COMMENTS
I, II	Introduction; definitions	-	-
III.A	Compliance With ASME Section III NB-2300	Yes	See Section 5.3.1.5.1.2 for discussion
III.B.1	Location and orientation of impact test specimens	Yes	See III A above
III.B.2	Materials used to prepare test specimens	No	Compliance except for CVN orientation and CVN upper shelf
IIII.B.3	Calibration of temperature, instrumentation, and Charpy test machines	No	Paragraph NB-2360 of the ASME Section III was not in existence at the time of purchase of the Unit 1 RPV. However the requirements of the 1971 edition of ASME Section III, Summer 1971 addenda are met. For the discussions of the GE interpretations of compliance and NRC acceptance, see References 5.3-3 and 5.3-4. The temperature instruments and Charpy test machines calibration data are retained until the next calibration. This is accordance with Regulatory Guide 1.88 (Section 1.8) and ANSI N45.2.9 (1974). Therefore, the instrument calibration data for Unit 1 are not currently available.
III.B.4	Qualification of testing personnel	No	No written procedures were in existence as now required by the regulation; however individuals were qualified by on-the-job training and past experience. For a discussion of the GE interpretation of compliance and NRC acceptance see References 5.3-3 and 5.3-4.
III.B.5	Test results recording and certification	Yes	See References 5.3-3 and 5.3-4.
III.C.1	Test condtions	No	See III.A, III.B.2, above
III.C.2	Materials used to prepare test specimens for reactor vessel beltline	Yes	Compliance on base metal and weld metal tests. Test welds were not necessarily made on the same heat as that of the base plate.

Table 5.3-4 (Cont'd)

---

(1) This table is complemented by Table 5.3-5.

Note 2: An initial Upper Shelf Energy (USE) of 73 ft-lb has been applied for the N-17 nozzle welds. The Safety Evaluation Report for the Measurement Uncertainty Recapture Power Uprate, Section 3.9.3, states that the NRC reviewed the CMTR CVN data for LGS Units 1 and 2, LPCI nozzle (N-17) weld materials and concluded that it would be conservative to assume an initial USE value of 73 ft-lb for the LGS Units 1 and 2 SMAW materials instead of the initial USE values resulting from testing performed at temperatures lower than 40 degrees F.

(1) Surveillance Program Material.

(2) Submerged arc welding.

(3) The most limiting value.

(4) Deleted.

(5) Single wire or tandem wire with submerged arc welding.

(6) The Unit 1 RPV design results in this component experiencing a predicted EOL fluence of 3.30×10^{17} n/cm^2 at ¼ of the thickness. This fluence, based on an assumed Cu content of 0.18% and a measured nickel content of 0.85%, yields an estimated EOL RT_{NDT} of +59.9°F. The EOL estimate is in accordance with Regulatory Guide 1.99 (Rev. 2).

(7) The Unit 2 RPV design results in this component experiencing a predicted EOL fluence of 3.19×10^{17} n/cm^2 at ¼ of the thickness. This fluence, based on an assumed Cu content of 0.18% and a measured nickel content of 0.82%, yields an estimated EOL RT_{NDT} of +60.2°F. The EOL estimate is in accordance with Regulatory Guide 1.99 (Rev. 2).

(8) The N16 nozzle is evaluated using the fluence and the limiting material properties (chemistry and initial RT_{NDT}) of the adjoining shell ring #2.

Elong:	18% in 2 in (min)
Impacts	30 ft-lb @ +40°F. Lateral Expansion and % Shear Fracture for information only.
Drop-Weights:	Type P-3 specimens with a NDT temperature no higher than +40°F.
Grain-Size:	Final Plate Grain-Size #5 or finer determined on a fully heat treated test coupon.

Table 5.3-6 (Cont'd)

LGS TYPICAL BELTLINE PLATE
(SURVEILLANCE PLATE)

(Unit 2)

Mill Order No: 51090-2

Requirements: SA533 Grade B
Class 1

Melt No: 0569

TEST RESULTS CHEMICAL
(Wt%)

Carbon	0.20
Manganese	1.26
Nickel	0.51
Silicon	0.23
Molybdenum	0.49
Phosphorous	0.009
Sulfur	0.018

MECHANICAL TEST RESULTS

Tensile Properties

UTS: 85,600 psi
88,500 psi

YLP: 65,100 psi
68,100 psi

% Elongation in 2 in: 26
24

Impact Properties

Specimen Type: Charpy V-Notch
Test Temp: +40°F
Energy (ft-lb): 68, 62, 68
83, 87, 66
Lateral Exp. (mil): 45, 50, 47
62, 50, 64

% Shear: 30, 30, 30
40, 40, 40

Drop-weight Test

TEST TEMP (°F)	TOP RESULTS	BOTTOM RESULTS
+10	No Break	No Break
0	No Break	No Break
-10	2	No Break -
-20	Break	2 No Break
-30	-	Break
	NDT = -20°F	NDT = -30°F

Table 5.3-6 (Cont'd)

(Unit 2)

Test Location

Drop-Weights - Top and Bottom - Longitudinal
Bend - Top Middle - Transverse
Tensions - Top and Bottom - Transverse
Impacts - Top and Bottom - Longitudinal
Tests ¼T from rolled surface
No closer than "T" from quenched and tempered edge

Specification

ASME SA533 Grade B CL-1 Pressure Vessel Quality

Ultrasonic Testing

Per Procedure LS-UT-4

Heat Treatment

Procedure LS-102 Revision 5

Plates

Austenitized at 1650°F held ½ hr/in (min), and water quenched.
Tempered at 1260°F held ½ hr/in (min), and air cooled.
Stress relieved at 1150°F held 1 hr (min) and air cooled.
Test coupons then cut from plate.

Tests only

Stress relieved @ 1150°F held 50 hr and furnace cooled to below 600°F, then air cooled.

Maximum Heating Rate	Maximum Cooling Rate
100°F/hr	100°F/hr

Mechanical Property Requirements

Tensile:	80/100,000 psi
Yield:	50 min 0.2% offset
Elong:	18% in 2 in (min)
Impacts:	30 ft-lb @ +40°F. Lateral Expansion and % Shear Fracture for information only.
Drop-Weights:	Type P-3 specimens with a NDT temperature no higher than +40°F.
Grain-Size	Final Plate Grain-Size #5 or finer determined on a fully heat treated test coupon.

[2] This material is in Plant B's vessel surveillance program.

Table 5.3-9

WELD PROCEDURE SPECIFICATION FOR VESSEL MATERIAL
REPRESENTATIVE OF LGS BELTLINE WELDS(1)

(Unit 1)

Reference Specifications

General WPS 800 Latest Revision
General WPS 820 Latest Revision

Procedure Qualification

No.	Position	Thickness Range (inches)
1890 (SMA)	V	3/16 to 8
1891 (SMA)	H	3/16 to 8
1892 (SMA)	OH, F	3/16 to 8
1893 (SA1)	F	3/16 to 8
2200 (SA2)	F	3/16 to 8

Postheat Treatment

Procedure qualified with 50 hours at 1150°F + 25°F/-50°F.

Postweld heat treatment of the weldment shall be in accordance with a Chicago Bridge and Iron approved procedure.

Base Metal

ASME SA533 Grade B Class 1 or SA508 Class 2
ASME Group No. P12B Subgroup 1

Shielding Gas: None

Backup Gas: None

Flux: Linde 124

Preheat Requirements

Minimum preheat of 300°F shall be applied uniformly to the full thickness of the weld joint and adjacent base material for a minimum distance of "T" or 6 inches, whichever is least, where "T" is the material thickness.

Maintain 300°F min preheat temperature until start of postweld heat treatment except for longitudinal and circumferential shell and head seams, preheat may be dropped to 250°F min 8 hours after completion of welding. All turnoff tabs and flux dams must be removed prior to dropping preheat below 300°F.

Table 5.3-9 (Cont'd)

Interpass Temperature Requirements

The interpass temperature shall not exceed 500°F maximum.

Filler Metal

Submerged Arc

Specification - N.A.
Classification - N.A.
Analysis - A3 (except Ni 0.50 to 1.25)

Unit 2 N16D Nozzle Weld Pad

Operation Description	Beads Layer	Weld Proc.	Electrode Size (in)	Current Type	Voltage (Amps)	(volts)	Travel
Machine Temper Bead GTAW	As Req'd	GTAW	1/16 3/32	DCSP	210-310 (primary) 115-130 (background)	9.5-10	

Heat Input Requirements/Allowable Wire Feed Speed Ranges

PARAMETER	LAYER 1	LAYER 2	LAYER 3	BALANCE
Primary Volts	9.5	9.8	10.0	10.0
Background Volts*	N/A	N/A	N/A	N/A
Primary Amps	210	280	280	310
Background Amps	115	120	120	130
Primary Wire (IPM)	36-44	54-66	54-66	54-66
Background Wire (IPM)	27-33	45-55	45-55	45-55
Primary Pulse Width (PPW)	40%	40%	40%	40%
Travel Speed (IPM)	4.5	4.0	4.0	3.8
Pulse Frequency (PPS)	2	2	2	2
Recommended Parameters Heat Input (J/in)	19,380	27,048	27,600	31,895 Max***
**MAX. Heat Input +10% (J/in)	21,318	29,752	30,360	N/A
**MIN. Heat Input -10% (J/in)	17,442	24,343	24,840	N/A

* Background Voltage is not applicable in the SAMP mode.
** Minimum and maximum heat input values are based on actual PQR parameters.
*** Maximum heat input used on the PQR balance of welding.

FORMULA FOR CALCULATING HEAT INPUT:
AVGAVC = PRIVOLT when in SAMP mode.
AVGAMP = (PRIAMP * PPW) + (BCKAMP * (1-PPW)
HEAT INPUT (J/in) = (AVGAVC * AVGAMP * 60) / TRAVEL SPEED

5.4 COMPONENT AND SUBSYSTEM DESIGN

5.4.1 REACTOR RECIRCULATION PUMPS

5.4.1.1 Safety Design Bases

The reactor recirculation system is designed to meet the following safety design bases:

a. An adequate fuel barrier thermal margin is ensured during postulated transients.

b. A failure of piping integrity does not compromise the ability of the reactor vessel internals to provide a refloodable volume.

c. The system maintains pressure integrity during adverse combinations of loadings and forces occurring during abnormal, accident, and special event conditions.

5.4.1.2 Power Generation Design Bases

The reactor recirculation system meets the following power generation design bases:

a. The system provides sufficient flow to remove heat from the fuel.

b. The system provides for changing reactor power without control rod movement over the range of approximately 55% to 100% rated power.

c. The system design minimizes maintenance situations that would require core disassembly and fuel removal.

5.4.1.3 Description

The reactor recirculation system consists of the two recirculation pump loops external to the reactor vessel. These loops provide the piping path for the driving flow of water to the reactor vessel jet pumps (Figure 5.4-1 and drawing M-43). Each external loop contains one high capacity, variable-speed, motor-driven recirculation pump and two motor-operated gate valves (for pump maintenance). Each loop contains a flow-measuring system. The recirculation loops are part of the RCPB and are located inside the drywell structure. The jet pumps are reactor vessel internals. Their location and mechanical design are discussed in Section 3.9.5. However, certain operational characteristics of the jet pumps are discussed in this section. The important design and performance characteristics of the reactor recirculation system are shown in Table 5.4-1. The head, NPSH, flow, and efficiency curves are shown in Figure 5.4-3. An instrumentation and control description is provided in Section 7.1.2.

The recirculated coolant consists of saturated water from the steam separators and dryers that has been subcooled by incoming feedwater. This water passes down the annulus between the reactor vessel wall and the core shroud. A portion of the coolant flows from the vessel, through the two external recirculation loops, and becomes the driving flow for the jet pumps. Each of the two external recirculation loops discharges high pressure flow into an external manifold from which individual recirculation inlet lines are routed to the jet pumps within the reactor vessel. The remaining portion of the coolant mixture in the annulus becomes the driven flow for the jet pumps. This flow enters the jet pump at suction inlets and is accelerated by the driving flow. The flows, both driving and driven, are mixed in the jet pump throat section and result in partial pressure recovery. The balance of

recovery is obtained in the jet pump diffuser (Figure 5.4-4). The adequacy of the total flow to the core is discussed in Section 4.4.

The allowable heatup rate for the recirculation pump casing is the same as for the reactor vessel. If one loop is shut down, it can be kept hot by leaving the discharge and suction gate valves open; this permits the reactor pressure plus the active jet pump head to cause reverse flow in the idle loop.

Because the removal of the reactor recirculation gate valve internals would require unloading the core due to the resulting draining of reactor coolant, the objective of the valve trim design is to minimize the need for maintenance of the valve internals. The valves are provided with high quality back-seats that permit renewal of stem packing while the system is full of water.

The feedwater flowing into the reactor vessel annulus during operation provides subcooling for the fluid passing to the recirculation pumps and jet pumps, thus providing additional NPSH available beyond that provided by the pump location below the reactor vessel water level. If feedwater flow is less than the minimum value necessary for adequate NPSH for full speed recirculation pump operation, the pump speed is automatically limited.

When preparing for hydrostatic tests, the nuclear system temperature must be raised above the vessel NDTT limit. The vessel is heated by operating the recirculation pumps and/or by core decay heat.

Each recirculation pump is a single-stage, variable-speed, vertical, centrifugal pump equipped with mechanical shaft seal assemblies. The pump is capable of stable and satisfactory performance while operating continuously at any speed corresponding to a power supply frequency range of 11.5 Hz to 57.5 Hz for 60 Hz power supply.

The recirculation pump shaft seal assembly consists of two individual seals built into a cartridge or cartridges that can be readily replaced without removing the motor from the pump. The seal assembly is designed to require minimum maintenance over a long period of time, regardless of whether the pump is stopped or is operating at various speeds with water at various pressures and temperatures. Each seal is designed for a life of one year, based on a 90% probability factor (original design). Each individual seal in the cartridge is capable of sealing against pump operating pressure so that any one seal can adequately limit leakage if the other seal fails. A breakdown orfice is provided in the pump casing to reduce leakage if there is a gross failure of both shaft seals. Provision is made for monitoring the pressure drop across each individual seal as well as the cavity temperature of each seal. Provision is also made for piping the seal leakage to a flow-measuring device. It should be noted that the original seals have been replaced with an improved design prone to less leakage in the event of a seal failure.

Each recirculation pump motor is a vertical, variable-speed, ac electric motor that can drive the pump over a controlled range of 28% to 99.2% of rated pump speed. The motor is designed to operate continuously at any speed within the power supply frequency range of 15.7 Hz to 55.6 Hz from 60 Hz power supply. Electrical equipment is designed, constructed, and tested in accordance with the applicable sections of the NEMA standards.

A variable-frequency ac ASD located outside the drywell supplies power to a recirculation pump motor. Each unit has two variable-frequency ac ASDs (one per recirculation pump motor). The pump motor is electrically connected to the ASD 4kV output generated by digitally controlled solid-state power electronics.

The ASD has no rotational inertia to add to the recirculation pump and motor to slow down the coast-down rate. However, per the GEH Transient Analysis Report (SDOC G-080-VC-00467 and SDOC G-080-VC-00470), it is determined that this lack of rotational inertia was either 1) not a factor in the transient, 2) had low consequence in the analysis or 3) was otherwise analyzed as not being a significant contributor to the event. The lack of additional coast-down inertia is not a concern for flow into the core.

Pump casing and valve bodies are designed for a 40 year life and are welded into the piping system with no plans to remove them from the system for maintenance or overhaul. Removable parts of the pump such as wear rings, impellers, bearings, etc, are designed for as long a life as practicable, and as a design objective they should have a life between overhaul or major maintenance cycle of more than five years. Pump seals and valve packings are expected to have a useful service life in excess of a refueling cycle, to afford convenient replacement during the refueling outage.

The recirculation system piping is of all-welded construction and is designed and constructed to meet the requirements of the ASME Code. The reactor recirculation system pressure boundary equipment is designed as seismic Category I. Design codes and standards are discussed in detail in Section 3.2.

Snubbers located at the top of the motor and at the bottom of the pump casing are designed to resist seismic reactions.

The recirculation piping, valves, and pumps are supported by hangers to avoid the use of piping expansion loops that would be required if the pumps were anchored. In addition, the recirculation loops are provided with a system of restraints designed so that reaction forces associated with the postulated pipe breaks do not jeopardize primary containment integrity. This restraint system provides adequate clearance for normal thermal expansion movement of the loop. Because possible pipe movement is limited to slightly more than the clearance required for thermal expansion movement, no impact loading on limit stops is considered. A more detailed discussion of the recirculation piping restraints is in Section 3.6.

The recirculation system piping, valves, and pump casings are covered with fiberglass-type thermal insulation and stainless steel jacketing. This insulation is removable for the purpose of inservice inspection.

5.4.1.4 Safety Evaluation

Postulated reactor recirculation system malfunctions that could lead to damage to the fuel barrier are described and evaluated in Chapter 15. It is shown in Chapter 15 that none of the malfunctions could result in significant fuel damage. The recirculation system has sufficient flow coast-down characteristics to maintain fuel thermal margins during abnormal operational transients.

The core flooding capability of a jet pump design plant is discussed in detail in the ECCS topical report (Reference 5.4-1). The ability to reflood the BWR core to the top of the jet pumps is shown schematically in Figure 5.4-5 and is discussed in Reference 5.4-1.

Piping and pump design pressures for the reactor recirculation system are based on peak steam pressure in the reactor dome, appropriate pump head allowances, and the elevation head above the lowest point in the recirculation loop. Piping and related equipment pressure-retaining components are chosen in accordance with applicable codes (Section 3.2). Use of the code design criteria ensures that a system designed, built, and operated within design limits has an extremely low probability of failure caused by any known failure mechanism.

GE purchase specifications require that the recirculation pump's first critical speed be not less than 130% of operating speed. Calculations were verified by GE design engineering.

GE purchase specifications require that the integrity of the pump case be maintained through all transients and that the pump remain operable through all normal and upset transients. The design of the pump and motor bearings is required to be such that the dynamic load capability at rated operating conditions is not exceeded during the SSE. Calculation submittal is required.

Pump overspeed occurs during the course of a postulated LOCA due to blowdown through the broken loop pump. Design studies determined that the overspeed is not sufficient to cause destruction of the motor, and consequently no provision is made to decouple the pump from the motor for such an event.

5.4.1.5 Inspection and Testing

Quality control methods were used during fabrication and assembly of the reactor recirculation system to ensure that design specifications are met. Inspection and testing were carried out as described in Section 3.9. The RCS was thoroughly cleaned and flushed before fuel was loaded initially.

During the preoperational test program, the reactor recirculation system was hydrostatically tested in accordance with the codes listed in Section 5.2.1. Preoperational tests on the reactor recirculation system also include checking the operation of the pumps, flow control system, and gate valves and are discussed in Chapter 14.

During the startup test program, horizontal and vertical motions of the reactor recirculation system piping and equipment were observed; supports were adjusted, if necessary, to ensure that components are free to move as designed. Nuclear system responses to recirculation pump trips at rated temperatures and pressure were evaluated during the startup tests, and plant power response to recirculation flow control was determined.

5.4.2 STEAM GENERATORS (PWR)

Section 5.4.2 is not applicable to LGS.

5.4.3 REACTOR COOLANT PIPING

The reactor coolant piping is discussed in Sections 3.9.3 and 5.4.1. The recirculation loops are shown in Figure 5.4-1 and drawing M-43, and the design characteristics are presented in Table 5.4-1.

5.4.4 MAIN STEAM LINE FLOW RESTRICTORS

5.4.4.1 Safety Design Bases

The main steam line flow restrictors are designed to:

a. Limit the loss of coolant from the reactor vessel following a steam line rupture outside the containment to the extent that the reactor vessel water level remains high enough to provide cooling within the time required to close the MSIVs

b. Withstand the maximum pressure difference expected across the restrictor, following complete severance of a main steam line

c. Limit radioactive release outside of the drywell before MSIV closure

d. Provide a trip signal for MSIV closure

5.4.4.2 Description

A main steam line flow restrictor (Figure 5.4-6) is provided for each of the four main steam lines. The restrictor is a complete assembly welded into the main steam line, and it is located in the drywell.

If a main steam line break occurs outside the containment, the restrictor limits the coolant blowdown rate from the reactor vessel to the maximum (choke) flow of 7.08×10^6 lb/hr at 1000 psig upstream pressure. The restrictor assembly consists of a venturi-type nozzle insert welded, in accordance with applicable code requirements, into the main steam line. The flow restrictor is designed and fabricated in accordance with ASME "Fluid Meters," 5th edition, 1959.

The flow restrictor has no moving parts. Its mechanical structure can withstand the velocities and forces associated with a main steam line break. The maximum differential pressure is conservatively assumed to be 1375 psi, the reactor vessel ASME Code limit pressure.

The ratio of venturi throat diameter to steam line inside diameter of approximately 0.55 results in a maximum pressure differential (unrecovered pressure) of about 11 psi at 105% of rated flow. This design limits the steam flow in a severed line to less than 200% rated flow, yet it results in negligible increase in steam moisture content during normal operation. The restrictor is also used to measure steam flow to initiate closure of the MSIVs when the steam flow exceeds preselected operational limits.

5.4.4.3 Safety Evaluation

If a main steam line breaks outside the containment, the critical flow phenomenon would restrict the steam flow rate in the venturi throat to 200% of the rated value. Before isolation valve closure, the total coolant losses from the vessel are not sufficient to cause core uncovering, and the core is thus adequately cooled at all times.

Analysis of a steam line rupture accident (Chapter 15) shows that the core remains covered with water and that the amount of radioactive materials released to the environment through the main steam line break does not exceed the guideline values of published regulations.

Tests on a scale model determined the final design and performance characteristics of the flow restrictor. The characteristics include maximum flow rate of the restrictor corresponding to the accident conditions, unrecoverable losses under normal plant operating conditions, and discharge moisture level. The tests showed that flow restriction at critical throat velocities is stable and predictable.

The steam flow restrictor is exposed to steam of about 0.2% moisture flowing at velocities of 150 ft/sec (steam piping ID) to 600 ft/sec (steam restrictor throat). ASTM A351 (Type 304) cast stainless steel is used for the steam flow restrictor material because it has excellent resistance to erosion/corrosion in a high velocity steam atmosphere. The excellent performance of stainless steel in high velocity steam appears to be due to its resistance to corrosion. A protective surface film forms on the stainless steel, which prevents any surface attack, and this film is not removed by the steam.

Hardness has no significant effect on erosion/corrosion. For example, hardened carbon steel or alloy steel erodes rapidly in applications where soft stainless steel is unaffected.

Surface finish has a minor effect on erosion/corrosion. If very rough surfaces are exposed, the protruding ridges or points erode more rapidly than a smooth surface. Experience shows that a machined or a ground surface is sufficiently smooth and that no detrimental erosion occurs.

5.4.4.4 Inspection and Testing

Because the flow restrictor forms a permanent part of the main steam line piping and has no moving components, no testing program is planned. Only very slow erosion occurs with time, and such a slight enlargement has no safety significance. Stainless steel resistance to corrosion has been substantiated by turbine inspections at the Dresden Unit 1 facility, which have revealed no noticeable effects from erosion on the stainless steel nozzle partitions. The Dresden inlet velocities are about 300 ft/sec, and the exit velocities are 600-900 ft/sec. However, calculations show that, even if the erosion rates are as high as 0.004 inch per year, after 40 years of operation the increase in restrictor choked flow rate would be no more than 5%. A 5% increase in the radiological dose calculated for the postulated main steam line break accident is not significant.

5.4.5 MAIN STEAM LINE ISOLATION SYSTEM

5.4.5.1 Safety Design Bases

The MSIVs, individually or collectively, perform the following functions:

a. Close the main steam lines within the time established by DBA analysis to limit the release of reactor coolant.

b. Close the main steam lines slowly enough that simultaneous closure of all steam lines does not induce transients that exceed the nuclear system design limits.

c. Close the main steam line when required despite single failure in either a valve or in the associated controls, to provide a high level of reliability for the safety function.

d. Use separate energy sources as the motive force to close independently the redundant isolation valves in the individual steam lines.

e. Use local stored energy (compressed air and springs) to close at least one isolation valve in each steam pipeline without relying on the continuity of any variety of electrical power to furnish the motive force to achieve closure.

f. Close the steam lines, either during or after seismic loadings, to ensure isolation if the nuclear system is breached.

g. Have capability for testing, during normal operating conditions, to demonstrate that the valves will function.

5.4.5.2 Description

Two isolation valves are welded in a horizontal run of each of the four main steam pipes; one valve is as close as possible to the inside of the drywell, and the other is just outside the primary containment.

Figure 5.4-7 shows an MSIV. Each is a 26 inch Y-pattern, globe valve. The rated steam flow rate through each valve is 3.543×10^6 lb/hr. The main disc or poppet is attached to the lower end of the

stem. Normal steam flow tends to close the valve, and higher inlet pressure tends to hold the valve closed. The bottom end of the valve stem closes a small pressure balancing hole in the poppet. When the hole is open, it acts as a pilot valve to relieve differential pressure forces on the poppet. Valve stem travel is sufficient to permit flow areas past the wide open poppet that are greater than the seat port area. The poppet travels approximately 90% of the valve stem travel to close the main seat port area; approximately the last 10% of valve stem travel closes the pilot valve. The gas (air for MSIVs outside containment, nitrogen for MSIVs inside containment, as described in Section 9.3) can open the poppet with a maximum differential pressure of 200 psi across the isolation valve in a direction that tends to hold the valve closed.

A 45° angle permits the inlet and outlet passages to be streamlined; this minimizes pressure drop during normal steam flow and helps prevent blockage by debris. The pressure drop at 105% of rated flow is 7 psi maximum.

Attached to the upper end of the stem is a gas cylinder that opens and closes the valve and a hydraulic dashpot that controls its speed. The speed is adjusted by a valve in the hydraulic return line bypassing the dashpot piston. Valve closing time is adjustable to between 3 seconds and 10 seconds.

The gas cylinder is supported on the valve bonnet by actuator support and spring guide shafts. Helical springs around the spring guide shafts close the valve on loss of pneumatic pressure to the gas cylinder. The motion of the spring seat member actuates switches in the 10% open, 90% open valve positions.

The valve is operated by pneumatic pressure and by the action of compressed springs. The control unit is attached to the gas cylinder. This unit contains three types of control valves (pneumatic, dc, and ac from another source) that open and close the main valve and exercise it at slow speed. Remote manual switches in the control room enable the operator to operate the valves.

Operating gas is supplied to the valves from the Instrument Air (outboard valves) and Primary Containment Instrument Gas (inboard valves) systems. A gas accumulator between the control valve and a check valve provides backup operating gas. The actuator and seals act as extensions of the accumulator and as such have specific leakage limits.

Each valve is designed to accommodate saturated steam at plant operating conditions, with a moisture content of approximately 0.25%, an oxygen content of 30 ppm, and a hydrogen content of 4 ppm. The valves are furnished in conformance with a design pressure and temperature rating in excess of plant operating conditions to accommodate plant overpressure conditions.

In the worst case, if the main steam line ruptures downstream of the valve, the steam flow would quickly increase to 200% of rated flow. Further increase is prevented by the venturi flow restrictor inside the containment.

During approximately the first 75% of closing, the valve has little effect on flow reduction, because the flow is choked by the venturi restrictor. After the valve is approximately 75% closed, flow is reduced as a function of the valve area versus travel characteristic.

The design objective for the valve is a minimum of 40 years' service at the specified operating conditions. Operating cycles (excluding exercise cycles) are estimated to be 50 cycles per year during the first year and 20 cycles per year thereafter.

In addition to the minimum wall thickness required by applicable codes, a 0.120 inch (minimum) corrosion allowance is added to provide for 40 years' service.

Design specification ambient conditions for normal plant operation are 150°F maximum temperature and 100% relative humidity, in a radiation field of 15 rad/hr gamma and 25 rad/hr neutron plus gamma, continuous for design life. The inside valves are not continuously exposed to maximum conditions, particularly during reactor shutdown, and valves outside the primary containment and shielding are in ambient conditions that are considerably less severe.

The MSIVs are designed to close under accident environmental conditions of 340°F for one minute at drywell design pressure. In addition, they are designed to remain closed under the following postaccident environment conditions:

a. For the balance of the first 3 hours; 340°F at a drywell pressure of 45 psig maximum

b. 320°F for an additional 3 hours at 45 psig maximum

c. 250°F for an additional 24 hours at 25 psig maximum

d. 200°F during the next 100 days at 20 psig maximum

To resist sufficiently the response motion from the SSE, the MSIV installations are designed as seismic Category I equipment. The valve assembly is manufactured to withstand the SSE forces applied at the mass center of the extended mass of the valve operator, assuming that the cylinder/spring operator is cantilevered from the valve body and the valve is located in a horizontal run of pipe. The stresses caused by horizontal and vertical seismic forces are assumed to act simultaneously. The stresses in the actuator supports caused by seismic loads are combined with the stresses caused by other live and dead loads, including the operating loads. The allowable stress for this combination of loads is based on a percentage of the allowable yield stress for the material. The parts of the MSIVs that constitute a process fluid pressure boundary are designed, fabricated, inspected, and tested as required by the ASME Section III. Design codes and standards are discussed in detail in Section 3.2.

5.4.5.3 Safety Evaluation

In a direct cycle nuclear power plant, the reactor steam goes to the turbine and to other equipment outside the containment. Radioactive materials in the steam are released to the environment through process openings in the steam system, or they can escape from accidental openings. A large break in the steam system can drain the water from the reactor core faster than it is replaced by feedwater.

The analysis of a complete, sudden steam line break outside the containment is described in Chapter 15. The analysis shows that the fuel barrier is protected against loss of cooling if MSIV closure is within specified limits, including instrumentation delay to initiate valve closure after the break. The calculated radiological effects of the radioactive material assumed to be released with the steam are shown to be well within the guideline values for such an accident.

The shortest closing time (approximately 3 seconds) of the MSIVs is also shown to be satisfactory in Chapter 15. The switches on the valves initiate reactor scram when specific conditions (extent of valve closure, number of pipelines included, and reactor power level) are exceeded (Section 7.2.1). The pressure rise in the system from stored and decay heat may cause the nuclear system relief

valves to open briefly, but the rise in fuel cladding temperature is insignificant. No fuel damage results.

The ability of this 45°, Y-design globe valve to close in a few seconds after a steam line break, under conditions of high pressure differentials and fluid flows with fluid mixtures ranging from mostly steam to mostly water, has been demonstrated in a series of dynamic tests. A full-size, 20 inch valve was tested in a range of steam-water blowdown conditions simulating postulated accident conditions (Reference 5.4-2).

The following specified hydrostatic, leakage, and stroking tests, as a minimum, are performed by the valve manufacturer in-shop tests:

a. To verify its capability to close at settings between 3 seconds and 10 seconds, each valve is tested at a pressure of 1000 psig and no flow (response time for full closure is set before plant operation at 3 seconds minimum, 5 seconds maximum). The valve is stroked several times, and the closing time is recorded. The valve is closed by springs only and by the combination of air cylinder and springs. The closing time is slightly greater when closure is by springs only.

b. Leakage is measured with the valve seated and back-seated. The specified maximum seat leakage, using cold water at design pressure, is 2 cm^3/hr/in of nominal valve size. In addition, an air seat leakage test is conducted using 50 psi pressure upstream. Maximum permissible leakage is 0.1 scfh/in of nominal valve size. There must be no visible leakage from either set of stem packing at hydrostatic test pressure. The valve stem is operated a minimum of three times from the closed position to the open position, and the packing leakage still must be zero by visual examination. (Valve stem backseat feature and valve packing leak off feature has been eliminated on all of the MSIVs by modification.)

c. Each valve is hydrostatically tested in accordance with the requirements of the applicable edition and addenda of the ASME Code. During valve fabrication, extensive nondestructive tests and examinations are conducted. The tests include radiographic, liquid penetrant, or magnetic particle examinations of casting, forgings, welds, hard-facings, and bolts.

d. The spring guides, the guiding of the spring seat member on support shafts, and rigid attachment of the seat member ensure correct alignment of the actuating components. Binding of the valve poppet in the internal guides is prevented by making the poppet in the form of a cylinder longer than its diameter and by applying stem force near the bottom of the poppet.

Each valve is tested after installation as discussed in Chapter 14.

Two isolation valves provide redundancy in each steam line so that either can perform the isolation function and either can be tested for leakage after the other is closed. The inside valve, the outside valve, and their respective control systems are separated physically.

The design of the MSIV has been analyzed for earthquake loading. The cantilevered support of the air cylinder, hydraulic cylinder, springs, and controls is the key area. The increase in loading caused by the specified earthquake loading does not result in stresses exceeding ASME allowable stresses or prevent the valve from closing as required.

Electrical equipment that is associated with the MSIVs and operates in an accident environment is limited to the wiring, solenoid valves, and position switches on the valves. The expected pressure and temperature transients following an accident are discussed in Chapter 15.

5.4.5.4 Inspection and Testing

The MSIVs can be functionally tested for operability during plant operation. The test provisions are listed below. During refueling outages the MSIVs can be functionally tested, leak tested, and visually inspected.

During plant operation the MSIVs can be tested and exercised individually to the 90% open position, because the valves still pass rated steam flow when 90% open.

During prestartup tests following an extensive shutdown, the valves receive the same hydro tests (approximately 400 psi) that are imposed on the primary system.

The MSIVs can also be tested and exercised individually to the fully closed position if reactor power is reduced sufficiently to avoid scram from reactor overpressure or high flow through the steam line flow restrictors in the remaining steam lines. Continued operation with one or both MSIV's closed on one Main Steam Line is permitted provided that reactor thermal power is maintained at or below 75% of rated (ref. 5.4-3).

Leakage from the valve stem packing can be detected during reactor operation from measurements of leakage into the drywell or from observations or similar measurements in the steam tunnel.

The leak rate through the valve seats (pilot and poppet seats) is measured accurately as a part of the 10CFR50, Appendix J LLRT program during shutdown.

Leak rates are determined by typical Appendix J, Type C, leak rate procedures which use a combination of flow-in, flow-out, pressure decay, and pressure differential elimination across valves to determine valve leakage at its test pressure required by technical specifications.

Such a test and leakage measurement program ensures that the valves are operating correctly and that any leakage trend is detected.

5.4.6 REACTOR CORE ISOLATION COOLING SYSTEM

5.4.6.1 Design Bases

The RCIC system is a safety system that consists of a turbine, pump, piping, valves, accessories, and instrumentation designed to ensure that sufficient reactor water inventory is maintained in the reactor vessel to permit adequate core cooling to take place. This prevents reactor fuel overheating during the following conditions:

a. The vessel is isolated and maintained in the hot standby condition.

b. The vessel is isolated, accompanied by loss of coolant flow from the reactor feedwater system.

c. A complete plant shutdown under conditions of loss of normal feedwater system is started before the reactor is depressurized to a level at which the shutdown cooling system can be placed into operation.

Following a reactor scram, steam generation continues at a reduced rate due to the core fission product decay heat. At this time the turbine bypass system diverts the steam to the main condenser, and the feedwater system supplies the makeup water required to maintain the reactor vessel inventory.

If the reactor vessel is isolated and the feedwater supply is unavailable, relief valves are provided to automatically (or remote manually) maintain vessel pressure within desirable limits. The water level in the reactor vessel drops due to continued steam generation by decay heat. On reaching a predetermined low level, the RCIC system is initiated automatically. The system then functions to restore adequate vessel water levels. On reaching a predetermined high level, the RCIC steam admission valve (F045) automatically closes, resulting in turbine shutdown. RCIC will automatically restart if the level returns to the low level trip point. The turbine-driven pump supplies makeup water from the CST to the reactor vessel. If the CST level falls below a predetermined low level, an alternate source of water is automatically made available from the suppression pool. The turbine is driven with a portion of the decay heat steam from the reactor vessel, and exhausts to the suppression pool. Suppression pool water may not be of condensate quality and hence it is preferred that it only be used if sources of condensate quality water are not available.

During RCIC operation, the suppression pool acts as the heat sink for steam generated by reactor decay heat. This results in a rise in pool water temperature. The RHR system heat exchangers are used to maintain pool water temperature within acceptable limits by cooling the pool water.

For design basis events RCIC needs to operate for a maximum of six hours in order to fulfill its safety functions.

5.4.6.1.1 Residual Heat and Isolation

5.4.6.1.1.1 Residual Heat

The RCIC system is designed to initiate and discharge, within 55 seconds, a specified constant flow into the reactor vessel over a specified pressure range. The temperature of the RCIC water discharged into the reactor vessel varies between 40°F and 140°F. Station Blackout (SBO) procedures directs the operation of the RCIC System for Reactor Pressure Level Control for the SBO 4-hour coping duration with water supply from the Suppression Pool. During the SBO event, the Suppression Pool water may reach up to 180 degrees F. The mixture of the cool RCIC water and the hot steam accomplishes the following:

a. Quenches the steam

b. Removes reactor residual heat by reducing the heat level (enthalpy) due to the temperature difference between the steam and water

c. Replenishes reactor vessel inventory

The HPCI system performs the same function, thereby providing single failure protection. Both systems use different electrical power sources of high reliability, which permits operation with either onsite or offsite power. Additionally, the RHR system performs a residual heat removal function.

The RCIC system design includes interfaces with redundant leak detection devices:

a. A high pressure drop across a flow device in the steam supply line equivalent to 300% of the steady-state steam flow at 1197 psia

b. A high area temperature, using temperature switches as described in the leak detection system; high area temperature is alarmed in the control room

c. A high pressure between the turbine exhaust rupture diaphragms

d. Reactor low pressure

These devices, activated by the redundant power supplies, automatically isolate the steam supply to the RCIC turbine.

Other isolation bases are defined below. Again, HPCI provides redundancy for RCIC if RCIC becomes isolated, thus providing single failure protection.

5.4.6.1.1.2 Isolation

Isolation valve arrangements include the following (additional information about containment isolation is given in Section 6.2.4):

a. Two RCIC lines penetrate the primary containment and form a part of the RCPB. The first is the RCIC steam supply line, which branches off the B main steam line between the reactor vessel and the inboard MSIV. This line has two automatic motor-operated isolation valves F007 and F008, which are key-locked open. One is located inside and the other outside primary containment. An automatic MOV, F076, is provided in the bypass line around the outboard RCIC isolation valve. The isolation signals noted earlier close these valves. The isolation signal is automatic and bypasses the key-lock when the valves must be closed in the case of an RCIC line break. For other accidents, it is more desirable to have steam available for RCIC operation than to preclude its operation because of a containment automatic isolation valve closure signal. If the isolation valves were closed, operator action would be required to reopen the valves to avoid water hammer and thermal shock. An isolation signal is given for a large pipe break by detecting flow rates greater than 300% of the steady-state steam flow. For leakage with flow rates less than 300% of steady-state steam flow, an isolation signal is signaled by use of area temperature sensors provided by the leak detection system.

   The RCIC pump discharge line is the other line that forms a part of the RCPB; however, it indirectly connects to the RPV. Outside containment, this line enters the feedwater line, which provides required isolation valves inside the primary containment. The RCIC system has an automatic MOV F013 outside primary containment for isolation. The above arrangements satisfy GDC 55 for RCPB lines penetrating containment.

b. The RCIC turbine exhaust line vacuum breaker system line has two automatic MOVs (F080, F084) and four check valves. This line runs between the suppression pool air space and the turbine exhaust line downstream of the exhaust line check valve.

Isolation is automatic via a combination of low reactor pressure and high drywell pressure. This design satisfies GDC 56 for primary containment isolation.

The vacuum breaker valve complex is placed outside primary containment, due to a more desirable environment. In addition, the valves are then readily accessible for maintenance and testing.

c. The RCIC pump suction line, minimum flow pump discharge line, turbine gland seal system vacuum pump discharge, and turbine exhaust line all penetrate the primary containment and terminate below the suppression pool water level. The isolation valves (F031, F019, F002 and F060, respectively) for the lines are all outside primary containment and require remote manual operation, except for the minimum flow valves, which operate automatically. This arrangement satisfies GDC 56 for primary containment isolation.

5.4.6.1.2 Reliability, Operability, and Manual Operation

5.4.6.1.2.1 Reliability and Operability

The RCIC system as shown in Table 3.2-1 is designed commensurate with the safety importance of the system and its equipment. Each component is individually tested to confirm compliance with system requirements. The system as a whole is tested during both the startup and preoperational phases of the plant to set a base-mark for system reliability. To confirm that the system maintains this mark, functional and operability testing is periodically performed.

A design flow functional test of the RCIC system may be performed during normal plant operation by drawing suction from the CST and discharging through a full flow test return line to the condensate storage tank. The discharge valve to the feedwater line remains closed during the test, and reactor operation remains undisturbed. All components of the RCIC system are capable of undergoing individual functional testing during normal plant operation. The system automatically aligns from test to operating mode if system initiation is required, but operator action is needed in the following instances:

a. Auto/manual switch is in manual on the flow controller. This feature is provided for operator flexibility during system operation.

b. Steam inboard/outboard isolation valves closed. Closure of either or both of these valves requires operator action to properly sequence their opening. An alarm sounds when either of these valves leaves the fully open position.

c. Parts of the system have been bypassed or otherwise deliberately rendered inoperable. These conditions are automatically indicated in the control room at the system level. Capability for manual initiation of system level indication exists for items not readily automated.

See also Section 5.4.6.2.4.

Four RCIC lines have a low design pressure and could possibly be overpressurized: the turbine exhaust line, the turbine leak-off to the barometric condenser, the cooling water line from PCV-1F015 to the barometric condenser, and the vacuum pump discharge line. These lines are shown on drawings M-49 and M-50. The turbine exhaust line is protected from overpressurization by two

rupture discs, PSE-1D001 and PSE-1D002. Pressure relief valves are provided to protect the other three lines from overpressurization.

5.4.6.1.2.2 Manual Operation

Provisions are included for remote manual startup, operation, and shutdown of the RCIC system.

As discussed in Section 5.4.7.1.1.5, the steam condensing mode of the RHR system has been removed from the plant.

See also Section 5.4.6.2.4.

5.4.6.1.3 Loss of Offsite Power

The RCIC system electrical power is derived from a highly reliable source that is maintained by either onsite or offsite power. See Section 5.4.6.1.1.

5.4.6.1.4 Physical Damage

The system is designed to the requirements shown in Table 3.2-1, which are commensurate with the safety importance of the system and its equipment. The RCIC system is located in a different area of the reactor enclosure and uses different divisional power (with separated electrical routings) than its redundant system (HPCI), as discussed in Sections 5.4.6.1.1 and 5.4.6.2.3.

5.4.6.1.5 Environment

The RCIC suction line that is exposed to the outdoor environment is provided with non-Class 1E heat tracing. Indication is provided in the control room if this heat tracing should become inoperative. Condensate level instrumentation for control room monitoring is located in the reactor enclosure and therefore is not exposed to the outdoor environment.

5.4.6.2 System Design

5.4.6.2.1 General

5.4.6.2.1.1 Description

A summary description of the RCIC system is presented in Section 5.4.6.1, which defines in general the system functions and components. The detailed description of the system, its components, and its operations is presented in the following sections.

5.4.6.2.1.2 Diagrams

The following diagrams are included for the RCIC system:

a. A P&ID (drawings M-49 and M-50) shows all components, piping, points where interface system and subsystems tie together, and instrumentation and controls associated with subsystem and component actuation.

b. A schematic process diagram (drawing E51-1020-G-002) shows temperature, pressures, and flows for RCIC operation and system process data hydraulic requirements.

5.4.6.2.1.3 Interlocks

The following electrical interlocks are provided:

a. There are four key-locked valves (F007, F008, F060, and F002) and two key-locked resets (the isolation resets).

b. Limit switches on valves F029 and F031 activate such that when both valves are fully open, F010 closes.

c. A limit switch on valve F060 activates when fully open and clears a permissive so valve F045 can open.

d. The limit switch on valve F045 actuates when F045 is partially open. The limit switch causes the valve to stop at the partially open position and also initiates a time delay relay. The valve remains in the partially open position until the time delay relay times out and activates the opening of the F045 valve. The time delay relay also initiates the ramp generator.

e. A limit switch on valve F045 activates when F045 is not fully closed, initiates startup ramp function and acts to lock out the following alarms for 15 seconds: RCIC pump low flow, RCIC low oil pressure, and RCIC vacuum tank low vacuum. This ramp resets each time F045 is closed.

f. The F045 limit switch activates when fully closed to permit valves F004, F005, F025, and F026 to open and causes valves F013 and F019 to close.

g. The turbine trip throttle valve (part of the turbine assembly) limit switch activates when fully closed and causes valves F013 and F019 to close.

h. The combined pressure switches at reactor low pressure and high drywell pressure, when activated, close valves F080 and F084.

i. High turbine exhaust pressure, low pump suction pressure, or an isolation signal, actuate to close the turbine trip throttle valve; when the signal is cleared, the trip throttle valve must be reset from the control room.

j. 124% overspeed trips both the mechanical trip at the turbine and the trip throttle valve; the former is reset at the turbine, and then the latter is reset in the control room

k. An isolation signal closes valves F007, F008, F076, and other valves, directly or indirectly, as noted in items f and h above.

l. An initiation signal opens valves F010 (if closed), F013, and F046; starts the barometric condenser vacuum pump; and causes valve F022 to close, if open.

m. A high RCIC steam line drain pot level signal causes valve F054 to open. The valve recloses when the high level signal clears.

n. The combined signal of low flow plus pump discharge pressure opens and, with increased flow, closes valve F019. See also items e and f above.

o. The switches for reactor low pressure, high turbine exhaust diaphragm pressure, steam line high differential pressure, or high area temperature, when activated, close valves F007, F008 and F076.

p. Limit switches on valves F029 and F031 activate such that when either valve is open, F022 closes.

q. High water level in the reactor vessel (level 8) initiates closure of the F045 and FO46 valves.

5.4.6.2.2 Equipment and Component Description

5.4.6.2.2.1 Design Conditions

The RCIC system components are as follows:

a. One 100% capacity turbine and accessories

b. One 100% capacity pump assembly and accessories

c. Piping, valves, and instrumentation for the following:

1. Steam supply to the turbine

2. Turbine exhaust to the suppression pool

3. Makeup supply from the CST to the pump suction

4. Makeup supply from the suppression pool to the pump suction including pump suction strainers described in Section 6.2.2.2.

5. Deleted

6. Pump discharge to the feedwater line, a test line to the CST, a minimum flow bypass line to the suppression pool, and a coolant water supply to accessory equipment.

5.4.6.2.2.2 Applicable Codes and Classifications

The RCIC system components within the drywell up to and including the outer isolation valve are designed in accordance with the ASME Section III, Class 1. The RCIC system is also designed as seismic Category I equipment. The RCIC electrohydraulic system integrated with the turbine governing valve is a safety-grade design, specified for seismic Category I design.

Other RCIC system component classifications are given in Table 3.2-1.

5.4.6.2.3 System Reliability Considerations

To ensure that the RCIC operates when necessary and in time to prevent inadequate core cooling, the power supply for the system is taken from immediately available energy sources of high reliability. Added assurance is given in the capability for periodic testing during station operation. The instrumentation design for the RCIC system is such that no failure of a single initiating sensor either prevents or falsely starts the system.

To ensure HPCI or RCIC availability for the operational events noted previously, certain design considerations are used in the design of both systems:

a. Physical independence. The two systems are located in separate rooms in the secondary containment. Piping runs are separated, and the water delivered from each system enters the reactor vessel via different nozzles.

b. Prime mover diversity and independence. Prime mover independence is achieved by using separate steam lines to drive the HPCI and RCIC steam turbines. Additionally, separate divisions of electrical power are used for HPCI and RCIC.

c. Control independence. Control independence is obtained by using different battery systems to provide control power to each system. Separate detection initiation logics are also used for each system.

d. Environmental independence. The safety-related equipment in the RCIC compartment does not rely upon auxiliary system support.

e. Periodic testing. A design flow functional test of the RCIC system is performed during plant operation by taking suction from the CST and discharging through the full flow test return line back to the CST. The discharge valve to the reactor feedwater line remains closed during the test, and reactor operation is undisturbed. Control system design provides automatic alignment from test to operating mode if system initiation is required during testing.

f. General. Periodic inspections and maintenance of the turbine-pump units are conducted in accordance with manufacturers' instructions. Valve position indication and instrumentation alarms are provided in the control room.

5.4.6.2.4 System Operation

Manual actions required for the various modes of RCIC are discussed in system operating and test procedures.

5.4.6.2.4.1 Automatic Operation

Automatic startup of the RCIC system due to an initiation signal from reactor low water level requires no operator action. Preparation of the system for the standby mode and manual actions required during operation and shutdown are defined by system operating procedures.

5.4.6.2.4.2 Test Loop Operation

This operating mode is manually initiated by the operator. Operator action is required as defined by surveillance test procedures and system operating procedures.

During all modes of manual MOV operation using the handswitch from the main control room, a "dead zone" is present for a portion of the valve travel. The "dead zone" is present when the valve is not fully closed and green light only indication exists. If the valve is stopped in the "dead zone", operator action is required to restart the valve.

5.4.6.2.4.1 Deleted

5.4.6.2.4.2 Deleted

5.4.6.2.4.3 Steam Condensing (Hot Standby) Operation

As discussed in Section 5.4.7.1.1.5, all the components which make up the steam condensing mode of the RHR system with the exception of an isolated vent line off each of the 2 Unit 2 RHR heat exchangers have either been abandoned in place or physically removed from the plant. Therefore, the mode is no longer functional.

5.4.6.2.4.4 Limiting Single Failure

The most limiting single failure of the high pressure recovery systems, HPCI and RCIC, is the failure of HPCI. If the capacity of the RCIC system is adequate to maintain reactor water level, the operator follows the station operating procedures. However, if the RCIC capacity is inadequate, the station operating procedures still apply, but additionally the ADS may be initiated as described in Section 6.3.2.

5.4.6.3 Performance Evaluation

The analytical methods and assumptions used in evaluating RCIC system performance are presented in Chapter 15. The RCIC system provides the flows required from the analysis (drawing E51-1020-G-002) within a 55 second interval based on considerations noted in Section 5.4.6.2.3.

5.4.6.4 Preoperational Testing

The preoperational and initial startup test program for the RCIC system is presented in Chapter 14.

5.4.6.5 Safety Interfaces

The BOP/NSSS safety interfaces for the RCIC system are:

a. Preferred water supply from the CST.

b. All associated wire, cable, piping, sensors, and valves that are outside the NSSS scope of supply.

c. Air supply for testable check and solenoid-actuated valves.

5.4.7 RESIDUAL HEAT REMOVAL SYSTEM

5.4.7.1 Design Bases

The RHR system is comprised of four independent loops. Each loop contains a motor-driven pump, piping, valves, instrumentation, and controls. Each loop takes suction from the suppression pool and is capable of discharging water to the reactor for low pressure coolant injection vessel via a separate vessel nozzle or back to the suppression pool via a full flow test line. In addition, loops A and B have heat exchangers that are cooled by RHRSW. These two loops can also take suction from the reactor recirculation system suction or from the spent fuel pool during refueling and can discharge into the reactor recirculation system discharge for residual heat removal. One of these two loops can be aligned to cool the spent fuel pool. The pumps in loops C and D can be aligned via crossties for use as alternates to the pumps in loops A and B, respectively. During cold shutdown and refueling operation condition, this results in the availability of four shutdown cooling subsystems (A heat exchanger with A RHR pump; A heat exchanger with C RHR pump; B heat exchanger with B RHR pump; and B heat exchanger with D RHR pump).

The Fire Protection system can be cross-tied to Loop B (Unit 1) and Loop A (Unit 2) RHR to provide an alternate source of water for the containment (drywell) spray mode of RHR. This cross-tie can only be used when there is no other method of injection to containment spray. Also, the cross-ties can provide an alternate source of water that can be injected through the LPCI injection line.

As discussed in Section 5.4.7.1.1.5, all the components comprising steam condensing mode of the RHR system have ether been abandoned in place or physically removed from the plant. Therefore, the mode is no longer functional.

5.4.7.1.1 Functional Design Basis

Each of the RHR modes has it's own functional requirements. Each subsystem is discussed separately below.

5.4.7.1.1.1 Residual Heat Removal Mode (Shutdown Cooling Mode)

a. The functional design basis of the shutdown cooling mode is to have the capability to remove decay and sensible heat from the reactor primary system so that the reactor outlet temperature is reduced to 125°F, approximately 20 hours after the control rods have been inserted, and to permit refueling when the RHRSW temperature is 85°F, assuming that the core is "mature" and the RHR heat exchanger tubes are completely fouled (see Section 5.4.7.2.2 for exchanger design details). The capacity of the heat exchangers is such that the time to reduce the vessel outlet water temperature to 212°F results in a cooldown rate in excess of 100°F per hour with both loops in service. However, the flushing operation associated with shutdown prevents the attainment of 212°F coolant temperature at a continuous 100°F per hour rate.

   Assuming 2 hours are used for flushing the system before operation, with all systems available the minimum time required to reduce vessel coolant temperature to 212°F is depicted by Figure 5.4-11.

b. The plant can be shut down using the capacity of a single RHR heat exchanger and related RHRSW system capability. Figure 5.4-12 shows the minimum time required to reduce vessel coolant temperature to 212°F using one RHR heat exchanger in the shutdown cooling mode and allowing 2 hours for flushing.

c. Each RHR heat exchanger can be aligned to one of two associated RHR pumps, constituting a shutdown cooling subsystem comprised of a heat exchanger, pump,

and piping flow path. This results in the availability of four shutdown cooling subsystems since each subsystem can be considered operable for shutdown cooling if it can be aligned (remote or local) for removal of decay heat.

d. The RHR heat exchangers can be aligned in the RHR Alternate Decay Heat Removal (ADHR) method when flooded-up during refueling. The heat exchangers are aligned to the spent fuel pool skimmer surge tanks and flow is returned to the reactor vessel. The functional design basis is to maintain the reactor and fuel pool water temperatures below 140°F while providing greater maintenance flexibility. In addition, the FPCC system(s) and the RHR fuel pool assist mode can be used for decay heat removal. See Section 9.1.3.1 for further details.

5.4.7.1.1.2 Low Pressure Coolant Injection Mode

The functional design basis for the LPCI mode is to pump 10,000 gpm of water per loop, using the separate loop pumps from the suppression pool into the core region of the vessel when the vessel pressure is 20 psid over drywell pressure. Injection flow commences at 295 psid vessel pressure above drywell pressure.

The initiating signals are reactor vessel low water level (level 1) or high drywell pressure coincident with low reactor pressure. The pumps attain rated speed in less than 40 seconds after their initiation signal, and the injection valves are in their fully open position in less than 40 seconds after the initiation signal.

The LPCI mode is discussed in greater detail in Section 6.3.

5.4.7.1.1.3 Suppression Pool Cooling Mode

The functional design basis for the suppression pool cooling mode is that it has the capacity to maintain the suppression pool temperature immediately after a blowdown below 170°F when the reactor pressure is above 135 psig.

5.4.7.1.1.4 Containment Spray Cooling Mode

The functional design basis for the containment spray cooling mode is that there are two (redundant) means to spray into the drywell and suppression pool vapor space to maintain internal pressure below the design limits.

5.4.7.1.1.5 Reactor Steam Condensing Mode

The reactor steam condensing mode is no longer functional. With the exception of an isolated vent line off each Unit 2 heat exchanger, components required for reactor steam condensing mode have been either abandoned in place or physically removed from the plant.

5.4.7.1.2 Design Basis for Isolation of RHR System from Reactor Coolant System

In the absence of a valid LOCA signal, the low pressure portions of the RHR system are isolated from full reactor pressure whenever the primary system pressure is above the RHR system design pressure (see Section 5.4.7.1.3 for further details). In addition, automatic isolation may occur for reasons of vessel water inventory retention, which is unrelated to piping pressure rating (see Section 5.2.5 for an explanation of the LDS and the isolation signals).

The RHR pumps are protected against damage from a closed discharge valve by the automatic minimum flow valves in the recirculation lines, which open on low main line flow and close on high main line flow. The minimum flow valve opens at main line flows of less than approximately 15% of pump rated flow (1500 gpm); this allows flow to return to the suppression pool through the low resistance low flow bypass line which branches off the main line upstream of the flow element.

The minimum flow valve closes at main line flows greater than approximately 1500 gpm; this closes the low resistance low flow bypass to the suppression pool and forces the entire pump discharge flow through the main line.

Under certain preplanned valve test scenarios, it is necessary and permissible to temporarily operate the RHR pumps at shutoff without minimum flow protection. These preplanned tests are conducted under explicit administrative controls. Continuous RHR pump operation at shutoff would eventually result in pump damage.

The minimum flow valve, valve control meets IEEE 279 requirements on the ECCS network level.

The minimum flow line restricting orifice is Quality Group B (i.e. seismic Category I, ASME Section III). The piping is rated at 300 lb (ANSI Primary Rating).

5.4.7.1.3 Design Basis for Pressure Relief Capacity

The relief valves in the RHR system are sized on one of two bases:

a. Thermal relief

b. Valve leakage

Transients are treated by item a; item b results from an excessive leak past isolation valves. Valves F025, F029 and F030 are set at or below the design pressure of the associated piping.

An interlock prevents the opening of valves to the low pressure suction piping when the reactor pressure is above the shutdown range. The same interlock initiates valve closure on increasing reactor pressure.

An additional interlock is provided for valve F008 to prevent a fire-induced valve open signal from causing both valves to open simultaneously while the reactor pressure is greater than the design capabilities of the RHR low-pressure piping.

In addition, check valves in the discharge lines to the vessel prevent reverse flow from the reactor if the reactor pressure increases above the RHR system pressure. Relief valves in the discharge piping are sized to account for leakage past the check valves.

5.4.7.1.4 Design Basis with Respect to GDC 5

With the exception of the fuel pool structures as discussed below, the RHR system for one unit does not share equipment or structures with the other unit. The RHRSW and ESW systems that provide cooling water to the RHR heat exchangers, and pump motor oil coolers, respectively, are common to both units. During OPCON 5, the spent fuel pools can be cross-tied with RHR on the shutdown unit taking suction from the reactor cavity or fuel pool. However, as discussed in Sections 3.1,

9.1.3.2.3, 9.2.2, and 9.2.3, this cannot compromise the ability of the RHR system to perform its safety-related functions.

5.4.7.1.5 Design Basis for Reliability and Operability

The shutdown cooling mode of the RHR system can be controlled by the operator from the control room. The only operations required to be performed outside of the control room for a normal shutdown are manual operation of keep fill valves (condensate transfer) to prevent addition to the reactor, and local alignment of the C and D RHR pumps to the respective A and B RHR heat exchangers for operation of the C and D subsystems of shutdown cooling.

The use of the RHR ADHR method will require the installation of the RHR/FPC spool piece, the manual alignment of several valves, and adjustment of the fuel pool overflow weirs.

Two separate shutdown cooling heat exchanger loops are provided, each with two alignable RHR pumps, and although both heat exchanger loops may be employed for shutdown, the reactor coolant can be brought to 212°F in approximately 20 hours with only one heat exchanger loop in operation. Interties are provided between the suction and discharge lines of the RHR pump in the direct injection LPCI loop (C and D pumps) and the suction and discharge lines of the associated RHR pump in the heat exchanger loop (A and B pumps, respectively) to allow use of the C and D pumps in the shutdown cooling mode, thus providing greater maintenance flexibility. During the cold shutdown and refueling operation conditions, this results in the existence of four shutdown cooling subsystems, each comprised of one of the two heat exchangers with one of its two alignable RHR pumps (A heat exchanger with A RHR pump; A heat exchanger with C RHR pump; B heat exchanger with B RHR pump; and B heat exchanger with D RHR pump). With the exception of the shutdown suction and shutdown return lines, the entire RHR system is part of the ECCS and containment cooling systems and is therefore required to be designed with the redundancy, flooding protection, piping protection, power separation, etc., required of such systems (see Section 6.3 for an explanation of the design bases for ECCS systems). Shutdown suction and discharge valves are powered from both offsite and onsite emergency power for isolation and shutdown following a LOOP. If either of the two shutdown supply valves fails to

operate, the design basis states that an operator is sent to open the valve by hand. If this is not feasible, the shutdown line is isolated using manual valve F077 and repairs are made to the shutdown valves so that they can be opened to supply shutdown suction to the RHR pumps. Residual heat is absorbed by the main condenser or by the suppression pool with pool cooling by the RHR system while repairs are in process (see Section 5.4.7.5 for a discussion of an alternate shutdown cooling flow path).

To increase the reliability of RHR shutdown cooling mode during refueling outages, the automatic isolation function of the RHR shutdown cooling mode supply and return valves are typically bypassed provided that automatic isolation is not required by the Technical Specifications or Technical Requirements Manual. Manual isolation capability is retained.

The RHR ADHR block valve (051-1193 and 051-2193) will be normally locked open to provide additional assurance that the valve is not inadvertently closed. Closure of this valve has no impact on ESF functions but could delay the start of shutdown cooling mode.

A non-limiting single active failure is a loss of a shutdown cooling return valve or testable check valve. In this case the other RHR heat exchanger loop is used, or if two required operable shutdown cooling subsystems are on the same heat exchanger loop and manual actions to restore valve operability are not successful, cooling water flow may be returned to the vessel through the LPCI injection line.

5.4.7.1.6 Design Basis for Protection from Physical Damage

Evaluation of the RHR system with respect to the following areas is discussed in the indicated sections:

a.	Protection from wind and tornado effects	Section 3.3
b.	Flood design	Section 3.4
c.	Missile protection	Section 3.5
d.	Protection against dynamic effects associated with the postulated rupture of piping	Section 3.6
e.	Seismic events	Section 3.7
f.	Environmental design	Section 3.11
g.	Fire protection	Section 9.5

5.4.7.2 Systems Design

5.4.7.2.1 System Diagrams

All of the components of the RHR system are shown in the P&ID (drawing M-51). A description of the controls and instrumentation is presented in Section 7.3 and 7.4.

The RHR process diagram (drawing E11-1020-G-002) contains both the process diagram and process data. All of the sizing modes of the system are shown in the process data. The FCD for the RHR system is provided in Section 7.3.

Interlocks are provided to prevent:

a. Draining the vessel water to the suppression pool during shutdown.

b. Opening the vessel suction valves above the suction line design pressure or the discharge line design pressure, with the pumps at shutoff head.

c. Inadvertent opening of the drywell spray valves while in shutdown.

d. A pump start when the suction valve(s) is not open.

NOTE: The pump start interlock when the suction valve(s) is not open is defeated during operation of certain modes of RHR.

5.4.7.2.2 Equipment and Component Description

a. System pumps:

The RHR pumps are motor-driven deep-well pumps with mechanical seals and cyclone separators. The motors are air cooled by the ventilating system and by lube oil coolers. The pumps are sized on the basis of the LPCI mode (Mode A) and the minimum flow mode (Mode G) in drawing E11-1020-G-002. Design pressure for the pump suction is 220 psig, with a temperature range from 40°F to 360°F. Design pressure for the pump discharge is 500 psig. The bases for the design temperature and pressure are maximum shutdown cut-in pressures and temperature, minimum ambient temperature, and maximum shutoff head. The pump pressure vessel is carbon steel, and the shaft and impellers are stainless steel. Available NPSH is calculated according to Regulatory Guide 1.1 and is greater than the required NPSH for all operating modes. NPSH calculations for the LPCI mode are provided in Section 6.3.2.2.4.1.

The reliability of the RHR pumps at LGS is enhanced by their "deep draft" design, which is based on many years of experience in industrial and power plant application. While their use in nuclear power plant application is more recent, the same proven design principles have been used in successful industrial applications.

The RHR pumps are designed for the life of the plant (40 years) and are tested for operability assurance and performances as follows:

i. In-shop tests including: (1) hydrostatic tests of pressure-retaining parts at 150% of the design pressure; (2) performance tests while the pump is operated with flow to determine the total developed head at zero flow and design flow; and (3) NPSH requirements.

ii. After the pump is installed in the plant, it undergoes the: (1) system hydro tests; (2) functional tests; and (3) required periodic inservice inspection of approximately once every three months for approximately an hour during normal plant operation, and approximately one month of operation each year for shutdown.

iii. In addition, the pumps are designed for a postulated single operation of 100 days for one accident during the unit's 40 year life.

The following shows the maximum expected accumulated operating time for the life of the plant (40 years):

Mode of Operation	RHR (days)
In-Shop Test	1
Preoperation	3
Monthly Testing	9.2
Yearly Testing	1.7
Post-LOCA	365
Shutdown	2520
	2899.9*

Furthermore, Ingersoll-Rand pumps similar to the ones installed at LGS have been installed in operating plants and have accumulated significant successful operating experience.

* The above information provided on maximum accumulated RHR pump operating time for the life of the plant is historical and is based on original plant design conditions. The evaluation did not include any expected RHR pump operating time to maintain Suppression Pool temperature within specified operating limits during plant operation. Suppression Pool cooling operation to offset heat addition (such as HPCI runs or SRV leakage) up to 10% cumulative RHR runtime per unit per year is evaluated as acceptable use and is offset by shutdown usage (due to shorter outage lengths than the original evaluation).

A summary of experience of Ingersoll-Rand RHR pumps currently available to GE through 1981 is as follows:

			RHR (hours)
Hatch	RHR Pump	2A	864
		2B	1112
		2C	629
		2D	569
Chinshan 1	RHR Pump		100
Chinshan 2	RHR Pump		75

Maintenance was not required or performed during the running times listed above.

No problems have been reported on these pumps.

A comparison of the pumps cited for operating experience and the LGS pumps is as follows:

		HATCH	CHINSHAN	LGS
Column Length	RHR	241"	187"	138"

RPM	RHR	1800	1800	1200

Thus, it may be noted that the LGS pumps are conservatively represented by the operating experience in that they are shorter than the operating pumps and run at a slower speed. Both of these features are conservative because they make the pump less susceptible to vibration that causes degradation and wear. In this context, it should also be noted that the LGS pumps are much shorter than the deep draft pumps that have experienced vibration problems in the past.

b. Heat exchangers:

The RHR system heat exchangers are sized on the basis of the duty for the shutdown cooling mode (Mode E of the process data). All other uses of these exchangers require less cooling surface.

Flow rates are 10,000 gpm (rated) on the shell side and 9,000 gpm (rated) on the tube side (service water side). The rated inlet temperature is 125°F shell side and 85°F tube side for the shutdown cooling mode. The overall heat transfer coefficient is 225 Btu/hr-ft^2-°F. The exchangers contain 6,281 ft^2 (Unit 1 and Unit 2A) and 6,073.56 ft^2 (Unit 2B) of effective surface. The design temperature range of both shell and tube sides is 40°F to 470°F. The design pressure is 450 psig on both sides, and original design fouling factors are .0005 (Unit 1 & 2) shell side and 0.0018 (Unit 1), and 0.002 (Unit 2A) and 0.001 (Unit 2B) tube side. The construction materials are carbon steel for the pressure vessel with stainless steel tubes and stainless steel clad tube sheet. The condition of the heat exchangers is controlled by administrative and test procedures to assure that the required heat removal capability is maintained. Refer to Section 6.2 for heat removal requirements.

c. Valves:

All of the directional valves in the system are conventional gate, globe, butterflies and check valves designed for nuclear service. The injection valves and reactor coolant isolation valves are high speed valves, as operation for LPCI injection or vessel isolation requires. Valve pressure ratings are, as necessary, to provide the control or isolation function; i.e., all vessel isolation valves are rated as Class 1 nuclear valves rated at the same pressure as the primary system.

d. ECCS portions of the RHR system:

The ECCS portions of the RHR system include those sections described through Mode A-1 of drawing E11-1020-G-002.

The route includes suppression pool suction strainers, suction piping, RHR pumps, discharge piping, injection valves, and drywell piping into the vessel nozzles and core region of the reactor vessel.

Pool cooling components include pool suction strainers, suction piping, pumps, heat exchangers, and pool return lines. The suction strainers are described in Section 6.2.2.2.

Containment spray components are the same as pool cooling except that the spray headers replace the pool return lines.

5.4.7.2.3 Controls and Instrumentation

Controls and instrumentation for the RHR system are described in Chapter 7. The RHR system incorporates relief valves to prevent the components and piping from inadvertent overpressure conditions. The relief valve setpoint, capacity, and method of collection are shown in Table 5.4-3.

5.4.7.2.4 Applicable Codes and Classifications

a. Piping, pumps, and valves:

1.	Process side	ASME III	Class 2
2.	Service water side	ASME III	Class 3

b. Heat exchangers

1.	Process side	ASME III (Refer to Table 3.2-3)	Class C
2.	Service water side	ASME VIII	Division 1

c. Electrical portions

1. IEEE 279

2. IEEE 308

5.4.7.2.5 Reliability Considerations

The ECCS portion of the RHR system includes the redundancy requirements of Section 5.4.7.1.5. Two redundant heat exchanger loops are provided to remove residual heat, each with two alignable RHR pumps powered from separate emergency buses. Either heat exchanger loop is capable of cooling down the reactor within a reasonable length of time. During cold shutdown and refueling operation conditions, this results in the availability of four shutdown cooling subsystems. The shutdown cooling suction line from the recirculation suction piping is common to all four shutdown cooling subsystems, and each heat exchanger and its associated discharge piping is common to its two alignable RHR pumps (A and C RHR pumps for the A heat exchanger, B and D RHR pumps for the B heat exchanger). When aligned in the shutdown cooling mode of operation, each heat exchanger and its discharge piping are passive components that are assumed not to fail.

5.4.7.2.6 Manual Action

a. Residual heat removal (shutdown cooling mode)

To align a loop of the RHR system for shutdown cooling, the minimum flow and suppression pool suction valves are closed to prevent inadvertent drainage of reactor water to the suppression pool. The RHRSW pump on the selected loop is started. A preoperational flush of the RHR suction and most of the discharge piping is performed to prewarm piping and reactor cavity water clarity by flushing reactor water through it. During flushing the reactor water is discharged to the suppression pool

through the test return line in a controlled manner. After verifying that the discharge lines are full, the RHR pump is started. The operator controls the cooldown rate by regulating the reactor coolant flow through the heat exchanger by using the heat exchanger outlet bypass valve, the heat exchanger bypass valve, and the heat exchanger outlet valve in various combinations. The total flow can be throttled with the shutdown cooling return outboard isolation valve. All of these operations except initial alignment of a LPCI dedicated RHR pump (C or D pump) for shutdown cooling use can be performed from the control room.

The operator determines the cooldown rate by monitoring temperature change with time. When the process computer is available, the operator can assign the process computer points to use in the trend function. The computer then drives a strip-chart recorder with the data from the computed points. The operator can display temperature/time information graphically by calling up information on the process computer and manually plotting the temperature information versus time. The operator can monitor temperature directly on recorders that provide a permanent record of cooldown transient information.

The manual actions required for the most limiting failure are discussed in Section 5.4.7.1.5.

b. Steam condensing mode

As discussed in Section 5.4.7.1.1.5, all components comprising the steam condensing mode of the RHR system have either been abandoned in place or physically removed from the plant. Therefore, the mode is no longer functional.

5.4.7.3 Performance Evaluation

The thermal performance of the RHR heat exchangers is based on the residual heat generated at 20 hours after rod insertion, a 125°F vessel outlet (exchanger inlet) temperature, and the flow of two loops in operation. Because shutdown is usually a controlled operation, maximum service water temperature (95°F) less 10°F is used as the service water inlet temperature (i.e., 85°F). These are nominal design conditions; if the service water temperature is higher, the exchanger capabilities are reduced and the shutdown time may be longer, and vice-versa.

5.4.7.3.1 Shutdown with All Components Available

No typical curve is included here to show vessel cooldown temperatures versus time due to the infinite variety of such curves that may be generated due to the following:

a. Clean steam systems that may allow the main condenser to be used as the heat sink when nuclear steam pressure is insufficient to maintain steam-air ejector performance

b. The fouling condition of the exchangers

c. Operator use of one or two cooling loops

d. Service water temperature

e. System flushing time

Since the exchangers are designed for the fouled condition with relatively high service water temperature, the heat exchangers have excess capability to cool when first cut-in at high vessel temperatures. The total flow and mix temperature must be controlled to avoid exceeding a 100°F per hour cooldown rate. See Section 5.4.7.1.1.1 for the minimum shutdown time to reach 212°F.

5.4.7.3.2 Shutdown with Most Limiting Failure

Shutdown under conditions of the most limiting failure is discussed in Section 5.4.7.1.1.1. The capability of the heat exchanger for any time period is balanced against residual heat, pump heat, and sensible heat. The excess over residual heat and pump heat is used to reduce the sensible heat.

5.4.7.4 Preoperational Testing

The preoperational test program and startup test program as discussed in Chapter 14 are used to generate data to verify the operational capabilities of each piece of equipment in the system: each instrument, each setpoint, each logic element, each pump, each heat exchanger, each valve, and each limit switch. In addition these programs verify the capabilities of the system to provide the flows, pressures, condensing rates, cooldown rates, and reaction times required to perform all system functions as specified for the system or component in the system data sheets and process data. Logic elements are tested electrically; valves, pumps, controllers, and relief valves are tested mechanically; finally, the system is tested for total system performance against the design requirements as specified above using both the offsite power and standby emergency power. Preliminary heat exchanger performance can be evaluated by operating in the pool cooling mode, but a vessel shutdown is required for the final check due to the small temperature difference available with pool cooling.

5.4.7.5 Conformance to Regulatory Guide 1.139

Although the LGS design was completed before the issuance of this guide, which provides guidance on shutdown cooling mode design, the LGS design satisfies the intent of the guide, subject to the following clarifications:

a. Provisions of shutdown cooling, assuming the most limiting single active failure (loss of the common suction line due to valve failure to open), as discussed in paragraph C.1 of the regulatory guide, is accomplished by an alternate flow path. In the alternate method the RHR pump pumps from the suppression pool to the reactor vessel via the RHR heat exchanger. Flow returns from the vessel to the suppression pool via manually opened ADS valves. The LGS ADS valves are three-stage Target Rock valves. Their operability under the fluid conditions expected to occur during the alternate shutdown cooling mode has been demonstrated by generic testing described in topical report NEDE-24988-P/NEDO-24988.

   The test results documented in the topical report verify the adequacy of the LGS valve operation and integrity under the expected liquid discharge conditions. The loads on the valve and piping induced by the liquid discharge were shown to be lower than the high pressure steam discharge loads for which the system is designed. The test results also provide flow capacity information, which shows that sufficient shutdown cooling flow is provided through 1 or 2 valves.

A safety-grade pneumatic supply is available for ADS valve actuation, as discussed in Section 9.3.1. A variation of this method is to pump to the vessel with a Core Spray Loop and operate the RHR system in the suppression pool cooling mode.

b. Regarding paragraph C.2.a of the regulatory guide, which discusses reactor high pressure interlocks and alarms, LGS conforms with the intent in that the two suction valves are interlocked with reactor pressure; two out of two low reactor pressure signals must be present to permit opening. On a high pressure signal, the valves close and the pump trips. A pump trip activates an "RHR system out of service" alarm that annunciates in the main control room. There is no high pressure alarm per se. Loss of power to the valve control logic causes suction valve closure and pump trip.

   An additional interlock is provided for valve F008 to prevent a fire-induced valve open signal from causing both valves to open simultaneously while the reactor pressure is greater than the design capabilities of the RHR low-pressure piping.

c. Pressure relief is not provided for a pressure transient during operation as discussed in paragraph C.3 of the regulatory guide; however, no rapid pressurization mechanism is known for a BWR. Pressure may increase gradually, and the automatic high pressure valve interlocks (closed on high pressure) are considered adequate for this case.

d. The RHR design is considered to conform to the pump protection discussion in paragraph C.4 of the regulatory guide, in that the pump motor is equipped with thermal overload protection and the stator and bearing temperatures are monitored on the plant computer. Cavitation can be detected by the vibration.

   Pump cavitation/NPSH protection is provided by automatic pump trip if any of the three suction valves leaves the fully open position. Automatic valve closure and pump trip occurs at low reactor water level (level 3), which protects the pump from inadequate NPSH.

e. On-line testing capability of isolation valve operability and interlock circuits, as discussed in paragraph C.5 of the regulatory guide, is not provided. However, the system is periodically tested as discussed in Chapter 16.

5.4.8 REACTOR WATER CLEANUP SYSTEM

The RWCU system is classified as a primary power generation system (not an engineered safeguard feature), a small part of which is part of the RCPB up to and including the second isolation valve. The other portions of the system are not part of the RCPB and are isolatable from the reactor. The RWCU system may be operated at any time during reactor operations, or it may be shut down if water quality is within the Technical Specification limits.

5.4.8.1 Design Basis

5.4.8.1.1 Safety Design Basis

The RCPB portion of the RWCU system meets the requirements of Regulatory Guide 1.26 and Regulatory Guide 1.29 (Section 3.2) to:

a. Prevent excessive loss of reactor coolant

b. Prevent the release of radioactive material from the reactor

c. Isolate the major portion of the RWCU system from the RCPB

5.4.8.1.2 Power Generation Design Basis

The RWCU system performs the following functions:

a. Removes solid and dissolved impurities from reactor coolant, maintains reactor water purity, and measures the reactor water conductivity in accordance with Regulatory Guide 1.56.

b. Discharges excess reactor water during startup, shutdown, and hot standby conditions to the main condenser, condensate storage tank (CST), or radwaste system.

c. Minimizes temperature gradients in the main recirculation piping and RPV during periods when the main recirculation pumps are unavailable.

d. Minimizes the RWCU system heat loss.

e. Enables the major portion of the RWCU system to be serviced during reactor operation.

f. Prevents the standby liquid reactivity control material from being removed by the RWCU system when required for shutdown.

g. Provide a means for monitoring the effectiveness of the Noble Metals Chemical Addition. An ECP monitor measures the electrochemical corrosion potential of the reactor water with respect to the Noble Metals treated piping. A Durability Monitor provides a source of tubing samples which can be analyzed to determine the surface density and wear rate of the deposition of the Noble Metals. A Data Acquisition System collects and stores the flow, temperature and ECP data from the Noble Metals Monitoring System.

5.4.8.2 System Description

The system takes its suction from the inlet of the "B" reactor main recirculation pump and from the RPV bottom head. The process fluid is circulated with the cleanup pump(s) through a regenerative and nonregenerative heat exchanger for cooling, through filter/ demineralizers for cleanup, and back through the regenerative heat exchanger for reheating. The processed water is returned to the RPV and/or the main condenser, CST, or radwaste (drawings M-44 and G31-1030-G-001).

The major equipment of the RWCU system is located outside the drywell. This equipment includes pumps, regenerative and nonregenerative heat exchangers, and filter/demineralizers with precoat equipment. Flow rate capacities for the major pieces of equipment are presented in Table 5.4-2.

The temperature of the filter/demineralizer units is limited by the resin operating temperature. Therefore the reactor coolant is cooled before being processed in the filter/demineralizer units. The regenerative heat exchanger transfers heat from the tube side (hot process inlet) to the shell side

(cold process inlet). The shell side flow returns to the reactor. The nonregenerative heat exchanger cools the process further by transferring heat to the reactor enclosure closed cooling water system.

The filter/demineralizer units (drawing M-45) are pressure precoat-type filters using filter aid and powdered, mixed ion exchange resins. Spent resins are nonregenerative and are sluiced from the filter/demineralizer unit to a backwash receiving tank from which they are transferred to the radwaste system for processing and disposal. To limit resins from entering the reactor recirculation system if there is failure of a filter/demineralizer resin support, a strainer is installed on the filter/demineralizer unit. Each strainer and filter/demineralizer vessel has a control room alarm that is energized by high differential pressure. On further increase in differential pressure from the alarm point, the filter/demineralizer automatically isolates.

The backwash and precoat cycle for a filter/demineralizer unit is entirely automatic to prevent human operational errors, such as inadvertent opening of valves, that would initiate a backwash or contaminate the reactor water with resins. The filter/demineralizer piping configuration is arranged to ensure that transfers are complete and crud traps are eliminated. A bypass line is provided around the filter/demineralizer units.

If there is low flow or loss of flow in the system, flow is maintained through each filter/demineralizer by its own holding pump.

Sample points are provided in the common influent header and in each effluent line of the filter/demineralizer units for continuous indication and recording of system conductivity to ensure that the reactor coolant quality is within limits, and as a check of filter/ demineralizer effectiveness. High conductivity is annunciated in the control room. The control room alarm setpoints for conductivity at the inlet and outlet of the filter/demineralizers are 1.0 μmho/cm and 0.1 μmho/cm, respectively. The effluent setpoint indicates impending resin exhaustion and, therefore, forestalls breakthrough of solubles, usually chlorides. The influent sample point is also used as the normal source of reactor coolant grab samples. Reactor water chloride content and pH will be determined from grab samples taken and analyzed in accordance with approved plant procedures. Additional water quality limits and corrective actions to be taken will be specified in the Technical Specifications.

A Noble Metals Monitoring System sample bypasses the RWCU system from the Regenerative Heat Exchanger Tube Side Inlet Piping to the Shell Side Outlet. An ECP Monitor, measures the electrochemical corrosion potential of the reactor water with respect to the piping. A Durability Monitor provides a source of tubing samples which can be analyzed to determine the surface density and wear rate of the deposition of the Noble Metals. A Data Acquisition System collects and stores the flow, temperature and ECP data from the Noble Metals Monitoring System.

The suction line (RCPB portion) of the RWCU system contains two motor-operated isolation valves, which automatically close in response to signals from reactor low water level, leak detection system, actuation of the SLCS, and nonregenerative heat exchanger high outlet temperature. Section 7.6 describes the leak detection requirements, and they are summarized in Table 5.2-7. This isolation prevents the loss of reactor coolant and release of radioactive material from the reactor, prevents removal of liquid reactivity control material by the cleanup system if the SLCS is in operation, and prevents damage of the filter/demineralizer resins due to high temperature. The RCPB isolation valves may be remotely manually operated to isolate the system equipment for maintenance or servicing. The requirements for the RCPB are specified in Section 5.2.

A remote manually operated spring assisted check valve and a simple check valve in the RWCU return line to feedwater provides instantaneous reverse flow isolation. The spring assisted check

valve is a containment isolation valve and is remote manually closed for long term leakage control as described in Section 6.2.4.

A motor operated globe valve in the return line to the reactor is provided for system flow control (throttling) and system isolation for maintenance.

The operation of the RWCU system is controlled from the control room. Resin changing operations, which include backwashing and precoating, are controlled from a local control panel. The time required to remove a unit from the line, backwash, and precoat is approximately 1 hour.

A FCD is provided in Section 7.7.

5.4.8.3 System Evaluation

The RWCU system in conjunction with the condensate cleanup system, and the FPCC system, maintains reactor water quality during all reactor operating modes (normal, hot standby, startup, shutdown, and refueling).

This type of "pressure precoat" cleanup system was first put into operation in 1971 and is used in all operating BWR plants that have been placed in operation since. Operating plant experience has shown that the RWCU system as designed in accordance with these criteria provides the required BWR water quality. The nonregenerative heat exchanger is sized to maintain the required process temperature for filter demineralization even when the cooling capacity of the regenerative heat exchanger is reduced due to bypassing a portion of the return flow to the main condenser, CST, or radwaste. The control requirements of the RCPB isolation valves are designed to the requirements of Section 7.3.1. The component design data (flow rates, pressure, and temperature) are presented in Table 5.4 2. All components are designed to the requirements listed in Section 3.2, according to the requirements of the P&IDs (drawings M-44 and M-45).

5.4.9 MAIN STEAM LINE AND FEEDWATER PIPING

The main steam piping is described in Section 10.3. The feedwater piping is described in Section 10.4.7. Additional design information concerning these lines is found in Sections 3.6, 3.9, and 5.2.

5.4.10 PRESSURIZER

Not applicable to BWRS

5.4.11 PRESSURIZER RELIEF DISCHARGE SYSTEM

Not applicable to BWRS

5.4.12 VALVES

5.4.12.1 Safety Design Bases

Line valves such as gate, globe, and check valves are located in the fluid systems to perform a mechanical function. Valves are components of the system pressure boundary and, having moving parts, are designed to operate efficiently to maintain the integrity of this boundary.

The valves operate under the internal pressure/temperature loading as well as the external loading experienced during the various system transient operating conditions. The design criteria, the design loading, and acceptability criteria are as discussed in Section 3.9.3 for ASME Class 1, 2, and 3 valves. Compliance with ASME Codes is discussed in Section 5.2.1.

5.4.12.2 Description

Line valves furnished are manufactured standard types, designed and constructed in accordance with the requirements of ASME Section III for Class 1, 2, and 3 valves. All materials exclusive of seals, packing, and wearing components are designed to endure the 40 year plant life under the environmental conditions applicable to the particular system when appropriate maintenance is periodically performed.

Power operators have been sized to operate successfully under the maximum differential pressure determined in the design specification.

5.4.12.3 Safety Evaluation

Line valves are shop tested by the manufacturer for performability. Pressure-retaining parts are subject to the testing and examination requirements of ASME Section III. To minimize internal and external leakage past seating surfaces, maximum allowable leakage rates are stated in the design specifications for the back-seat as well as the main seat for gate and globe valves.

Valve construction materials are compatible with the maximum anticipated radiation dose for the service life of the valves.

5.4.12.4 Inspection and Testing

Valves that serve as containment isolation valves and must remain closed or open during normal plant operation may be partially exercised during this period to ensure their operability at the time of an emergency or faulted conditions. Other valves, serving as a system block for throttling valves, may be exercised when appropriate.

Leakage from critical valve stems is monitored by the use of double-packed stuffing boxes with an intermediate lantern leak-off connection for detection and measurement of leakage rates.

Motors used with valve actuators are furnished in accordance with applicable industry standards. Each motor actuator is assembled, factory tested, and adjusted on the valve for proper operation, position and torque switch setting, position transmitter function (where applicable), and speed requirements. Valves are additionally tested to demonstrate adequate stem thrust (or torque) capability to open (or close) the valve within the specified time at specified differential pressure. Tests verify that there is no mechanical damage to valve components during full stroking of the valve. Suppliers are required to furnish assurance of acceptability of the equipment for the intended service based on any combination of the following:

a. Test stand data

b. Prior field performance

c. Prototype testing

d. Engineering analysis

Preoperational and operational testing performed on the installed valves consists of total circuit checkout and performance tests to verify speed requirements for specified differential pressure.

5.4.13 SAFETY AND RELIEF VALVES

5.4.13.1 Safety Design Bases

Overpressure protection is provided at isolatable portions of systems in accordance with the rules set forth in ASME Section III, for Class 1, 2, and 3 components.

5.4.13.2 Description

Pressure relief valves are designed and constructed in accordance with the same code class as that of the line valves in the system.

Table 3.2-1 lists the applicable code classes for valves, and system design pressures and temperatures are given in Section 5.2.2.4.2.1. The design criteria, design loadings, and design procedures are described in Section 3.9.3.

5.4.13.3 Safety Evaluation

The use of pressure-relieving devices ensures that overpressure does not exceed 10% above the design pressure of the system. The number of relieving devices on a system or portion of a system is determined on this basis.

5.4.13.4 Inspection and Testing

No provisions are to be made for in-line testing of pressure relief valves. Certified set pressures and relieving capacities are stamped on the body of the valves by the manufacturer, and further examinations would necessitate removal of the component.

5.4.14 COMPONENT SUPPORTS

Support elements are provided for the components included in the RCPB and the connected systems.

5.4.14.1 Design Bases

Design loading combinations, design procedures, and acceptability criteria are described in Section 3.9.3. Stress analysis calculations for ASME Section III, Class 1, 2, and 3, and ANSI B31.1 piping conform to the requirements of the appropriate code.

The spacing and size of pipe support elements are based on piping stress analyses performed in accordance with the appropriate codes and as further described in Section 3.7.

Materials, fabrication, and inspection of pipe supporting elements for nuclear piping are in accordance with the USAS B31.7 "Nuclear Power Piping" code, the 1969 issue through the 1971 addenda. Pipe supporting elements for conventional steam and service piping are in accordance with the Code for Power Piping, ANSI B31.1 through the Winter 1974 addenda.

5.4.14.2 Description

The use of rigid-type supports, variable or constant spring-type supports, snubbers, and anchors is determined by stress analysis performed on the piping system. Component support elements are generally manufacturers' standard items.

5.4.14.3 Safety Evaluation

Design loadings used for the determination of component support systems included transient loading conditions expected by each component. Provisions are made to prevent damage to the piping system and the spring-type supports during initial deadweight loading due to hydrostatic testing.

5.4.14.4 Inspection and Testing

After completion of the installation of a support system, component support elements are visually examined to ensure that they are in correct adjustment to their cold setting positions. Verification of satisfactory component support performance is made in accordance with the requirements of Chapter 14.

Table 5.4-3
RHR SYSTEM RELIEF VALVE DATA

VALVE LOCATION	VALVE NO.	SETPOINT (psig)	CAPACITY (gpm)[1]	METHOD OF COLLECTION[3]
Shutdown supply line (outside containment)	PSV-1F029	140	10	RW
Pump suction line	PSV-1F030 A,B,C&D	170	10	Suppression pool
Pump discharge line	PSV-1F025 A,B,C,D	420	10	RW
Heat exchanger (shell side)[2]	PSV-106 A,B	450	Thermal relief only	Suppression pool
Heat exchanger (tube side)[2]	PSV-105 A,B	450	Thermal relief only	RW
Thermal relief valve on shutdown cooling suction line (inside containment)	PSV-155	1200	2	RW
Thermal relief valve on head spray line, Unit 1 only (ABANDONED)	PSV-122	1200	2	RW

(1) Capacity is based on setpoint plus 10% accumulation
(2) GE supplied valves
(3) RW = liquid radwaste collection system

Figure Marked *"Historical"*
Reference Figure 1.2-84, "Reactor System Heat Balance," for current operating conditions

	Pressure (psai)	Flow (lb/hr)	Temperature (° F)	Enthalpy (Btu/lb)
1. Core Inlet	1091	100.0×10^6	535	530.7
2. Core Outlet	1071	100.0×10^6	553	650.0
3. Separator Outlet (Steam Dome)	1060	14.986×10^6	552	1190.7
4. Steam Line (Turbine Inlet)	1005	14.986×10^6	545	1190.7
5. Feedwater Inlet (includes RWCU)	1088	15.087×10^6	425	403.3
6. Recirculation Pump Suction	1066	33.0×10^6	535	530.6
7. Recirculation Pump Discharge	1248	33.0×10^6	536	531.4

CHAPTER 6 - ENGINEERED SAFETY FEATURES

TABLE OF CONTENTS

6.0 INTRODUCTION

6.1 ENGINEERED SAFETY FEATURE MATERIALS

6.1.1 Metallic Materials
6.1.1.1 Materials Selection and Fabrication
6.1.1.1.1 NSSS Supplied Components
6.1.1.1.2 Non-NSSS Supplied Components
6.1.1.1.3 Controls for Austenitic Stainless Steel
6.1.1.2 Composition, Compatibility, and Stability of Containment and Core Spray Coolants

6.1.2 Organic Materials
6.1.2.1 NSSS Supplied Components
6.1.2.2 Non-NSSS Supplied Components
6.1.2.3 Insoluble Debris

6.1.3 Postaccident Chemistry

6.2 CONTAINMENT SYSTEMS

6.2.1 Containment Functional Design
6.2.1.1 Pressure-Suppression Containment
6.2.1.1.1 Design Bases
6.2.1.1.2 Design Features
6.2.1.1.3 Design Evaluation
6.2.1.1.4 Negative Pressure Design Evaluation
6.2.1.1.5 Steam Bypass of the Suppression Pool
6.2.1.1.6 Suppression Pool Dynamic Loads
6.2.1.1.7 Asymmetric Loading Conditions
6.2.1.1.8 Containment Environment Control
6.2.1.1.9 Postaccident Monitoring
6.2.1.2 Containment Subcompartments
6.2.1.3 Mass and Energy Release Analyses for Postulated LOCAs
6.2.1.3.1 Mass and Energy Release Data
6.2.1.3.2 Energy Sources
6.2.1.3.3 Reactor Blowdown Model Description
6.2.1.3.4 Effects of Metal-Water Reaction
6.2.1.3.5 Thermal-Hydraulic Data for Reactor Analysis
6.2.1.4 Pressurized Water Reactor - Not Applicable
6.2.1.5 Pressurized Water Reactor - Not Applicable
6.2.1.6 Testing and Inspection
6.2.1.7 Instrumentation Requirements
6.2.1.8 Containment System Response at Rerate Power

TABLE OF CONTENTS (Cont'd)

6.2.2 Containment Heat Removal System
6.2.2.1 Design Bases
6.2.2.2 System Design
6.2.2.3 Design Evaluation
6.2.2.4 Tests and Inspections
6.2.2.5 Instrumentation Requirements

6.2.3 Secondary Containment Functional Design
6.2.3.1 Design Bases
6.2.3.2 System Design
6.2.3.2.1 Secondary Containment Design

CHAPTER 6 - ENGINEERED SAFETY FEATURES

6.0 INTRODUCTION

Engineered safety features are provided to mitigate the consequences of postulated serious accidents, even though these accidents are very unlikely. The following ESFs are discussed in this chapter:

a. Containment systems (Section 6.2)

1. Primary containment
2. Secondary containment
3. Containment heat removal system
4. Containment isolation system
5. Containment atmospheric control system

b. ECCS (Section 6.3)

1. HPCI system
2. ADS
3. Core spray system
4. LPCI system

c. Control room habitability system (Section 6.4)

d. Fission product removal and control systems (Section 6.5)

In addition to the ESFs discussed in this chapter, other ESF systems discussed elsewhere are provided to limit the consequences of postulated accidents. The ESF systems are described in the sections of Chapter 6 and those sections referenced in Table 6.1-1; therefore, no optional sections are required.

The information provided herein demonstrates the following:

a. The concepts on which the operation of each system is predicated have been proven by tests under simulated accident conditions and/or by conservative extrapolations from present knowledge and experience.

b. Component reliability, system interdependency, redundancy, and separation of components or portions of systems, etc., ensure that the ESF accomplishes its intended purpose and functions for the period required.

c. Provisions for testing, inspection, and surveillance are made to ensure that the ESF is dependable and effective on demand.

d. The material used can withstand the postulated accident environment, including radiation levels, and the radiolytic decomposition products that may occur cannot interfere with any ESF.

6.1 ENGINEERED SAFETY FEATURE MATERIALS

The materials used in the LGS ESF systems have been selected on the basis of an engineering review and evaluation for compatibility with:

a. The normal and accident service conditions of the ESF system

b. The normal and accident environmental conditions associated with the ESF system

c. The maximum expected normal and accident radiation levels to which the ESF system will be subjected

d. Other materials to preclude material interactions that could potentially impair the operation of the ESF systems

The materials selected for the ESF systems are expected to function satisfactorily in their intended service without adverse effects on the service, performance, or operation of any ESF.

6.1.1 METALLIC MATERIALS

In general, metallic materials used in ESF systems comply with the material specifications of ASME Section II. Pressure-retaining materials of the ESF systems comply with the quality requirements of their applicable quality group classification and ASME Section III classification. Adherence to these requirements ensures that materials for the ESF systems are of the highest quality. Where it is not possible to adhere to the ASME material specifications, metallic materials have been selected in compliance with other nationally recognized standards, e.g., ASTM, where practicable, or chosen in compliance with current industry practice.

6.1.1.1 Materials Selection and Fabrication

Metallic materials in ESF systems have been selected for a service life of 40 years, with due consideration of the effects of the service conditions on the properties of the material, as required by ASME Section III, Articles NB-2160, NC-2160, and ND-2160.

Pressure-retaining components are designed with appropriate corrosion allowances, considering the service conditions to which the material will be subjected, in accordance with the general requirements of ASME Section III, Articles NB-3120, NC-3120, and ND-3120.

6.1.1.1.1 NSSS Supplied Components

6.1.1.1.1.1 NSSS Material Specifications

Table 6.1-2 lists the principal pressure-retaining materials and the appropriate material specifications for the NSSS supplied ESF components.

6.1.1.1.1.2 Compatibility of NSSS Construction Materials with Core Cooling Water and Containment Sprays

Section 5.2.3.2.3 discusses compatibility of the reactor coolant with construction materials exposed to the reactor coolant. These same construction materials are found in other ESF components.

6.1.1.1.1.3 Controls for Austenitic Stainless Steel

a. Control of the use of sensitized stainless steel

   Where practicable, stainless steel with a carbon content of less than 0.02% is used.

   Controls to avoid severe sensitization are discussed in Section 5.2.3.4.1.1. Compliance with Regulatory Guide 1.44 is discussed in Section 5.2.3.4.

b. Process controls to minimize exposure to contaminants

   Process controls for austenitic stainless steel and compliance with Regulatory Guide 1.37 are discussed in Section 5.2.3.4.

c. Use of cold-worked austenitic stainless steel

   Cold-worked austenitic stainless steel with a yield strength greater than 90,000 psi is not used in ESF systems.

d. Avoidance of hot-cracking of stainless steel

   Process controls to avoid hot-cracking and compliance with Regulatory Guide 1.31 are discussed in Section 5.2.3.4.

6.1.1.1.2 Non-NSSS Supplied Components

6.1.1.1.2.1 Non-NSSS Material Specifications

Material specifications for the principal pressure-retaining ferritic, austenitic, and nonferrous metals for non-NSSS supplied components are listed in Table 6.1-3.

6.1.1.1.2.2 Compatibility of Non-NSSS Construction Materials with Core Cooling Water and Containment Sprays

Materials that would be exposed to the core cooling water and containment sprays if there is a LOCA are identified in Table 6.1-3. The metallic materials of the ESF systems have been evaluated for their compatibility with core cooling water and containment sprays. Demineralized water, with no additives, is employed for core cooling water and containment sprays. No radiolytic or pyrolytic decomposition of ESF material can occur during accident conditions, and the integrity of the containment or function of any other ESF cannot be affected by the action of core cooling water or containment spray systems.

6.1.1.1.3 Controls for Austenitic Stainless Steel

a. Control of the use of sensitized stainless steel

Design specifications call for ASME material, which is to be supplied in the solution annealed condition. Design specifications prohibit the use of materials that have been exposed to sensitizing temperatures in the range of 800°F to 1500°F unless they are subsequently solution annealed and water quenched or bright annealed. Where practicable, stainless steel with a carbon content of less than 0.02% is used. Compliance with Regulatory Guide 1.44 is discussed in Section 5.2.3.4.

b. Process controls to minimize exposure to contaminants

Design specifications for austenitic stainless steel components require that the material be cleaned using low halide cleaning solutions and that special care be exercised in the fabrication, shipment, storage, and construction to avoid contaminants. Conformance with Regulatory Guide 1.37 is discussed in Section 5.2.3.4.

c. Use of cold-worked austenitic stainless steel

Cold-worked austenitic stainless steels with yield strengths greater than 90,000 psi are not used in ESF systems. Therefore, there are no compatibility problems with core cooling water or the containment sprays.

d. Use of nonmetallic thermal insulation for austenitic stainless steel

Austenitic stainless steel piping inside the primary containment is insulated with nonmetallic thermal insulating materials. These nonmetallic insulating materials are either jacketed or encapsulated in stainless steel to protect against water entry. (Nukon insulation is not required to be jacketed or encapsulated since it meets all G.E. specifications requirements for leachable chlorides, fluorides, sodium and silicates without jacketing.) Leachable concentrations of chlorides, fluorides, sodium, and silicates for all nonmetallic insulation on austenitic stainless steel inside the primary containment meet the positions of Regulatory Guide 1.36. Conformance with Regulatory Guide 1.36 is discussed in Section 5.2.3.2.

e. Avoidance of hot-cracking of stainless steel

Process controls to avoid hot-cracking and compliance with Regulatory Guide 1.31 are discussed in Section 5.2.3.4.

6.1.1.2 Composition, Compatibility, and Stability of Containment and Core Spray Coolants

The HPCI system is supplied from either the CST or the suppression pool. The core spray and LPCI are supplied from the suppression pool only. The containment spray mode of the RHR system, which uses the suppression pool as its source of supply, does not induce radiolytic or pyrolytic decomposition of ESF materials.

The Suppression Pool and CST water chemistry is normally maintained within the following guidelines:

a. pH: 5.3 to 8.6 at 25°C

b. Chloride: <0.5 ppm

c. Conductivity: <10 μmho/cm at 25°C

No corrosion inhibitors or other additives are present in either the CST water or the suppression pool water.

The makeup water for the SLCS (SLCS is not an ESF system but does have a safety-related function and is described in Section 9.3.5), is supplied from the demineralized water storage tank. The makeup water for the CST is supplied from both the demineralized water storage tank and treated liquid radwaste. The makeup water to the suppression pool can be supplied from either the CST or the Refueling Water Storage Tanks. Water supplied to the demineralized water storage tank and the CST is continuously monitored by conductivity measuring devices that initiate alarms and divert flow to waste on high conductivity. Treated liquid radwaste is sampled and analyzed prior to transfer to the CST. This ensures water quality.

Chloride concentration in the SLCS tank is controlled by specifications on the sodium pentaborate and the demineralized water that is added to the tank.

Water quality is maintained in the CST by using the "A" condensate filter/demineralizer to remove impurities from the water. CST water is processed from the CST with the refueling water transfer pump and refueling water transfer system. Water quality is maintained in the suppression pool by a bleed and feed method. Water is drained from the suppression pool with the suppression pool cleanup pump. This water goes to the hotwell for cleanup with the condensate cleanup system. Makeup water comes from the CST.

6.1.2 ORGANIC MATERIALS

Tables 6.1-4 and 6.1-5, respectively, list the significant organic materials and coatings that exist within the primary containment. These materials in ESF components have been evaluated with regard to the expected service conditions and have been found to have no adverse effects on service, performance, or operation.

6.1.2.1 NSSS Supplied Components

The only significant organic materials on NSSS equipment are the protective coatings used on carbon steel components. Most of the equipment is painted with a primer coat of inorganic zinc. The quality assurance requirements in Regulatory Guide 1.54 were not imposed on painting material and paint application, because most equipment was ordered before the issuance of the guide.

Equipment specifications in place at the time of ordering much of the LGS equipment specified a primer coat of inorganic zinc. These coatings are not considered qualified under the guide because the specifications did not require the near white blasted surface needed to meet nuclear qualification.

The total amount of unqualified paint in the containment on NSSS equipment is estimated to be less than 12 kg. Equipment tightly covered with thermal insulation is not included in this total because potential paint debris could not escape to the suppression pool during a LOCA.

6.1.2.2 Non-NSSS Supplied Components

The drywell liner is coated with modified phenolic epoxy, and exposed metal surfaces inside the drywell are coated with an inorganic zinc compound. These coatings have been qualified in accordance with ANSI N101.2. No radiolytic or pyrolytic decomposition or interaction with other ESF materials can occur.

The suppression pool liner is coated with an inorganic zinc compound that has been qualified in accordance with ANSI N101.2. Since the failure mode of inorganic zinc coatings is particulate rather then flaking in nature, this amount is not considered significant. No radiolytic or pyrolytic decomposition or interaction with other ESF materials can occur.

Non-NSSS coating practice and procedures are in conformance with ASTM D3843-93 as discussed in the Quality Assurance Topical Report (NO-AA-10).

6.1.2.3 Insoluble Debris

Insoluble debris formed under DBA conditions inside containment, from unqualified organic paint surfaces and from corrosion products from galvanized steel and zinc paints without qualified organic top coats, will not adversely affect the performance of the LGS RHR or the containment spray systems which take suction from the suppression pool.

a. The total amount of unqualified paint on both non-NSSS and NSSS supplied components has been reviewed and is summarized below. All coatings on non-NSSS equipment within the primary containment are qualified with the following exceptions:

    1. Unqualified primers and mill coats have been applied to pipe, inside the drywell, that has insulation covering the coating. The insulation will prevent any potential debris from entering the suppression pool.

NOTE: The information presented above regarding the quality of unqualified coatings in the primary containment is historical and is based on an original design estimate and does not represent the current unqualified coatings inventory. Unqualified coatings in the primary containment are administratively controlled to ensure that the design basis limits for debris are not exceeded.

    2. Heavy support steel in the drywell is coated with an inorganic zinc coating that passed DBA testing and is fully documented. Unqualified coatings on NSSS equipment have been reviewed and found to be less than 11.7 kg in total, as identified in Table 6.1-6. NSSS equipment has either 2-5 mils coating of inorganic zinc or 3-6 mils organic coating. The major equipment, the recirculation pump motors, have two coats of epoxy paint at 3-6 mils per coat.

b. The following discussion explains why insoluble debris from unqualified organic paints and corrosion products from galvanized steel and zinc paints without qualified organic top coat will not adversely affect the performance of the RHR or containment spray systems.

    As discussed above, the only unqualified organic paints that could reach the suppression pool are on NSSS equipment. Due to the limited supply of NSSS unqualified paint noted in Table 6.1-6, it is not expected that the ECCS suction strainers would be sufficiently plugged so as to impair ECCS or containment spray

performance. The redundant pair of suction strainers on each HPCI and RCIC suction line are sized to provide the design flow rate with each of the strainers 50% plugged and are centered approximately midway between the suppression pool surface and wetwell floor. The RHR and Core Spray strainers are designed based on debris loading and zone of influence of the worst case pipe location. The suction strainers are discussed in detail in Section 6.2.2.2.

Galvanized steel and zinc paints without qualified organic top coats were used for various applications in the primary containment. The demineralized suppression pool water, which is used for containment spray, is maintained near-neutral and the containment atmosphere is inerted during plant operating conditions to reduce the corrosion of exposed galvanized steel or zinc paints to the lowest possible rate. Typical zinc corrosion products produced in a neutral or near-neutral environment are zinc oxide and zinc carbonate. They are loosely adherent fluffy white substances. Because the zinc corrosion products are loosely adherent, they will not plug the ECCS suction strainers, containment spray nozzles, or ECCS pump seal flushing water circuits.

6.1.3 POST-ACCIDENT CHEMISTRY

This section is not applicable to BWR plants.

NOTE: The information presented above regarding the quality of unqualified coatings in the primary containment is historical and is based on an original design estimate and does not represent the current unqualified coatings inventory. Unqualified coatings in the primary containment are administratively controlled to ensure that the design basis limits for debris are not exceeded.

(1) Material may be subjected to containment spray or core cooling water if there is a LOCA.
(2) See Table 6.1-2 for material designations.

Table 6.1-4

ORGANIC MATERIALS WITHIN THE PRIMARY CONTAINMENT

MATERIAL	USE	QUANTITY
Kerite Type FR-HT/ Kerite Type FR	Low voltage electrical power cable jacketing and insulation material	Throughout drywell
EPR/hypalon	Medium voltage electrical power cable jacketing and insulation material	Throughout drywell
XLPE	Instrumentation cable insulation/jacketing material	Throughout drywell
XLPE/neoprene	Instrumentation cable insulation/jacketing material	Throughout drywell
Cross-linked polyolefin/ alkaneimide polymer	Instrumentation coaxial and triaxial insulation/ jacketing material	Throughout drywell
Lube oil	Reactor recirculation pump motor (two motors per unit)	120 gal Unit 1 208 gal Unit 2
Gear lube	Valve motor operators	206 lbs per unit
Silicone rubber	Drywell duct-work and damper gaskets and seals	Throughout drywell
Cross-linked polyethylene/ chlorinated polyethylene	480VAC and 120VAC outage power cable insulation/ jacketing material	Throughout drywell (396 lbs per Unit)
Cross-linked polyethylene (XLPE) and polyvinyl chloride (PVC)	Armored coaxial cable for video signals from drywell video cameras, also armored multiconductor cable for drywell video camera control and audio signals. XLPE is used as insulating material, PVC as jacketing material.	Throughout drywell

(1) Generic coating systems acceptable for containment use have been selected from suppliers who are prequalified to project standards and test criteria. Systems other than those listed are acceptable for specific units based on analysis of requirements.
(2) Concrete coating limited to minimum area required for decontamination purposes.
(3) No coating needed since material is galvanized.
(4) No coating needed since aluminum is used.
(5) No coating needed since material is stainless steel.
(6) Cables are insulated (EPR insulation and polyolefin insulation).
(7) Exterior coating system is identical to the pipe system in which the valve is installed.
(8) Bakelite is used inside terminal boxes.

Table 6.1-6

ESTIMATED WEIGHT OF UNQUALIFIED PAINT
ON NSSS CONTAINMENT EQUIPMENT

COMPONENT	WEIGHT (lbs)
Nuclear Boiler System	3.8
Reactor Recirculation System	6.9
CRD System	6.7
In-Vessel Service Equipment	<0.1
Under-Vessel Servicing Equipment	6.0
RWCU System	<0.4
RWCU Filter/Demineralizer System	1.9
TOTAL	25.8
	(11.7 kg)

NOTE: The information presented above regarding the quality of unqualified coatings in the primary containment is historical and is based on an original design estimate and does not present the current unqualified coatings inventory. Unqualified coatings in the primary containment are administratively controlled to ensure that the design basis limits for debris are not exceeded.

6.2 CONTAINMENT SYSTEMS

6.2.1 CONTAINMENT FUNCTIONAL DESIGN

6.2.1.1 Pressure-Suppression Containment

6.2.1.1.1 Design Bases

The pressure-suppression containment system is designed to have the following functional capabilities:

a. The containment has the capability to maintain its functional integrity during and following the peak transient pressures and temperatures which would occur following any postulated LOCA. The design basis LOCA includes the worst single active failure (which leads to maximum containment pressure and temperature) and is further postulated to occur simultaneously with LOOP and a SSE. A discussion of the LOCA events is contained in Section 6.2.1.1.3.3.

b. The containment, in combination with other accident mitigation systems, limits fission product leakage during and following the postulated DBA to values less than leakage rates that would result in offsite doses greater than those set forth in 10CFR50.67.

c. The containment system can withstand coincident fluid jet forces associated with the flow from the postulated rupture of any pipe within the containment.

d. The containment is designed to accommodate flooding up to the refueling floor elevation to permit removal of fuel assemblies from the reactor core after the postulated LOCA.

e. The containment system is protected from and designed to withstand missiles from internal sources and excessive motion of pipes that could directly or indirectly endanger the integrity of the containment.

f. The containment system provides the means to channel the flow from postulated pipe ruptures in the drywell to the pressure-suppression pool.

g. The containment system is designed to allow for periodically conducted tests at the peak pressure calculated to result from the postulated DBA in order to confirm the leak-tight integrity of the containment and its penetrations.

h. The containment system is provided with pressure relief capability for use following a postulated accident accompanied by the loss of containment heat removal capability when high containment radiation levels do not exist.

6.2.1.1.2 Design Features

Section 3.8 describes the design features of the containment structure and internal structures. Figures 3.8-1 through 3.8-8 show the general arrangement of the containment and internal structures.

6.2.1.1.2.1 Protection from Dynamic Effects

The containment structure and ESF system functions are protected from dynamic effects of postulated accidents as described in Sections 3.5 and 3.6.

6.2.1.1.2.2 Codes, Standards, and Guides

Table 3.8-1 lists the applicable codes, standards, guides, and specifications for the containment structure and internal structures.

6.2.1.1.2.3 Functional Capability Tests

The functional capability of the containment structure is verified by:

a. Pressure testing the containment structure to 1.15 times the design pressure as required by Regulatory Guide 1.18 (Rev 1), and

b. Leak rate testing the containment structure to the design accident pressure as required by 10CFR50, Appendix J.

Refer to Sections 3.8.1.7, 3.8.2.7, 3.8.3.7, and 6.2.6 for a description of the structural integrity test and the integrated leak rate test.

6.2.1.1.2.4 External Pressure Loading Conditions

The containment structure is designed for an external to internal differential pressure of 5 psid.

6.2.1.1.2.5 Trapped Water that Cannot Return to Containment Sump

Not applicable to pressure-suppression containment.

6.2.1.1.2.6 Containment and Subcompartment Atmosphere

Sections 9.4.5 and 3.11 describe the pressure, temperature, and humidity limits within which all the Class 1E equipment located inside the containment structure is qualified to operate. Section 9.4.5 also describes the system that maintains these limits during normal plant operation.

6.2.1.1.3 Design Evaluation

The information presented in this section is historical and is based on the original design basis conditions and does not represent current plant conditions or current methodology used to analyze the containment response following a LOCA. The methods and results that bound current plant conditions are described in Section 6.2.1.8. Table 6.2-4A provides the plant conditions used for the current analysis. The results presented here, however, do provide the basis for determining which events are limiting. They also demonstrate the relationship of the containment response to different input assumptions.

The limiting cases were reanalyzed in Section 6.2.1.8 for the current plant conditions using the current analysis methodology. The current reactor power and RPV pressure have been increased over the original design basis conditions. The short-term containment pressure and pool swell load response is dependent on the initial reactor pressure. The double-ended guillotine recirculation line break was reanalyzed for the current plant conditions because this break results in the limiting peak containment pressures and pool swell loads. The long-term containment pool temperature response is dependent on the initial reactor power. Case C (loss of offsite power with no containment spray)

was reanalyzed for the current plant conditions because this case results in the highest suppression pool temperature. The intermediate and small line breaks result in the highest peak drywell temperature however, these breaks were not reanalyzed at the current operating conditions. As described in Section 6.2.1.1.3.3.5.4, the limiting drywell temperature response is determined by steam enthalpy properties and is not sensitive to the increase in reactor operating pressure or power level. The main steam line break was not reanalyzed for the current plant operating conditions. The containment pressure and pool swell load response for the main steam break is bounded by the recirculation line break results. The drywell temperature response for the main steam line break is bounded by the small and intermediate line break results.

6.2.1.1.3.1 Summary Evaluation

The key design values and the maximum calculated accident values of these parameters for the pressure-suppression containment are as follows:

Parameter	Design Value	Calculated Accident Value
Drywell design pressure	55 psig	44.0 psig*
Drywell design temperature	340°F	340°F
Suppression chamber design pressure	55 psig	30.57 psig*
Suppression chamber design temperature	220°F	212.5°F*
Peak drywell deck downward differential pressure	30 psid	25.995 psid*

*NOTE: The calculated values presented in this table are based on the original design basis conditions. The calculated results for current plant conditions as shown in Table 6.2-5A.

The foregoing design and maximum calculated accident parameters are not determined from a single accident event but from an envelope of accident conditions. As a result, there is no single DBA for this containment system.

A maximum drywell and suppression chamber pressure occurs near the end of the blowdown phase of a LOCA. Approximately the same peak pressure occurs for the break of either a recirculation line or a main steam line. Both accidents are evaluated.

The most severe drywell temperature condition (peak temperature and duration) occurs for a small primary system rupture above the reactor water level that results in the blowdown of reactor steam to the drywell (small steam break). In order to demonstrate that breaks smaller than the rupture of the largest primary system pipe do not exceed the containment design parameters, the containment system responses to an intermediate size liquid break and a small size steam break are evaluated. The results show that the containment design conditions are not exceeded for these smaller break sizes.

All of the analyses assume that the primary system and containment are initially at the maximum normal operating conditions. References are provided that describe relevant experimental verification of the analytical models used to evaluate the containment system response.

6.2.1.1.3.2 Containment Design Parameters

Table 6.2-1 provides a listing of the key design parameters of the primary containment system including the design characteristics of the drywell, suppression pool, and the pressure-suppression vent system.

A diagram showing the geometric configuration of the downcomer is shown in Figure 6.2-1.

As described in Section 9.4.5, vacuum relief valve assemblies are provided to limit the degree to which suppression chamber pressure can exceed drywell pressure, and to prevent the drywell design negative pressure from being exceeded as described in Section 6.2.1.1.4. There are four assemblies, each mounted on the side of a downcomer on the flanges shown in Figure 6.2-1. Each assembly consists of two vacuum relief valves mounted in series. A schematic diagram of a single vacuum relief valve is shown in Figure 9.4-6. The required number and size of the vacuum relief valve assemblies was determined as described in Section 6.2.1.1.3.3.1.5.

Table 6.2-2 provides the performance parameters of the related ESF systems that supplement the design conditions of Table 6.2-1 for containment cooling purposes during postblowdown long-term accident operation. Performance parameters given include those applicable to full capacity operation and those applicable to the conservatively reduced capacities assumed for containment analyses.

6.2.1.1.3.2.1 Downcomer Vent Flow Loss Coefficient

The downcomer vent flow loss coefficient, K, is defined by:

$$K = \frac{\Delta P}{\rho V^2 / 2g_c} \qquad \text{(EQ. 6.2-1)}$$

and is calculated from standard references (References 6.2-1 and 6.2-2). In the above equation ΔP is the total pressure drop across the downcomer, ρ is the fluid density, and V is the flow velocity.

The total downcomer flow loss coefficient is modeled as the sum of three contributors: an entrance loss (K_1), a length loss (K_2), and an exit loss (K_3). The entrance loss coefficient (K_1) is calculated from Reference 6.2-1 using a hooded duct entrance geometry that very nearly approximates the standoff jet deflector shield feature of the LGS downcomer and (K_1) is calculated to be 0.90. The length loss (K_2) is represented by a resistance coefficient (fL/D) loss with (f) calculated from Reference 6.2-2 and (K_2) calculated to be 0.33. The exit loss coefficient (K_3) is calculated to be 1.0 from Reference 6.2-2, which when combined with the above yields an overall loss coefficient value of K = 2.23.

6.2.1.1.3.3 Accident Response Analysis

The containment functional evaluation is based on the consideration of several postulated accident conditions resulting in the release of reactor coolant to the containment. These accidents include the following:

a. An instantaneous guillotine rupture of a recirculation line

b. An instantaneous guillotine rupture of a main steam line

c. An intermediate size liquid line rupture

d. A small size steam line rupture

Energy release from these accidents is discussed in Section 6.2.1.3.

6.2.1.1.3.3.1 Recirculation Line Break

NOTE: The information presented in this section is historical and is based on the original design basis conditions. See the explanation at the beginning of Section 6.2.1.1.3.

Immediately following the rupture of the recirculation line, the flow out both sides of the break is limited to the maximum allowed by critical flow considerations. The total effective flow area is given in Figure 6.2-2. In the side adjacent to the suction nozzle, the flow corresponds to critical flow in the pipe cross-section. In the side adjacent to the injection nozzle, the flow corresponds to critical flow at the ten jet pump nozzles associated with the broken loop. Table 6.2-3 provides a summary of the break areas.

6.2.1.1.3.3.1.1 Assumptions for Reactor Blowdown

The response of the RCS during the blowdown period of the accident is analyzed using the following assumptions:

a. The initial conditions for the recirculation line break accident are such that the system energy is maximized and the system mass is minimized. That is:

   1. The reactor is operating at 105% of rated steam flow. This maximizes the postaccident decay heat.

   2. The service water temperature is at the maximum normal value.

   3. The suppression pool mass is at the low water level.

   4. The suppression pool temperature is at the maximum normal value.

b. The recirculation line is considered to be severed instantly. This results in the most rapid coolant loss and depressurization of the vessel, with coolant being discharged from both ends of the break.

c. Reactor power generation ceases at the time of accident initiation because of void formation in the core region. Scram occurs in less than one second from receipt of

the high drywell pressure signal. The difference in time between accident initiation and shutdown is negligible.

d. The vessel depressurization flow rates are calculated using Moody's critical flow model (Reference 6.2-3) assuming "liquid only" outflow, since this assumption maximizes the energy release to the drywell. "Liquid only" outflow implies that all vapor formed in the RPV by bulk flashing rises to the surface instead of being entrained in the existing flow. Actually, some of the vapor would be entrained in the break flow which would significantly reduce the RPV discharge flow rates. Further, Moody's critical flow model which assumes annular, isentropic flow, thermodynamic phase equilibrium, and maximized slip ratio, accurately predicts vessel outflows through small diameter orifices. Actual rates through larger flow areas, however, are less than the model indicates because of the effects of a near homogeneous two-phase flow pattern and phase nonequilibrium. These effects are conservatively neglected in the analysis.

e. The core decay heat and the sensible heat released in cooling the fuel to initial average coolant temperature are included in the RPV depressurization calculation. The rate of energy release is calculated using a conservatively high heat transfer coefficient throughout the depressurization period. The resulting high energy release rate causes the RPV to maintain nearly rated pressure for approximately 20 seconds. The high RPV pressure increases the calculated blowdown flow rates, which is again conservative for analysis purposes. The sensible energy of the fuel stored at temperatures below the initial average coolant temperature is released to the vessel fluid along with the stored energy in the vessel and internals as vessel fluid temperatures decrease during the remainder of the transient calculation.

f. The MSIVs start closing 0.5 seconds after the accident. They are fully closed in the shortest possible time of three seconds following closure initiation. In actuality, the closure signal for the MSIVs occurs from low-low-low reactor water level (level 1), so the valves do not receive a signal to close for greater than four seconds, and the closing time may be as long as five seconds. By assuming rapid closure of these valves, the RPV is maintained at a high pressure, which maximizes the calculated discharge of high energy water into the drywell.

g. Reactor feedwater flow is assumed to stop instantaneously at time t = zero. Since feedwater flow tends to depressurize the RPV, thereby reducing the discharge of steam and water into the drywell, this assumption is conservative for the short-term analysis.

h. A complete LOOP occurs simultaneously with the pipe break. This condition results in the loss of power conversion system equipment and also requires that all vital systems for long-term cooling be supported by onsite power supplies.

6.2.1.1.3.3.1.2 Assumptions for Containment Pressurization

The pressure response of the containment during the blowdown period of the accident is analyzed using the following assumptions:

a. Thermodynamic equilibrium exists in the drywell and suppression chamber. The analysis assumes complete mixing and the error introduced by this assumption is negligible.

b. The fluid flowing through the downcomers is formed from a homogeneous mixture of the fluid in the drywell. The use of this assumption results in complete carryover of the drywell air and a higher positive flow rate of liquid droplets that conservatively minimizes downcomer pressure losses.

c. The fluid flow in the downcomers is compressible except for the liquid phase.

d. No heat loss occurs from the gases inside the primary containment. Actually condensation of some steam on the drywell surfaces would occur.

6.2.1.1.3.3.1.3 Assumptions for Long-Term Cooling

Following the blowdown period, the ECCS (discussed in Section 6.3) provides water for core flooding, containment spray, and long-term decay heat removal. The containment pressure and temperature responses during this period are analyzed using the following assumptions:

a. The RHR pumps are used to flood the core within 600 seconds after the accident (LPCI mode).

b. After 600 seconds, flow from one RHR pump can be diverted from the RPV to the containment cooling. This is a manual operation. Containment spray need not be actuated at all to keep the containment pressure below the containment design pressure. Analytically, no credit may be assumed for containment cooling earlier than 600 seconds after the accident and cooling is assumed to begin at 600 seconds. However, containment cooling will be initiated in accordance with plant emergency operating procedures based on plant conditions.

c. The effects of decay energy, stored energy, sensible energy, energy added by ECCS pumps, and energy from the metal-water reaction on the suppression pool temperature are considered.

d. The suppression pool is the only heat sink available in the containment system prior to initiation of the RHRSW system.

e. After 600 seconds, the RHR heat exchangers are activated to remove energy from the containment via the RHR suppression pool cooling mode in conjunction with RHRSW system.

The performance of the ECCS equipment during the long-term cooling period is evaluated in Section 6.2.1.1.3.3.1.6 for each of the three cases of interest.

6.2.1.1.3.3.1.4 Initial Conditions for Accident Analyses

Table 6.2-4 provides the initial RCS and containment conditions used in all the accident response evaluations. The tabulation includes parameters for the reactor, the drywell, and the suppression chamber.

Table 6.2-3 provides the initial conditions and numerical values assumed for the recirculation line break accident as well as the sources of energy considered prior to the postulated pipe rupture. The assumed conditions for the reactor blowdown are also provided.

The mass and energy release sources and rates for the containment response analyses are given in Section 6.2.1.3.

6.2.1.1.3.3.1.5 Short-Term Accident Response

The calculated containment pressure and temperature responses for the recirculation line break are shown in Figures 6.2-3 and 6.2-4, respectively.

The suppression chamber is pressurized by the carryover of noncondensables from the drywell and by heatup of the suppression pool. As the vapor formed in the drywell is condensed in the suppression pool, the temperature of the suppression pool water peaks and the suppression chamber pressure stabilizes. The drywell pressure stabilizes at a slightly higher pressure, the difference being equal to the downcomer submergence. During the RPV depressurization phase, most of the noncondensable gases initially in the drywell are forced into the suppression chamber. However, following depressurization the noncondensables redistribute between the drywell and suppression chamber via the vacuum relief valve system. This redistribution takes place as steam in the drywell is condensed by the relatively cool ECCS water which is beginning to cascade from the break causing the drywell pressure to decrease.

In the early design phase of the plant, conservative hand calculations were performed to establish the minimum number of operating vacuum breaker assemblies required. Two cases leading to potentially rapid drywell depressurization were considered for wetwell-to-drywell vacuum breaker sizing:

a. The inadvertent actuation of one drywell spray train (10,000 gpm @ 90°F, assumed)

b. Maximum ECCS spillage (7750 lb_m/sec @ 140°F exit temperature, assumed) during the depressurization phase of the large recirculation outlet line break LOCA

Each case was to determine the number of vacuum breaker valve assemblies required to ensure that the maximum differential pressure across the diaphragm slab in the upward direction does not exceed allowables. For the analyses, a conservatively low 3 psid across the diaphragm slab was used, well below the present design allowable of 20 psid upward.

In the analyses done for both cases, a. and b., it was conservatively assumed that all noncondensables have been removed to the wetwell vapor region prior to drywell depressurization. In addition to this, for the Case a. accident a 100% spray efficiency, together with a drywell temperature of 273°F, combine with the assumptions regarding spray rate and inlet temperature noted above, to render this analysis conservative. This results in a net drywell energy removal rate of approximately 321,000 Btu/sec.

The analysis for Case b. assumes a drywell saturation temperature of 262°F, an ECCS drop fall height of 42 feet, an average drop diameter of 1 inch (for calculating condensation heat transfer to the falling ECCS spillage), and an average heat transfer coefficient of 2300 Btu/hr-ft^2-°F (for calculating heat transfer from the drywell vapor region to the pool of ECCS spillage collected on the drywell floor). These considerations, combined with the assumptions regarding noncondensables and ECCS spillage rate and temperature, yield a net drywell energy removal rate of approximately 318,000 Btu/sec for an ECCS spillage spray effectiveness of 34%.

The two cases yield drywell energy removal rates of the same order of magnitude, with the inadvertent containment spray case being the larger, 321,000 Btu/sec. As such, this inadvertent spray actuation case controls the vacuum breaker sizing. The hand calculation established that three operable vacuum breaker valve assemblies each having a seat inner diameter of 18 inches, were required.

Subsequently, the inadvertent spray actuation (ISA) case was reanalyzed using a dynamic computer model, described in Section 6.2.1.1.4. This analysis was performed to verify that vacuum relief valve capacity is sufficient to prevent drywell depressurization below the design value of -5 psig. For purposes of vacuum relief valve sizing, primary containment negative pressure is more limiting than diaphragm slab differential pressure. The computer model conservatively approximated vacuum relief valve flow characteristics based on actual test data. Additional conservative assumptions were made to maximize the negative pressure in the drywell. The results confirmed that two operable vacuum relief valve assemblies were sufficient to prevent excessive drywell depressurization, as discussed in Section 6.2.1.1.4.

The ECCS supplies sufficient core cooling water to control core heatup and limit metal-water reaction to less than 1%. After the RPV is flooded to the height of the jet pump nozzles, the excess flow discharges through the recirculation line break into the drywell. This flow of water (steam flow is negligible), in the form of hot water which flows into the suppression chamber via the downcomers, transports the core decay heat out of the RPV through the broken recirculation line. This flow provides a heat sink for the drywell atmosphere, and thereby causes the drywell to depressurize.

Table 6.2-5 provides the peak pressure, temperature, and time parameters for the recirculation line break as predicted for the conditions of Table 6.2-4 and as correspond with Figures 6.2-3 and 6.2-4. Figure 6.2-5 shows the time-dependent response of the drywell floor (diaphragm slab) differential pressure.

During the blowdown period of the LOCA, the downcomers conduct the flow of the steam-water gas mixture in the drywell to the suppression pool for condensation of the steam. The pressure differential between the drywell and suppression pool controls this flow. Figure 6.2-6 provides the mass flow versus time relationship through the downcomers for this accident.

6.2.1.1.3.3.1.6 Long-Term Accident Responses

NOTE: The information in this Section is based on the original design basis conditions. Only case C (Loss of Offsite Power with no Containment Spray) was reanalyzed for the current plant conditions because this case results in the highest suppression pool temperature. The methods and results that bound current plant conditions are described in Section 6.2.1.8.

In order to assess the adequacy of the containment following the initial blowdown transient, an analysis was made of the long-term temperature and pressure responses following the accident for each of three cases. The results of these analyses are described below. The analyses assumptions

for these cases are those discussed in Section 6.2.1.1.3.3.1.3. The initial pressure response of the containment (the first 600 seconds after the break) is the same for each case.

CASE A: All ECCS equipment operating - with containment spray

This case assumes that offsite ac power is available to operate all cooling systems. During the first 600 seconds following pipe break, the HPCI, core spray, and all LPCI pumps are assumed to operate. All flow is injected directly into the reactor vessel.

After 600 seconds, RHRSW pumps are started and both RHR heat exchangers are aligned to remove energy from the containment. During this mode of operation the flow from two RHR pumps is routed through their associated RHR heat exchanger where it is cooled before being discharged into the drywell and suppression chamber spray headers. The CS system continues operation during this mode with both loops injecting into the vessel.

The containment pressure response to this set of conditions is shown as curve A in Figure 6.2-7. The corresponding drywell and suppression pool temperature responses are shown as curve A in Figures 6.2-8 and 6.2-9. After the initial blowdown and subsequent depressurization due to CS and LPCI core flooding, energy addition due to core decay heat results in a gradual pressure and temperature rise in the containment.

When the energy removal rate of the RHR system equals the energy addition rate from the decay heat, the containment pressure and temperature reach a second peak value and decrease gradually. Table 6.2-6 summarizes the equipment operation, the peak long-term containment pressure following the initial blowdown peak, and the peak suppression pool temperature.

CASE B: LOOP - with containment spray

This case assumes that no offsite power is available following the accident with only minimum diesel power. The RHR system and the drywell and suppression chamber sprays are in operation after 600 seconds. During this mode of operation the RHR system flows through only one RHR heat exchanger and is directed to the spray headers while one LPCI pump and one CS loop continue to inject water into the vessel. The containment pressure response to this set of conditions is shown as curve B in Figure 6.2-7. The corresponding drywell and suppression pool temperature responses are shown as curve B in Figures 6.2-8 and 6.2-9. A summary of this case is given in Table 6.2-6.

CASE C: LOOP - no containment spray

This case assumes that no offsite power is available following the accident with only minimum diesel power. After 600 seconds the sprays may be manually activated to further reduce containment pressure if desired. This analysis assumes that the drywell and suppression chamber sprays are not activated.

After 600 seconds, the RHRSW system and one RHR heat exchanger are activated to remove energy from the containment. The flow from one RHR pump is cooled by the RHR heat exchanger before being discharged into the reactor vessel while another RHR pump and one CS loop inject directly into the vessel.

The containment pressure response to this set of conditions is shown as curve C in Figure 6.2-7. The corresponding drywell and suppression pool temperature responses are shown as curve C in Figures 6.2-8 and 6.2-9. A summary of this case is given in Table 6.2-6.

When comparing the "spray" case B with the "no spray" case C, the same RHR heat exchanger duty is obtained since the suppression pool temperature response is approximately the same, as shown in Figure 6.2-9. Thus, the same amount of energy is removed from the pool whether the exit flow from the RHR heat exchanger is injected into the reactor vessel, into the suppression pool, or into the drywell as spray. However, the peak containment pressure is higher for the "no spray" case, but the pressure is still much less than the containment design pressure.

Figure 6.2-10 shows the rate at which the RHR system heat exchanger removes heat from the suppression pool following a LOCA (Section 6.2.2 describes the containment cooling mode of the RHR system). The heat removal rate is shown for the three cases of interest (A, B and C). The first assumes that all the ECCS equipment is available, in addition to both RHR heat exchangers and their associated RHRSW pumps. The second and third cases are for the very degraded minimum cooling condition that limits the heat removal capacity to one heat exchanger. For all cases, it is conservatively assumed that at the time of the accident the RHRSW is at its maximum design temperature, as defined in Table 6.2-2.

6.2.1.1.3.3.1.7 Energy Balance During Accident

In order to establish an energy distribution in the containment as a function of time (short-term or long-term) for this accident, the following energy sources and sinks are required:

a. Blowdown energy release rates

b. Decay heat rate and fuel relaxation sensible energy

c. Sensible heat rate (vessel and internals)

d. Pump heat rate

e. Heat removal rate from suppression pool (Figure 6.2-10)

f. Metal-water reaction heat rate

Items a, b, c, d, and f are discussed in Section 6.2.1.3. A complete energy balance for the recirculation line break accident is given in Table 6.2-7 for the reactor system, the containment and the containment cooling systems at time zero, at the time of peak drywell pressure, at the end of reactor blowdown, and at the time of the long-term peak pressure in the containment.

6.2.1.1.3.3.1.8 Chronology of Accident Events

A complete description of the containment response to the recirculation line break has been given in Sections 6.2.1.1.3.3.1.5 through 6.2.1.1.3.3.1.7. Results for this accident are shown in Figures 6.2-3 through 6.2-10. A chronological sequence of events for this accident from time zero is provided in Table 6.2-8.

6.2.1.1.3.3.2 Main Steam Line Break

NOTE: The information in this section for the main steam line break is based on the original design basis conditions. See explanation at the beginning of Section 6.2.1.1.3. The main steam line break was not reanalyzed for current plant conditions. The containment pressure and pool swell load response for the main steam line break is bounded by the small and intermediate line break results and remains unchanged by the change in plant operating conditions. The information presented in this section reasonably represents the general characteristics of the main steam line break analysis.

The assumed sudden rupture of a main steam line between the reactor vessel and the flow restricting orifice results in the maximum flow rate of primary system fluid and energy to the drywell. This would in turn result in the maximum drywell differential pressure. The sequence of events immediately following the rupture of a main steam line between the reactor vessel and the flow restricting orifice has been determined. The flow on both sides of the break accelerates to the maximum allowed by the critical flow considerations. On the side adjacent to the reactor vessel, the flow corresponds to critical flow in the steam line break area. Blowdown through the other side of the break occurs because the steam lines are all interconnected at a point upstream of the turbine by the bypass header. This interconnection allows primary system fluid to flow from the three unbroken steam lines through the header and back into the drywell via the broken line. Flow is limited by critical flow in the steam line flow restricting orifice. The total effective flow area is given in Figure 6.2-11. The MSIVs are assumed to start closing at 0.5 seconds and are fully closed in the maximum time of 5 seconds following closure initiation. By assuming slow closure of these valves, a large effective break area is maintained for a longer period of time. The peak drywell floor differential pressure occurs before the reduction in effective break area and is therefore insensitive to any additional delay in closure of the isolation valves. An MSIV closure time longer than the 5 second maximum closure time would increase the break flow rate from the inventory side of the break (break to MSIV valve). However, this is offset by a lower flow rate from the vessel side of the break due to a decreasing vessel pressure. The net effect on the peak drywell pressure would be on the order of 1 psi. Section 6.2.1.3 provides the mass and energy release rates.

Immediately following the break, the total steam flow rate leaving the vessel exceeds the steam generation rate in the core, causing an initial depressurization of the RPV. Void formation in the reactor vessel water causes a rapid rise in the water level. It is conservatively assumed that the water level reaches the vessel steam nozzles one second after the break occurs. The water level rise time of one second is the minimum that can occur under any reactor operating condition. From that time on, a two-phase mixture is discharged from the break. During the first second of the blowdown, the blowdown flow consists of saturated steam. This steam enters the containment in a superheated condition at approximately 330°F.

Figures 6.2-12 and 6.2-13 show the pressure and temperature responses of the drywell and suppression chamber during the primary system blowdown phase of the steam line break accident.

Figure 6.2-13 shows that the drywell atmosphere temperature approaches a peak after approximately one second of primary system steam blowdown. At that time, the water level in the vessel reaches the steam line nozzle elevation and the blowdown flow changes to a two-phase mixture. This increased flow causes a more rapid drywell pressure rise. The peak differential pressure occurs shortly after the vent clearing transient. As the blowdown proceeds, the primary system pressure and fluid inventory decrease and this results in reduced break flow rates. As a consequence, the flow rate in the downcomers and the differential pressure between the drywell and suppression chamber begin to decrease.

Table 6.2-5 presents the peak pressures, peak temperatures and corresponding times of this accident as compared to the recirculation line break.

After the primary system pressure has dropped to the drywell pressure, the blowdown is over. At this time the drywell contains saturated steam, and the drywell and suppression chamber pressures stabilize. The pressure difference corresponds to the hydrostatic pressure of downcomer submergence.

The drywell and suppression pool remain in this equilibrium condition until the reactor vessel refloods. During this period, the ECCS pumps inject cooling water from the suppression pool into the reactor. This injection of water eventually floods the reactor vessel to the level of the steam line nozzles and the ECCS flow spills into the drywell. The water spillage condenses the steam in the drywell and thus reduces the drywell pressure. As soon as the drywell pressure drops below the suppression chamber pressure, the primary containment vacuum breakers open and noncondensable gases from the suppression chamber flow back into the drywell until the pressures in the two regions equalize.

6.2.1.1.3.3.3 Hot Standby Accident Analysis

This section is not applicable to BWR 4.

6.2.1.1.3.3.4 Intermediate Size Breaks

The information presented in this section for the intermediate size break is based on the original design basis conditions. As described in Section 6.2.1.1.3.5.4, the limiting drywell temperature response is determined by steam enthalpy properties and is not sensitive to the change in plant operating conditions. These breaks were not reanalyzed at the current operating conditions. The information presented in this section reasonably represents the general characteristics of the intermediate size break analysis. (See explanation at beginning of Section 6.2.1.1.3.)

An intermediate size break is analyzed as part of the containment performance evaluation to demonstrate that the consequences are no more severe than from a rupture of the largest primary system pipe. This classification covers those breaks for which the blowdown results in reactor depressurization and operation of the ECCS. This section describes the consequences to the containment of a 0.1 ft^2 break below the RPV water level. This break area is chosen as being representative of the intermediate size break area range. These breaks can involve either reactor steam or liquid blowdown.

The 0.1 ft^2 break was assumed to occur below the vessel water level to maximize the mass and energy release rates to the drywell. Based on the Moody slip flow model for the same-sized break, the total mass and energy release is greater for liquid break than for a steam break.

The initial reactor and containment conditions used in the analysis were the same as those used for the design basis accident as presented in Tables 6.2-1 and 6.2-4 and discussed in Section 6.2.1.1.3.3.1.

Following the 0.1 ft^2 break, the drywell pressure increases at approximately 1 psi/sec. This drywell pressure transient is sufficiently slow so that the dynamic effect of the water in the downcomers is negligible and the downcomers clear when the drywell-to-suppression chamber differential pressure is equal to the downcomer submergence hydrostatic pressure.

Figures 6.2-14 and 6.2-15 show the short-term drywell and suppression chamber pressure and temperature response, respectively. The ECCS response is discussed in Section 6.3. Approximately 5 seconds after the 0.1 ft^2 break occurs, air, steam, and water start to flow from the drywell to the suppression pool; the steam is condensed and the air enters the suppression chamber free space. The continual purging of drywell air to the suppression chamber results in a gradual pressurization of both the wetwell and drywell. The containment continues to gradually increase in pressure due to the long-term pool heatup.

The ECCS is initiated as a result of the 0.1 ft^2 break as described in Section 7.3.1 and Table 6.3-2 and provides emergency cooling of the core. The operation of these systems is such that the reactor is depressurized in approximately 600 seconds. This terminates the blowdown phase of the transient.

In addition, the suppression pool temperature at the end of blowdown is the same as that of the recirculation line break because essentially the same amount of primary system energy is released during the blowdown. After reactor depressurization and reflood, water from the ECCS begins to flow out the break. This flow condenses the drywell steam and eventually causes the drywell and suppression chamber pressures to equalize in the same manner as happens following a recirculation line break.

The subsequent long-term suppression pool and containment heatup transient is essentially the same as for the recirculation line break.

In comparison to the short-term drywell pressure and temperature responses for a large recirculation line break, it can be concluded that the consequences of an intermediate size break are less severe than those of a recirculation line break. The comparison of the short-term wetwell pressure and temperature responses shows that the intermediate size break is not significantly more severe than the large recirculation line break.

6.2.1.1.3.3.5 Small Size Breaks

The information presented in this section for the small size break is based on the original design basis conditions. As described in Section 6.2.1.1.3.3.5.4, the limiting drywell temperature response is determined by steam enthalpy properties and is not sensitive to the change in plant operating conditions. These breaks were not reanalyzed at the current operating conditions. The information presented in this section reasonably represents the general characteristics of the small size break analysis. (See explanation at beginning of Section 6.2.1.1.3.)

6.2.1.1.3.3.5.1 Reactor System Blowdown Considerations

This section discusses the containment transient associated with small primary system line breaks. The sizes of primary system ruptures in this category are those that do not result in reactor depressurization due either to loss of reactor coolant or automatic operation of the ECCS equipment. Following the occurrence of a break of this size, it is assumed that the reactor operators will initiate an orderly plant shutdown and depressurization of the reactor system. The thermodynamic process associated with the blowdown of primary system fluid from such a break is one of constant enthalpy. If the primary system break is below the water level, the blowdown flow will consist of reactor water. Blowdown from reactor pressure to the drywell pressure will flash approximately one-third of this water to steam and two-thirds will remain as liquid. Both phases of the blowdown flow will be at saturation conditions corresponding to the drywell pressure. Thus, if the drywell is at atmospheric pressure (for example) the steam and liquid associated with the liquid blowdown would be at 212°F.

If the primary system rupture is located above the RPV water level so that the blowdown flow consists of reactor steam only, the resultant steam temperature in the containment is significantly higher than the temperature associated with liquid blowdown. This is because the constant enthalpy depressurization of high pressure, saturated steam results in superheated conditions.

A small reactor steam leak (resulting in superheated steam) imposes the most severe temperature conditions on the drywell structures and the safety equipment in the drywell. For larger steam line breaks, the superheat temperature is nearly the same as for small breaks, but the duration of the high temperature condition is less for the larger break. This is because the larger breaks depressurize the reactor more rapidly than the orderly reactor shutdown that is assumed to be initiated for the small break.

6.2.1.1.3.3.5.2 Containment Response

For drywell design considerations, the following sequence of events is assumed to occur. With the reactor and containment operating at the maximum normal conditions, a small break occurs that allows blowdown of reactor steam to the drywell. The resulting pressure increase in the drywell leads to a high drywell pressure signal that scrams the reactor and activates the containment isolation system. The drywell pressure continues to increase at a rate dependent upon the size of the steam leak. The pressure increase lowers the water level in the downcomers until the level reaches the bottom of the downcomers. At this time, air and steam start to enter the suppression pool. The steam is condensed and the air carried over to the suppression chamber free space. The air carryover results in a gradual pressurization of the suppression chamber at a rate dependent upon the size of the steam leak. Once all the drywell air is carried over to the suppression chamber, short-term pressurization of the suppression chamber ceases and the system reaches an equilibrium condition. The drywell contains only superheated steam, and continued blowdown of reactor steam condenses in the suppression pool. The suppression pool temperature continues to increase until the RHR heat exchanger heat removal rate is equal to the decay heat release rate.

6.2.1.1.3.3.5.3 Recovery Operations

The reactor operators are alerted to the incident by the high drywell pressure signal and the reactor scram. For the purpose of evaluating the duration of the superheat condition in the drywell, it is assumed that their response is to shut the reactor down in an orderly manner using the main condenser while limiting the reactor cooldown rate to 100°F per hour. This results in the reactor primary system being depressurized within 6 hours. At this time, the blowdown flow to the drywell ceases and the superheat condition is terminated. If the plant operators elect to cool down and depressurize the reactor primary system more rapidly than at 100°F per hour, then the drywell superheat condition will be shorter.

6.2.1.1.3.3.5.4 Drywell Design Temperature Considerations

For drywell design purposes, it is assumed that there is a blowdown of reactor steam for the 6 hour cooldown period. The design temperature is determined by finding the combination of primary system pressure and drywell pressure that produces the maximum steam temperature. The maximum steam temperature occurs when the primary system is at approximately 450 psia and the drywell pressure is maximum. Thus, for design purposes, it is assumed that the drywell is at 35 psig; this results in a conservative temperature of 340°F for the first 3 hours. After the first 3 hours of blowdown of reactor steam, the primary system pressure is reduced to a level that results in a temperature which is conservatively bounded by 320°F for the remaining 3 hours.

6.2.1.1.3.4 Accident Analysis Models

NOTE: The information presented in this section for the accident analysis models is based on the original analysis models and does not represent the current methodology used to analyze the containment response following a LOCA. See explanation at the beginning of Section 6.2.1.1.3.

6.2.1.1.3.4.1 Short-Term Pressurization Model

The analytical models, assumptions, and methods used to evaluate the containment response during the reactor blowdown phase of a LOCA are described in References 6.2-4 and 6.2-5.

6.2.1.1.3.4.2 Long-Term Cooling Mode

Once the RPV blowdown phase of the LOCA is over, a fairly simple model of the drywell and suppression chamber may be used. During the long-term, postblowdown transient, the RHR containment cooling system flow path (Section 6.2.2.2) is a closed-loop and the suppression pool mass is constant. Schematically, the cooling loop mode used for analysis is shown in Figure 6.2-16. Since there is no change in mass storage in the system (the RPV is reflooded during the blowdown phase of the accident), the mass flow rates shown in the figure are equal, thus:

$$\dot{m}_{Do} = \dot{m}_{So} = \dot{m}_{eccs} \qquad \text{(EQ. 6.2-2)}$$

where:

$\dot{m}_{Do}$ = mass flow rate out of RPV, lb_m/sec

$\dot{m}_{So}$ = mass flow rate out of suppression pool, lb_m/sec

$\dot{m}_{eccs}$ = mass flow rate into RPV, lb_m/sec

6.2.1.1.3.4.3 Analytical Assumptions

The key assumptions employed in the model are as follows:

a. The drywell and suppression chamber atmospheres are both saturated (100% relative humidity).

b. The drywell atmosphere temperature is equal to the temperature of the coolant spilling from the RPV, or to the spray temperature if the sprays are activated.

c. The suppression chamber atmosphere temperature is equal to the suppression pool temperature or to the spray temperature if the sprays are activated.

d. No credit is taken for heat losses from the primary containment or to the containment internal structures.

6.2.1.1.3.4.4 Energy Balance Considerations

The rate of change of energy in the suppression pool, (E_p) , is given by:

$$\frac{dE_p}{dt} = \frac{d}{dt}(M_{wS} \cdot u_S) = u_S \cdot \frac{dM_{wS}}{dt} + M_{wS} \frac{du_s}{dt} \quad \text{(EQ. 6.2-3)}$$

where:

M_{wS} = mass of water in suppression pool, lb_m

u_S = internal energy of water in suppression pool, Btu/lb_m

Since $\frac{dM_{wS}}{dt} = 0$ (because there is no change in mass storage), and at the conditions existing in the containment:

$$\frac{du_S}{dt} = C_v \cdot \frac{dT_S}{dt} \quad \text{(EQ. 6.2-4)}$$

where:

C_v = 1.0 for the constant volume specific heat of water, Btu/lb_m-°F

T_S = suppression pool temperature, °F

The pool energy balance yields:

$$M_{wS} \cdot C_v \cdot \frac{dT_S}{dt} = \dot{M}_{Do} \cdot h_D - \dot{M}_{So} \cdot h_S \quad \text{(EQ. 6.2-5)}$$

where:

h_D = enthalpy of water leaving RPV, Btu/lb_m

h_S = enthalpy of water in suppression pool, Btu/lb_m

This equation can be rearranged to yield:

$$\frac{dT_S}{dt} = \frac{\dot{M}_{Do} \cdot h_D - \dot{M}_{So} \cdot h_s}{C_v \cdot M_{wS}} \quad \text{(EQ. 6.2-6)}$$

An energy balance on the RHR heat exchanger yields:

$$h_c = h_s - \frac{\dot{q}_{HX}}{\dot{M}_{So}} \qquad \text{(EQ. 6.2-7)}$$

where:

h_c = enthalpy of water entering RPV, Btu/lb_m

q_{HX} = heat removal rate of heat exchanger, Btu/sec

Similarly, an energy balance on the RPV yields:

$$h_D = h_c + \frac{\dot{q}_D + \dot{q}_e}{\dot{M}_{eccs}} \qquad \text{(EQ. 6.2-8)}$$

where:

q_D = core decay and pump heat rate, Btu/sec

q_e = sensible energy release rate, Btu/sec

Combining Equations 6.2-2, 6.2-6, 6.2-7 and 6.2-8 gives:

$$\frac{dT_S}{dt} = \frac{\dot{q}_D + \dot{q}_e - \dot{q}_{HX}}{C_v M_{wS}} \qquad \text{(EQ. 6.2-9)}$$

This differential equation is integrated by finite-difference techniques to yield the suppression pool temperature transient.

6.2.1.1.3.4.5 Containment Thermodynamic Conditions

Once the energy equations are solved, the drywell and suppression chamber atmospheric temperatures can be calculated.

For the case in which no containment spray is operating, the suppression chamber temperature, (T_W), will, at any time, be equal to the current temperature of the pool, (T_S), and the drywell temperature, (T_D), will be equal to the temperature of the fluid leaving the RPV. Thus:

$$T_D = T_S + \frac{\dot{q}_D + \dot{q}_e - \dot{q}_{HX}}{C_p \dot{M}_{eccs}} \text{ and } T_W = T_S \qquad \text{(EQ. 6.2-10)}$$

where:

C_p = constant pressure specific heat of water, Btu/lb_m-°F

For the case in which the containment spray is assumed to be operating, both the drywell and suppression chamber atmosphere will be at the spray temperature, T_{sp}, where:

$$T_{sp} = T_S - \frac{\dot{q}_{HX}}{C_p \dot{M}_{eccs}} \text{ and } T_D = T_W = T_{sp} \qquad \text{(EQ. 6.2-11)}$$

Using the suppression chamber and drywell atmosphere temperatures, and assumption (a) of Section 6.2.1.1.3.4.3 (drywell and suppression chamber saturated), it is possible to solve for the containment total pressures, since:

$$P_D = P_{aD} + P_{vD} \qquad \text{(EQ. 6.2-12)}$$

$$P_S = P_{aS} + P_{vS} \qquad \text{(EQ. 6.2-13)}$$

where:

P_D = drywell total pressure, psia

P_{aD} = partial pressure of air in drywell, psia

P_{vD} = partial pressure of water vapor in drywell, psia

P_S = suppression chamber total pressure, psia

P_{aS} = partial pressure of air in the suppression chamber, psia

P_{vS} = partial pressure of water vapor in the suppression chamber, psia

and, from the Ideal Gas Law:

$$P_{aD} = \frac{M_{aD} \cdot RT_D}{V_D \cdot 144} \qquad \text{(EQ. 6.2-14)}$$

$$P_{aS} = \frac{M_{aS} \cdot RT_W}{V_S \cdot 144} \qquad \text{(EQ. 6.2-15)}$$

where:

M_{aD} = mass of air in the drywell, lb_m

M_{aS} = mass of air in the suppression chamber, lb_m

R = gas constant for air, $ft\text{-}lb_f/lb_m\text{-}°R$

V_D = drywell free volume, ft^3

V_S = suppression chamber free volume, ft^3

With known values of T_D and T_W Equations 6.2-12, 6.2-13, 6.2-14, and 6.2-15 can be solved by transient analysis and iteration. This iteration procedure is also used to calculate the unknown quantities M_{aD} and M_{aS}.

6.2.1.1.3.4.6 Solution of Equations

The transient analysis is based on successive time step integration of the suppression pool temperature. When this integration has been performed and the value of T_S at the end of a time step has been calculated, a pressure balance is made. Using values of M_{aD} and M_{aS} from the end of the previous time step and the updated values of T_D and T_S, a check is made to determine if P_S is greater than or equal to P_D using equations 6.2-12, 6.2-13, 6.2-14 and 6.2-15. If P_S is greater than or equal to P_D , then the two values are made equal. The vacuum breakers between the drywell and suppression chamber ensure that P_S cannot be greater than P_D.

Hence, with $P_D = P_S$ and knowing that:

$$M_{aD} + M_{aS} = \text{constant;} \qquad \text{(EQ. 6.2-16)}$$

where the constant is the known total initial mass of air in the suppression chamber and drywell prior to the accident, Equations 6.2-12, 6.2-13, 6.2-14, and 6.2-15 can be solved for M_{aS}, M_{aD}, and P_a. It is conservatively assumed that the total mass of air remains constant, which ignores any containment leakage that might occur during the transient.

If, as a result of the end-of-time step pressure check,

$$P_S \leq P_D \leq P_S + \frac{H \cdot g}{V_W \cdot 144 \cdot g_c} \qquad \text{(EQ. 6.2-17)}$$

where:

g = acceleration of gravity, ft/sec^2

g_c = constant of proportionality ft-lb$_m$/lb$_f$-sec^2

H = submergence of downcomers, feet

V_W = specific volume of fluid in downcomer, ft^3/lb$_m$

then the pressure in the drywell is higher than the pressure in the suppression chamber but not sufficiently so to depress the water to the bottom of the downcomers and thus permit air to flow from the drywell to the suppression chamber. Under these circumstances, no air transfer is assumed to have occurred during the time step, and Equations 6.2-12, 6.2-13, 6.2-14, and 6.2-15 are solved during the time step, and Equations 6.2-12, 6.2-13, 6.2-14, and 6.2-15 are solved using the updated temperatures with the same M_{aS} and M_{aD} values from the previous time step.

If the end-of-time step pressure check shows:

$$P_D > P_S + \frac{H \cdot g}{V_W \cdot 144 \cdot g_c} \qquad \text{(EQ. 6.2-18)}$$

then the drywell pressure is set to the value:

$$P_D = P_S + \frac{H \cdot g}{V_W \cdot 144 \cdot g_c} \qquad \text{(EQ. 6.2-19)}$$

This requires that the drywell pressure can never exceed the suppression chamber pressure by more than the hydrostatic head associated with the submergence of the downcomers. To maintain this condition, some transfer of drywell air to the suppression chamber is required. The amount of air transfer is calculated by using Equation 6.2-16 and combining Equations 6.2-12, 6.2-13, 6.2-14, 6.2-15, and 6.2-19 to give:

$$P_{vD} + \frac{M_{aD} \cdot RT_D}{144V_D} = P_{vS} + \frac{M_{aS} \cdot RT_W}{144V_S} + \frac{H \cdot g}{144V_W g_c} \qquad \text{(EQ. 6.2-20)}$$

which can be solved for the unknown air masses. The total pressures can then be determined.

6.2.1.1.4 Negative Pressure Design Evaluation

The primary containment has been designed for a negative pressure of -5 psig. The worst case for this consideration results from actuation of the drywell sprays. During such a transient, cold spray water is passed through the drywell atmosphere resulting in a drop in vapor region temperature and a corresponding drop in vapor region pressure. This condition was analyzed for LGS and a peak negative pressure of -4.85 psig was obtained for actuation of one drywell spray network. With three operable vacuum relief valve assemblies (two operating and one redundant), a sensitivity study indicates that actuation of both drywell spray networks concurrently results in a pressure below -5 psig if the suppression pool temperature is below approximately 105°F, assuming worst case conditions for all other variables. Actuation of both drywell spray networks is administratively controlled whenever the suppression pool temperature is below 105°F.

Operation of the drywell sprays at LGS will be governed by appropriate EOPs, which will be written and revised to implement the BWROG EPGs. There will be no other procedural requirements or administrative directives that will cause drywell sprays to be used. In accordance with the EOPs, prior to initiating drywell sprays, the operators will be directed first to determine if the present combination of drywell temperature and drywell pressure fall below the drywell spray initiation limit. If the combination of parameters is below the limit, the operator is directed to initiate drywell spray with a flow rate as specified in the EOPs. The drywell spray initiation limit and minimum drywell spray flow rate are calculated in accordance with the BWROG EPGs. These limits prevent the generation of drywell negative pressures relative to secondary containment and suppression pool that could be damaging to the containment vessel.

The inadvertent actuation of both drywell spray trains is also prevented by the type and location of the control room switches. The outboard valves are normally closed and have key-locked switches that are approximately 8 feet apart.

To determine the temporal pressure and temperature of the primary containment the conservation equations of mass and energy, along with the state equations for steam and air (noncondensable), were written for the drywell and wetwell regions. A schematic of these two regions is presented in Figure 6.2-17. The various terms for the mass and energy transfer mechanisms are also presented in this figure. The systems of differential equations for each region are presented in the following sections (definition of nomenclature is provided below):

A_{cond} = suppression pool free surface area, ft^2

A_{VB} = vent area through vacuum breakers, ft^2

C_{VB} = vacuum breaker flow coefficient

C_P = specific heat at constant pressure for H_2O, 1 Btu/lb_m-°F

C_P^* = specific heat at constant pressure for N_2, O.247 Btu/lb_m-°R

C_V = specific heat at constant volume for H_2O, 1 Btu/lb_m-°F

C_v^* = specific heat at constant volume for N_2, 0.176 Btu/lb_m-°R

E = energy content, Btu

g_c = gravitational constant, 32.174 $ft\text{-}lb_m/lb_f\text{-}sec^2$

h = specific enthalpy, Btu/lb_m

k = ratio of specific heats

M = mass, lb_m

M_{nc} = noncondensable mass, lb_m

M_{cond} = condensate mass, lb_m

M_{drop} = dropout mass, lb_m

M_{evap} = evaporated steam mass, lb_m

M_{stm} = steam mass, lb_m

P = pressure, psi

R = gas constant, $lb_f\text{-}ft/lb_m$-°R

Q = transferred energy, Btu

T = temperature, °F

T^* = absolute temperature, °R

t = time, sec

U_{stm} = steam specific energy, Btu/lb_m

V = volume, ft^3

v = specific volume, ft^3/lb_m

Greek Symbols

ξ	=	heat exchanger effectiveness
ε	=	spray efficiency
ϕ	=	minimum heat exchanger flow rate, lb_m/sec
ρ	=	density, lb_m/ft^3

Subscripts

D	-	drywell region
f	-	final, saturated liquid
g	-	saturated vapor
S	-	suppression pool liquid region, sump
sat	-	saturated conditions
spray	-	spray
sv	-	suppression pool vapor region
VB	-	vacuum breaker

6.2.1.1.4.1 Drywell Region

As indicated in Figure 6.2-17, there are several mass transfer terms for the drywell region. These are: drywell spray rate ($\dot{m}_{spray}$), drywell vapor region condensation rate (or "rainout" due to dropping saturation temperature) ($\dot{m}_{cond}$), and wetwell-to-drywell vacuum breaker flow rate ($\dot{m}_{VB}$). A mass balance on the drywell vapor region yields:

$$\frac{dM_D}{dt} = \frac{dM_{nc}}{dt} + \frac{dM_{stm}}{dt} \qquad \text{(EQ. 6.2-21)}$$

$$= (\dot{M}_{VB} + \dot{M}_{spray})_{in} - (\dot{M}_{cond} + \dot{M}_{spray})_{out}$$

The spray water is assumed to be removed directly to the wetwell liquid region to disallow any potential for re-evaporation to the drywell, as well as to maintain a larger drywell vapor region volume, both of which serve to induce conservatism in the analysis. The requirement of maintaining saturation conditions for the steam component is imposed and results in the following relationship:

$$M_{stm} = \frac{V_D}{v_g(T_D)} \quad \text{or} \quad \frac{dM_{stm}}{dt} = -\frac{V_D}{v_g^2(T_D)} \cdot \frac{dv_g}{dT_D} \cdot \frac{dT_D}{dt} \qquad \text{(EQ. 6.2-22)}$$

The energy balance for this region is:

$$\frac{dE_D}{dt} = (\dot{M}_{spray} C_p (T_{out} - 32) + \dot{Q}_{VB})_{in} \qquad \text{(EQ. 6.2-23)}$$

$$-(\dot{M}_{spray}\, C_p (T_f - 32) + \dot{M}_{cond}\, h_f (T_f))_{out}$$

$$= \dot{M}_{spray}\, C_p (T_{out} - T_f) - \dot{M}_{cond}\, h_f (T_f) + \dot{Q}_{VB}$$

But,

$$\frac{dE_D}{dt} = \left[C_V^* \, T_D^* \, \frac{dM_{nc}}{dt} + u_g \, (T_D) \, \frac{dM_{stm}}{dt} \right] + \left[M_{nc} C_V^* + M_{stm} \, \frac{du_g}{dT_D} \right] \frac{dT_D}{dt} \qquad \text{(EQ. 6.2-24)}$$

so,

$$\left[C_V^* \, T_D^* \, \frac{dM_{nc}}{dt} + u_g \, (T_D) \, \frac{dM_{stm}}{dt} \right] + \left[M_{nc} C_V^* + M_{stm} \, \frac{du_g}{dT_D} \right] \frac{dT_D}{dt} \qquad \text{(EQ. 6.2-25)}$$

The spray efficiency, ε, is defined as follows:

$$\varepsilon = \frac{T_f - T_{out}}{T_D - T_{out}} = f\left(\frac{M_{stm}}{M_{nc}}\right) \qquad \text{(EQ. 6.2-26)}$$

The functional relationship is determined in the work of Reference 6.2-4 and is illustrated in Figure 6.2-18.

6.2.1.1.4.2 Wetwell Region

The wetwell region is modeled in much the same way as the drywell region except that, due to the presence of the suppression pool, two subregions are identified: one to represent the wetwell vapor region, and one to represent the wetwell liquid region (suppression pool). The vapor region is denoted by subscript (sv). Mass and energy balances on this subregion yield the following:

$$\frac{dM_{sv}}{dt} = \frac{d(M_{nc})_{sv}}{dt} + \frac{d(M_{stm})_{sv}}{dt}$$

$$= (\dot{M}_{evap})_{in} - (\dot{M}_{VB} + \dot{M}_{cond})_{sv} + \dot{M}_{drop})_{out} \qquad \text{(EQ. 6.2-27)}$$

As was the case in the drywell region, the wetwell vapor region is assumed to maintain saturated conditions. Therefore,

$$(M_{stm})_{sv} = \frac{V_{sv}}{v_g(T_{sv})} \quad \text{or} \qquad \text{(EQ. 6.2-28)}$$

$$\frac{d(M_{stm})_{sv}}{dt} = \frac{1}{v_g(T_{sv})} \cdot \frac{dV_{sv}}{dt} - \frac{V_{sv}}{v^2 g(T_{sv})} \cdot \frac{dv_g}{dT_{sv}} \cdot \frac{dT_{sv}}{dt}$$

From volume considerations, V_{sv} can change less than 2% and does so gradually throughout the transient. Therefore, the approximation is made that,

$$\frac{dV_{sv}}{dt} \sim 0 \qquad \text{(EQ. 6.2-29)}$$

The suppression pool represents a large surface for condensation and evaporation, thus resulting in a net mass transfer between the liquid and vapor subregions. This effect serves to maintain the wetwell vapor region in a saturated state and is therefore modeled with the terms $\dot{m}_{evap}$ and $\dot{m}_{drop}$. The kinetic theory of condensation (Reference 6.2-5) is used to determine these mass transfer rates. This results in the following expressions:

$$(\dot{M}_{cond})_{sv} = 144\ \Gamma\ A_{cond} \left(\frac{g_c}{2\pi R_{stm}} \right)^{1/2} \frac{(P_{stm})_{sv}}{(T_{sv})^{1/2}} \qquad \text{(EQ. 6.2-30)}$$

$$\dot{M}_{evap} = 144\ A_{cond} \left(\frac{g_c}{2\pi R_{stm}} \right)^{1/2} \cdot \frac{(P_{sat})_s}{(T_s^*)^{1/2}} \qquad \text{(EQ. 6.2-31)}$$

where:

$$\Gamma = -w\ (\pi)^{1/2}\ (1 + \text{erf}(w)) - e^{-w^2} \qquad \text{(EQ. 6.2-32)}$$

$$w = \frac{G_{net}}{G_{std}} = \frac{(\dot{M}_{evap} + (\dot{M}_{cond})_{sv})}{-A_{cond}\ \rho_{stm}\ (2g_c R_{stm} T^*_{sv})^{1/2}} \qquad \text{(EQ. 6.2-33)}$$

$$\text{erf}(w) = \frac{2}{(\pi)^{1/2}} \int_0^w e^{-z^2}\ dz \qquad \text{(EQ. 6.2-34)}$$

For the energy balance,

$$\frac{dE_{sv}}{dt} = C_v^* T_{sv}^* \frac{d(M_{nc})_{sv}}{dt} + (M_{nc})_{sv}\ C_v^* \frac{dT_{sv}^*}{dt} + u_g(T_{sv}) \frac{d(M_{nc})_{sv}}{dt} \qquad \text{(EQ. 6.2-35)}$$

$$= (M_{stm})_{sv} \frac{du_g}{dT_{sv}^*} \cdot \frac{dT_{sv}}{dt}$$

$$= (\dot{M}_{evap}\ h_g(T_S))_{in} - (\dot{Q}_{VB} + (\dot{M}_{cond})_{sv} h_f(T_{sv}) + \dot{M}_{drop}\ h_g(T_{sv}))_{out}$$

The suppression pool region is denoted by subscript (S). Mass and energy balances on this subregion yield the following:

$$\frac{dM_s}{dt} = (\dot{M}_{drop} + \dot{M}_{cond} + (\dot{M}_{cond})_{sv})_{in} - (\dot{M}_{evap})_{out} \qquad \text{(EQ. 6.2-36)}$$

$$\frac{dE_s}{dt} = C_v\ (T_s - 32)\ \frac{dM_s}{dt} + M_s C_v\ \frac{dT_s}{dt} \qquad \text{(EQ. 6.2-37)}$$

$$= (\dot{M}_{cond}\ h_f(T_f) + (\dot{M}_{cond})_{sv} h_f(T_{sv}) + \dot{M}_{drop}\ h_f(T_{sv})$$

$$+ (\dot{M}_{spray}\ C_p(T_f - T_s))_{in} - (\dot{M}_{evap} h_g(T_s))_{out}$$

Two additional mass and energy transfer mechanisms need further definition. These are vacuum breaker flows and RHR heat exchangers, discussed in the next two sections.

6.2.1.1.4.3 Vacuum Breakers Flows

When sufficient differential pressure has built up across the diaphragm slab, the wetwell-to-drywell vacuum breaker assemblies open, allowing for transfer of mass and energy between these two regions. This transfer is described as follows:

$$\dot{M}_{VB} = \begin{cases} C^*_{VB} A_{VB} \left(\dfrac{2 g_c K_{sv}}{K_{sv} - 1}\ r_{sv} P_{sv}\ \left(\left(\dfrac{P_D}{P_{sv}} \right)^{2/Ksv} - \left(\dfrac{P_D}{P_{sv}} \right)^{(Ksv+1)/Ksv} \right) \right)^{1/2} \\ \quad \text{For } \left(\dfrac{P_D}{P_{sv}} \right) > \left(\dfrac{2}{K_{sv}+1} \right)^{K_{sv}/(K_{sv}-1)} \\ C^*_{VB}\ A_{VB} \left(g_c K_{sv} P_{sv} r_{sv} \left(\dfrac{2}{K_{sv}+1} \right)^{(Ksv+1)/(Ksv-1)} \right)^{1/2} \\ \quad \text{For } \left(\dfrac{P_D}{P_{sv}} \right) \le \left(\dfrac{2}{K_{sv}+1} \right)^{Ksv/(Ksv-1)} \end{cases} \qquad \text{(EQ. 6.2-38)}$$

$$(\dot{M}_{VB})_{stm} = \left(\frac{M_{stm}}{M_{stm} + M_{nc}} \right)_{sv} \bullet \dot{M}_{VB} \qquad \text{(EQ. 6.2-39)}$$

$$(\dot{M}_{VB})_{nc} = \left(\frac{M_{nc}}{M_{stm}+M_{nc}}\right)_{sv} \cdot \dot{M}_{VB} \qquad \text{(EQ. 6.2-40)}$$

$$K_{sv} = \left(\frac{P_{NC}}{P_{tot}}\right)_{sv} \cdot K_{nc} + \left(\frac{P_{stm}}{P_{tot}}\right)_{sv} \cdot K_{stm} \qquad \text{(EQ. 6.2-41)}$$

and,

$$\dot{Q}_{VB} = (\dot{M}_{VB})_{stm} h_g(T_{sv}) + (\dot{M}_{VB})_{nc} C_p^* T_{sv}^* \qquad \text{(EQ. 6.2-42)}$$

6.2.1.1.4.4 RHR Heat Exchangers

In the drywell spray mode, the RHR system draws water from the suppression pool, passes it through the RHR heat exchangers, and injects it into the drywell vapor region. As such, the RHR heat exchangers must be modeled to reflect this condition. Therefore,

$$\dot{Q}_{HX} = \dot{M}_{spray} C_p (T_S - T_{out}) = \phi\xi C_p (T_S - T_{sw}) \qquad \text{(EQ. 6.2-43)}$$

where:

$$\phi = \min(\dot{M}_{spray}, \dot{M}_{sw}) \qquad \text{(EQ. 6.2-44)}$$

Combining these yields,

$$T_{out} = T_S - \frac{\phi\xi}{\dot{M}_{spray}}(T_S - T_{sw}) \qquad \text{(EQ. 6.2-45)}$$

6.2.1.1.4.5 Summary

The preceding equations, combined with the state equations for steam and air, yield a set of coupled equations which, when reduced and solved simultaneously, determine the dynamic response of the primary containment system to the postulated drywell spray accident.

The inherent conservatisms of this model are: to neglect transfer of sensible heat energy from equipment and structures to the drywell vapor region, to disallow re-evaporation of the condensed drywell steam, to maintain a large volume for the drywell region by transferring condensed steam mass directly to the suppression pool, and to require saturated conditions in the primary containment vapor regions.

In addition to the modeling conservatisms, initial conditions for the primary containment are also chosen to induce conservatism in the analysis. The presence of any noncondensables in the drywell tends to hold-up the depressurization rate of this region following spray actuation. Thus, a condition is postulated wherein a small break occurs within the drywell serving to pressurize this region and drive all the noncondensables from the drywell vapor space. This sets the initial pressure distribution

and, along with the assumptions regarding saturated conditions for the steam phase, the temperature distribution for all three regions - drywell, wetwell vapor region, and suppression pool. Normally the noncondensables are driven from the drywell to the wetwell. However, when evaluating the reduction from 4 operable vacuum breakers to 3 operable vacuum breakers, it was assumed for a worst case analysis that a small amount of noncondensables is discharged to the reactor enclosure, prior to purge valve closure, and the remainder are driven to the wetwell vapor space. These initial conditions are presented under the heading "t_o" in Table 6.2-9.

The results of this analysis are illustrated in Figures 6.2-19 and 6.2-20. These results indicate a maximum negative drywell pressure of -4.85 psig.

6.2.1.1.5 Steam Bypass of the Suppression Pool

NOTE: The information in this section for the steam bypass of the suppression pool is based on the original basis conditions. See explanation at the beginning of Section 6.2.1.1.3.

6.2.1.1.5.1 Protection Against Bypass Paths

The pressure boundary penetrations between drywell and suppression chamber include the downcomers, which are fabricated, erected, and inspected in accordance with ASME Section III, Subsection NC, 1971 Edition with the exception of the tees supporting the primary containment vacuum relief valves. This special construction, inspection, and quality control ensures the integrity of this boundary. The design pressure differential and temperature for this boundary are defined in Table 6.2-1. Actual peak accident differential pressure and temperature for this boundary are provided in Table 6.2-5.

All penetrations of this boundary are welded except the vacuum relief valves supported by four tees and the blinds closing 10 spare nozzles in the downcomers. All penetrations are available for periodic visual inspection.

All potential bypass leakage paths have been considered. Every path has at least two isolation valves in the potential leakage path. These valves are high quality leak-tight containment isolation valves that are all normally closed and receive an isolation signal to close. All AOVs in these paths are failed closed.

6.2.1.1.5.2 Reactor Blowdown Conditions and Operator Response

In the highly unlikely event of a primary system leak in the drywell accompanied by the existence of an open bypass path leakage between the drywell and suppression chamber, the suppression chamber is pressurized by the steam that enters through the leakage path (bypassing the suppression pool). For a given primary system break area, the maximum leakage that can be allowed is the amount that results in the containment pressure just reaching the design pressure at the end of reactor blowdown. The most limiting conditions, in terms of the smallest allowable leakage flow path area, occur for those primary system break sizes that do not cause rapid reactor depressurization, but do have a long leakage duration. This corresponds to break sizes less than approximately 0.4 ft^2, which require some operator action to terminate the reactor blowdown.

Immediately after the postulated conditions given for a small primary system break, there is a fairly rapid rise in containment pressure as the noncondensable gases in the drywell are carried over to the suppression chamber. During this portion of the transient, it is assumed that the plant operators are unaware that a leakage path exists. For the maximum allowable leakage calculations, it is assumed that the plant operators become aware of a potential leakage only when the drywell

pressure reaches 30 psig. For conservatism, an additional 30 minute delay is assumed to occur before any corrective action to terminate the transient takes effect. At that time, the drywell pressure would be equal to the design pressure if the allowable leakage had occurred. The operator will be alerted to the existence of significant steam bypass leakage by the attendant drywell pressure increase which the operator will be monitoring as part of the EOPs. The operator will initiate the wetwell spray in accordance with the EOPs which will be based on the BWROG EPGs. The BWROG EPGs explicitly consider the possibility of suppression pool bypass leakage in determining spray initiation points.

Termination of the wetwell (and drywell) pressure increase is assured by the operation of only one of the two wetwell sprays.

6.2.1.1.5.3 Analytical Assumptions

When calculating the allowable leakage capacities for a spectrum of break sizes, the following assumptions are made:

a. Flow through the postulated leakage path is pure steam. For a given leakage path, if the leakage flow consists of a mixture of liquid and vapor, the total leakage mass flow rate is higher but the steam flow rate is less than for the case of pure steam leakage. Since only the steam entering the suppression chamber free space results in the additional containment pressurization, this is a conservative assumption.

b. There is no condensation of the leakage flow on either the suppression pool surface or the containment and vent system structures. Since condensation acts to reduce the suppression chamber pressure, this is a conservative assumption. For an actual containment there is condensation, especially for the larger primary system break where vigorous agitation at the pool surface occurs during blowdown.

The following assumptions were made in performing the small break bypass leakage computations to demonstrate that operator action is not required for at least 30 minutes.

a. The steam that leaks into the wetwell air space does not mix with the air already there.

b. No portion of the steam that has leaked into the wetwell air space condenses.

c. Only steam leaks into the wetwell; any air moving from the drywell into the wetwell goes through the vents.

d. All of the air initially in the drywell is cleared into the wetwell before the moment when the operator is alerted.

e. The vents do not refill with water during the time span considered in this procedure.

f. The flow of steam through leakage paths is treated as being incompressible.

g. The pressure difference across the leakage path is assumed to be constant and equal to the vent submerged hydrostatic pressure difference.

h. The drywell pressure at which the operator is alerted is 30 psig.

i. The wetwell air temperature when the operator is alerted to the occurrence of bypass leakage is assumed to be equal to the initial wetwell temperature (95°F). Later, when

the drywell pressure is reduced due to operator action, the wetwell air temperature is assumed to be 50°F greater than the initial wetwell temperature, i.e., 145°F.

j. Maximum allowable leakage area $A/(k)^{½}$ = 0.05 ft^2.

k. The wetwell air space is saturated at the time of spray initiation.

The initial conditions assumed were:

Drywell Temperature	135°F ①
Drywell Pressure	15.45 psia
Drywell Relative Humidity	20%
Wetwell Temperature	95°F
Wetwell Relative Humidity	100%
Drywell Volume	248390 ft^3 (HWL)*
Wetwell Volume	149425 ft^3 (HWL)*
Vent Submergence	12.25 ft (HWL)

Using the above assumptions and initial conditions, a small break LOCA in the drywell produces a constant drywell-to-wetwell pressure differential equivalent to the vent submergence static head (5.28 psid). The resulting bypass steam flow through the leakage path of $A/(k)^{½}$ = 0.05 ft^2 is 3.76 lb_m/sec. The operator becomes alerted to the existence of bypass leakage when the drywell pressure reaches 30 psig. For the drywell pressure to increase from 30 psig to 55 psig (design pressure), the corresponding wetwell pressure rise is from 24.72 to 49.72 psig. Therefore, based on the amount of bypassed steam needed to produce this pressure rise, the operator has about 31 minutes to complete an action that will terminate the pressure increase.

The following shows the minimum required spray efficiency as a function of spray temperature. Because the wetwell airspace is saturated when the spray is initiated (this conservative assumption maximizes pressurization at a given temperature), no net evaporation from hot downcomer surfaces will occur to counteract the spray depressurization effect. The mass flow rate of one spray system is 500 gpm. With two spray systems in operation, the required efficiency would be halved. The spray efficiency is typically on the order of 0.7 and, therefore, even with a single system is operation, the termination of the wetwell (and drywell) pressure increase is assured.

① The assumed initial condition for Drywell temperature of 135°F conservatively bounds an initial Drywell Temperature of 150°F.

* See Table 6.2-1 for final design volumes.

Spray Temperature	Required Efficiency of 1 Wetwell Spray System
70°F	0.22
90°F	0.24
120°F	0.28

6.2.1.1.5.4 Analytical Results

The containment has been analyzed to determine the allowable leakage between the drywell and suppression chamber. Figure 6.2-21 shows the allowable leakage capacity ($A/(k)^{½}$) as a function of the primary system break area. (A) is the area of the leakage flow path and (K) is the total geometric loss coefficient associated with the leakage flow path.

Figure 6.2-21 is a composite of two curves. If the break area is greater than approximately 0.4 ft^2, natural reactor depressurization rapidly terminates the transient and maximum allowable leakage is correspondingly high. For break areas less than approximately 0.4 ft^2, however, reactor blowdown is of long duration and the maximum allowable leakage is limited to small values. The smallest maximum allowable leakage capacity is at $A/(K)^{½}$ = .046 ft^2.

6.2.1.1.5.5 Tests and Inspections

A visual inspection will be conducted at each refueling outage to detect possible drywell-to-suppression bypass leakage paths. A visual inspection of each primary containment vacuum relief valve assembly will be conducted during each refueling outage to verify that it is clear of foreign matter.

Vacuum breakers will be tested for operability at an interval specified by the Technical Specifications. This surveillance testing will be in accordance with the Technical Specifications.

6.2.1.1.5.6 Instrumentation

The vacuum relief valve position indicator system has adequate sensitivity to detect a total valve opening, for all valves, that is less than the bypass capability for a small break. Outboard valve opening is detectable at a disk lift of 0.050 inch or greater off the valve seat. Inboard valve opening is detectable at a disk lift of 0.120 inch or greater off the valve seat. Even assuming that one outboard valve is in the fully open position and all other

valves are open to their minimum detectable position, the total $A/(k)^{½}$ is below 0.05 ft^2. Therefore, the valve leakage, which is based on the assumption that the valve opening is evenly divided among all the vacuum breakers assemblies with one outboard valve in the fully open position, is well within the limits of acceptable bypass leakage.

6.2.1.1.6 Suppression Pool Dynamic Loads

Hydrodynamic loads due to MSRV discharge and a LOCA are described in Appendix 3A.

6.2.1.1.7 Asymmetric Loading Conditions

Asymmetric loads considered for the design of the containment structure include horizontal seismic and localized missile and pipe rupture loads. Refer to Section 3.7 for a description of the seismic analysis methods. Refer to Sections 3.6 and 3.8 for descriptions of the analytical methods used for pipe rupture and missile loads.

6.2.1.1.8 Containment Environment Control

The functional capability of the containment ventilation system to maintain the temperature, pressure, and humidity of the containment and subcompartments is discussed in Section 9.4.5.

6.2.1.1.9 Postaccident Monitoring

A description of the postaccident monitoring systems is provided in Section 7.5.

6.2.1.2 Containment Subcompartments

The containment subcompartments considered for LGS are the biological shield annulus and the drywell head region. The modeling procedures and considerations are presented in Appendix 6A.

6.2.1.3 Mass and Energy Release Analyses for Postulated LOCAs

The information presented in this section for the mass and energy release analyses for postulated LOCAs is based on the original design basis conditions. The information presented in this section reasonably represent the general characteristics for the mass and energy release following a postulated LOCA. (See explanation at beginning of Section 6.2.1.1.3.)

This section presents information concerning the transient energy release rates from the reactor primary system to the containment system following a LOCA. Where the ECCS enter into the determination of energy released to the containment, the single failure criterion has been applied in order to maximize the energy release to the containment following a LOCA. Long-term responses and single failure analyses are discussed in Section 6.2.1.1.3.3.1.6.

6.2.1.3.1 Mass and Energy Release Data

Table 6.2-10 provides the mass and enthalpy release data for the recirculation line break. Blowdown steam and liquid flow rates approach zero in approximately 40 seconds and do not change significantly during the remainder of the 24 hour period following the accident. Figures 6.2-22 and 6.2-23 show the blowdown flow rates for the recirculation line break graphically. These data were employed in the containment pressure-temperature transient analyses reported in Section 6.2.1.1.3.3.1.

Table 6.2-11 provides the mass and enthalpy release data for the main steam line break. Blowdown steam and liquid flow rates approach zero in approximately 60 seconds and do not change significantly during the remainder of the 24 hour period following the accident. Figure 6.2-24 shows the vessel blowdown flow rates for the main steam line break as a function of time after the postulated rupture. This information has been employed in the containment response analyses presented in Section 6.2.1.1.3.3.2.

6.2.1.3.2 Energy Sources

The RCS conditions prior to the line break are presented in Tables 6.2-3 and 6.2-4. Reactor blowdown calculations for containment response analyses are based on these conditions during a LOCA.

The energy released to the containment during a LOCA is comprised of the following:

a. Energy stored in the reactor system

b. Energy generated by fission product decay

c. Energy from fuel relaxation

d. Sensible energy stored in the reactor structures

e. Energy being added by the ECCS pumps

f. Metal-water reaction energy

These energy additions are discussed or referenced in this section. The pump heat rate used in evaluating the containment response to the LOCA is conservatively selected as a constant input of $.00434 \times 10^6$ Btu/sec to the system. The pump heat rate is added to the decay heat rate for inclusion in the analysis.

Following each postulated accident event, the stored energy in the reactor system and the energy generated by fission product decay are released. The rate of release of core decay heat for the evaluation of the containment response to a LOCA is provided in Table 6.2-12 as a function of time after accident initiation.

Following a LOCA, the sensible energy stored in the reactor primary system metal is transferred to the recirculating ECCS water and thus contributes to the suppression pool and containment heatup.

Figure 6.2-25 shows the temperature transients of the various primary system structures that contribute to this sensible energy transfer. Figure 6.2-26 shows the variation of the sensible heat content of the reactor vessel and internal structures during a recirculation line break accident based on the temperature transient responses.

6.2.1.3.3 Reactor Blowdown Model Description

NOTE: The reactor blowdown model description provided below is for the original analysis models and do not represent the methods used to analyze current plant conditions. Refer to the explanation provided at the beginning of Section 6.2.1.1.3.

The reactor primary system blowdown flow rates are evaluated with the model described in References 6.2-4 and 6.2-5.

6.2.1.3.4 Effects of Metal-Water Reaction

The containment systems are designed to accommodate the effects of metal-water reactions and other chemical reactions that may occur following a LOCA. The amount of metal-water reaction that can be accommodated is consistent with the performance objectives of the ECCS. Section 6.2.5.3 provides a discussion on the generation of hydrogen within the containment by metal-water reaction. In evaluating the containment response, 0.002077×10^6 Btu/sec of heat from metal-water reaction is included for the first 120 seconds. The containment response is insensitive to the reaction time, even for the extremely conservative case where all of the energy is included prior to the occurrence of peak drywell pressure.

6.2.1.3.5 Thermal-Hydraulic Data for Reactor Analysis

Sufficient data to perform confirming thermodynamic evaluations of the containment are provided in Section 6.2.1.1.3.3 and associated tables, in particular, Table 6.2-4.

6.2.1.4 Pressurized Water Reactor - Not Applicable

6.2.1.5 Pressurized Water Reactor - Not Applicable

6.2.1.6 Testing and Inspection

Preoperational containment testing and inspection programs are described in Section 3.8 and Chapter 14. Operational containment leakage rate testing and inspection programs are described in Section 6.2.6. The requirements and bases for acceptability are described in Chapter 16.

6.2.1.7 Instrumentation Requirements

Containment pressure and temperature sensing and the associated actuating input to the ESF systems are discussed in Section 7.3. Refer to Section 7.5 for a discussion of the display instrumentation.

Containment airborne radioactivity monitoring is described in Section 12.3.4. Containment hydrogen monitoring is described in Section 6.2.5.

6.2.1.8 Containment System Performance at Power Rerate

The UFSAR provides the results of analyses of the containment response to various postulated accidents that constitute the design basis for the containment. Operation with power rerate changes some of the conditions for the containment analyses. For example, the short-term DBA-LOCA containment response during the blowdown is governed by the blowdown flow rate. This blowdown flow rate is dependent on the reactor initial thermal-hydraulic conditions, such as vessel dome pressure and the mass and energy of the vessel fluid inventory, which change slightly with power rerate. Also, the long-term heat up of the suppression pool following a LOCA or a transient is governed by the ability of the RHR to remove decay heat. Since the decay heat depends on the initial reactor power level, the long-term containment response is affected by power rerate. The LGS containment response has been conservatively re-analyzed to demonstrate the plant's capability to operate at 110% of the original rated power.

The analyses were performed in accordance with Regulatory Guide 1.49 and Reference 6.2-25 using GE codes and models. The M3CPT code was used to model the short-term containment pressure and temperature response. The modeling used in M3CPT is described in References 6.2-26 through 6.2-28. Reference 6.2-26 and 6.2-27 describe the basic containment analytical models used in GE codes. Reference 6.2-28 describes the more detailed RPV model used in the containment analyses for power rerate. The SHEX code was used to model the long-term containment pressure and temperature response. The key models in SHEX are based on models described in References 6.2-26 and 6.2-27. The GE models and methods have been reviewed by the NRC (Reference 6.2-29). The

NRC has approved the use of SHEX on a plant-specific basis, as described in Reference 6.2-30. The significant input parameters and initial conditions for the power rerate containment analyses are shown in the Table 6.2-4A.

The effects of power rerate on the containment dynamic loads due to a LOCA or SRV discharge have also been evaluated as described in Section 6.2.1.8.2. These loads were previously defined generically during the Mark II Containment Program as described in Reference 6.2-31 and accepted by the NRC in Reference 6.2-32 and 6.2-33. Plant-specific dynamic loads were also defined for the plant (Section 3A), which were accepted by the NRC in Reference 6.2-34. The evaluation of the LOCA containment dynamic loads is based primarily on the results of the short-term analysis described in Section 6.2.1.8.1.3. The SRV discharge load evaluation considers the change in the SRV opening setpoints with power rerate.

6.2.1.8.1 Containment Pressure and Temperature Response

The short-term analysis is directed primarily at determining the containment pressure response during the initial blowdown of the reactor vessel inventory to the containment following a large break inside the drywell. The long-term analysis is directed primarily at the pool temperature response, considering the decay heat addition to the pool. The impact of power rerate on the events which yield the limiting containment pressure and temperature response is provided below.

6.2.1.8.1.1 Long-Term Suppression Pool Temperature Response

6.2.1.8.1.1.1 Bulk Pool Temperature

The long-term bulk suppression pool temperature response for LGS with power rerate was evaluated for the DBA LOCA and includes the increased decay heat loads from SIL 636. The analysis was performed at 3528 MWt (Ref. 6.2-40, 6.2-41). Table 6.2-5A compares the calculated peak values for LOCA bulk pool temperature. The suppression pool temperature response is shown in Figure 6.2-9A. The peak bulk suppression pool temperature calculated is 203.4°F. This temperature is within the suppression pool water temperature structural design value (220°F), and does not exceed the low pressure ECCS pump limit of 212°F.

6.2.1.8.1.1.2 Steam Bypass Case

A concern during a LOCA event is steam bypass of the suppression pool due to leakage between the drywell and the wetwell airspace. Excess leakage could result in overpressurization of the primary containment. A steam bypass analysis was performed at 3694 MWt to ensure that there is sufficient time for a manual actuation of the containment spray to prevent the containment pressure from exceeding the design limit of 55 psig. The evaluation shows that power rerate has negligible impact on the suppression pool steam bypass effects. Reference 6.2-41 qualitatively equates the steam bypass event at 3458 MWt with the decay heat rates of SIL 636. At these conditions, it is expected that sufficient time for manual equation of containment spray is available to prevent containment pressure from exceeding 55 psig.

6.2.1.8.1.2 Containment Gas Temperature Response

The drywell design temperature (340°F) has been determined based on a bounding analysis of the superheated gas temperature which can be reached with blowdown of steam to the drywell during a LOCA. A small reactor steam leak (resulting in superheated steam) imposes the most severe temperature conditions on the drywell structures and the safety-related equipment in the drywell. For larger steam line breaks, the superheat temperature is nearly the same as for the small breaks, but the duration of the high temperature condition is less for the large break. This is because the larger breaks depressurize the reactor more rapidly than the orderly reactor shutdown that is assumed to be initiated for the small breaks. The changes in the reactor vessel conditions with power rerate will increase the calculated long-term peak drywell gas temperature during a small break LOCA by a

maximum of a few degrees. However, it has been evaluated that the small break drywell gas temperature response with power rerate will not exceed the drywell design value. The short-term drywell and wetwell gas temperature response is shown in Figure 6.2-4A. The long-term drywell gas temperature response is shown in Figure 6.2-8A.

The wetwell gas space peak temperature response is calculated assuming short-term thermal equilibrium between the pool and wetwell gas space. For the long term containment response, the heat and mass transfer between the suppression pool and the wetwell air space is mechanically calculated. Table 6.2-5A shows the peak bulk pool temperature is 203.4°F due to power rerate and SIL 636 (Reference 6.2-41). The peak wetwell gas space temperature is 210.7°F. These temperatures are well below the design temperature of 220°F.

6.2.1.8.1.3 Short-Term Containment Pressure Response

Short-term containment pressure response analyses were performed for the limiting DBA LOCA which assumes a double-ended guillotine break of a recirculation suction line to demonstrate that operation with power rerate will not result in exceeding the containment design limits. The short-term analysis covers the blowdown period during which the maximum drywell pressure, wetwell pressure, and differential pressure between the drywell and wetwell occur. This analysis was conservatively performed at 102% of 110% of original rated power. The results of this short-term analysis are summarized in Table 6.2-5A. The short-term containment pressure response for power rerate is shown in Figure 6.2-3A. The long-term containment pressure response is shown in Figure 6.2-7A. Table 6.2-5A also includes comparisons of the pressure values calculated with power rerate to the design pressures values from previous calculations reported in the UFSAR. As shown by these results, the peak pressure values are below the design values.

6.2.1.8.2 Containment Dynamic Loads

6.2.1.8.2.1 LOCA Containment Dynamic Loads

The LOCA containment dynamic loads analysis for power rerate is based primarily on the short-term LOCA analyses described in Section 6.2.1.8.1.3. These analyses provide calculated values for the controlling parameters for the dynamic loads throughout the blowdown. The key parameters are drywell and wetwell pressure, vent flow rate and suppression pool temperature. The LOCA dynamic loads which are considered in the power rerate evaluation include pool swell, condensation oscillation (CO), and chugging.

The short-term containment response conditions with power rerate are within the conditions used to define the pool swell loads. The initial drywell pressurization rate used to define the pool swell load is negligibly affected by rerated power. The short-term containment response conditions for vent flow rate and pool temperature with power rerate are negligibly affected by power rerate. In addition, the containment conditions with power rerate in which CO and chugging would occur are within the range of test conditions used to define the CO and chugging loads. Therefore, the LOCA dynamic loads are not affected by power rerate.

6.2.1.8.2.2 SRV Containment Dynamic Loads

Hydrodynamic loads generated by the actuation of Safety/Relief Valve (SRV) include both internal and external hydrodynamic loads. Internal loads include SRV discharge line loads and load on the quencher discharge device. External hydrodynamic loads include the suppression pool boundary pressure loads and the submerged structure loads. These loads are influenced by SRV opening

setpoint pressure, SRVDL geometry and submergence, initial air volume in SRVDL, quencher design and suppression pool geometry. The only parameter change introduced by power rerate which can affect SRV loads is the increase in SRV opening setpoint pressure which results in higher SRV flow rates and, therefore higher SRV loads.

The SRV analytical limits for setpoints show a 3.5% increase in the analytical values of the SRV opening pressure with power rerate. The increase in SRV setpoint pressure results in a corresponding 3.5% increase in flow rate and hydrodynamic loads. However, the original SRV external hydrodynamic load specification and the load specification on quenchers are defined based on a reference RPV pressure of 1276 psig. Comparison shows that the rerate increased SRV setpoint pressure and flow rate are still bounded by the referenced flow rate used to define the LGS T-quencher hydrodynamic loads (Reference 6.2-35). Therefore, the original containment dynamic and submerged structure loads remain bounding for power rerate. The same conclusion is also valid for the hydrodynamic loads on the quencher. The SRV discharge piping loads are included in the evaluation discussed in Appendix 3A and 3B.

6.2.1.8.2.3 Subcompartment Pressurization

The design loads on the shield wall due to a postulated pipe break in the annulus between this wall and the reactor vessel are acceptable for the higher reactor pressure at rerated conditions. The shield wall design remains adequate because the original analyzed loads were based on mass and energy releases which bound the rerated conditions. The subcompartment pressurization evaluations for power rerate are provided in Appendix 6A.

6.2.2 Containment Heat Removal System

6.2.2.1 Design Bases

The containment heat removal system (containment cooling system) prevents excessive containment temperatures following a LOCA so that containment integrity is maintained. To fulfill this purpose, the containment cooling system meets the following design bases:

a. The system is designed to limit the long-term bulk temperature of the suppression pool without spray operation when considering the energy additions to the containment following a LOCA (see Reference 6.2-4). These energy additions, as a function of time, are provided in Section 6.2.1.3.2.

b. The system is designed with sufficient capacity and redundancy so that a single failure of any active component, assuming a LOOP, cannot impair its capability to perform its safety-related function. The system is designed to remain operable following an SSE.

c. The system is designed to operate under any of the following conditions: LOOP, adverse natural phenomena (such as tornadoes, hurricanes, earthquakes, floods, etc.), and site related events (such as high and moderate energy pipe breaks, externally generated missiles, and transportation accidents).

d. Each active component of the system is testable during normal operation of the nuclear power plant.

6.2.2.2 System Design

The containment cooling system is an integral part of the RHR system as described in Section 5.4.7 and designed to seismic Category I requirements. The system is designed, fabricated, erected, and tested to quality Group B standards with the exception of the drywell and wetwell spray headers which were originally designed, fabricated, and erected to quality Group C standards but have been upgraded to quality Group B (Table 3.2-1). In the containment cooling mode, water is drawn from the suppression pool through redundant suction strainers, pumped through one or both RHR heat exchangers, and delivered to the vessel, the suppression pool, the drywell spray header, and/or the suppression pool vapor space spray header. Water from the RHRSW system is pumped through the heat exchanger tube side to remove heat from the suppression pool water. Two 100% capacity cooling loops are provided; each being mechanically and electrically separate from the other to achieve redundancy (Section 9.2.3). Power is supplied from the safeguard buses (Section 8.3). A P&ID and process diagram, including the process data, are provided in Section 5.4 for all design operating modes and conditions.

All ECCS and RCIC suction piping originating in the suppression pool is designed based on the following criteria:

a. The allowable pressure drop across the redundant pair of strainers for each RCIC and HPCI suction line is 2 psi maximum at the design flow rate with each of the strainers 50% plugged in order to exceed the minimum required NPSH provided to the associated pump.

b. The allowable dirty pressure drop across the redundant strainers for each of the RHR and Core Spray suction lines is 5 psi and 3.8 psi maximum, respectively, at the design flow rate in order to satisfy the minimum required NPSH provided to the associated pump. The dirty strainer pressure drop is based on the entire amount of fibrous debris generated in the drywell during a design basis LOCA (within the zone of influence of the worst case pipe break location) transported to the suppression pool and all fibrous debris is available to clog the strainer.

c. The strainer mesh openings are sized to allow foreign particles of no greater than 0.0625 inches to pass through in order to prevent plugging of the containment spray nozzles and pump seal flushing water circuits.

d. Each strainer is designed to withstand all seismic and hydrodynamic loads postulated to occur in the suppression pool. A dynamic loading analysis has been performed for the ECCS suction strainers that demonstrates their capability to adequately accommodate inertial loads (earthquake, SRV discharge, and LOCA condensation oscillation and chugging), operational loads (pressure and temperature), dead weight loads, and direct hydrodynamic loads. The latter loads are due to direct hydrodynamic SRV discharge (SRV air bubble loads) and downcomer discharges (LOCA air bubble, CO, chugging, water jet, and pool-swell loads). The mentioned loads are combined in accordance with Table 3A-20. Figure 3A-27 presents elevations, dimensions, and orientations of the piping systems inside containment that are associated with the ECCS suction strainers.

e. The RHR suction piping is arranged in the suppression pool considering the locations of the discharge piping, so that when operating in the suppression pool cooling mode the suppression pool is uniformly cooled.

Each pump suction line penetrates the vertical wall of the suppression pool, leading directly to a "T" arrangement. The "T"s for the RCIC line and HPCI line are oriented vertically. The remaining "T"s are horizontal. The centerline of this "T" is 23 inches maximum from the suppression pool wall and 11'-11" below the minimum Technical Specification suppression pool water level. Each arm of the "T" is the same nominal pipe size as the suction line. The strainers are bolted to the arms of each "T" except Core Spray strainers which are attached to one arm of each "T". Each of the two strainers for each suction line provides more than 100% of the cross-sectional area of the suction line. The design drawing for the RCIC and HPCI strainers is shown in Figure 6.2-51. The design drawings for the RHR and Core Spray strainers are shown in Figure 6.2-51.

In the unlikely event of a high energy pipe break within the primary containment, debris created might migrate to the suppression pool and build-up on the RCIC and HPCI pump suction strainers, impairing operation of these pumps. Such debris considerations are part of USI A-43, "Containment Emergency Sump Performance." The manufacturer has addressed this concern on a generic basis in a topical report which has been reviewed and accepted by the NRC (Reference 6.2-23). A plant specific review of this concern was made.

The only credible sources of LOCA generated debris inside the primary containment that have the potential to clog pump suction strainers are the thermal insulation materials on piping and equipment. There are four types of insulation materials used inside the primary containment:

a. Metallic reflective - used on reactor vessel.

b. Fiberglass (Nukon) - used on piping, valves, and pumps.

c. Fiberglass (antisweat) - used on chilled water piping.

d. Stainless steel encapsulated low conductivity insulation - used on piping at the pipe whip restraints.

Fiberglass insulation inside primary containment is protected with stainless steel jackets except where it is not practical (pipe hangers, supports) or where shapes are not suitable (some valves and reactor nozzles). Insulation added in the Unit 1 drywell during power ascension testing was installed without jackets to simplify installation.

Insulation debris can enter the suppression pool only through the wetwell downcomers (Figure 6.2-1). There are several physical barriers that will minimize the amount and size of debris that enters the downcomers, as described below:

a. Floor grating, walkways, stairs, structural steel, piping, etc., located above the drywell floor will trap the majority of dislodged insulation pieces before they can reach the drywell floor where the downcomers are located.

b. Covers over downcomer openings will prevent debris from falling directly into a downcomer.

c. Downcomer openings are above the floor. The downcomer pipes extend 18 inches above the drywell floor. This feature prevents entry of all heavier insulation debris due to the specific gravity of the debris and low velocity of the water converging on the downcomer rims. Floating debris, in most cases, will be partially submerged, which will prevent them from passing over the downcomer rim.

d. The clearances around the jet deflector assembly covering the downcomer openings are such that debris with dimensions larger than 10 inches will be blocked from entering the downcomer.

In the case of metallic reflective insulation, it will immediately sink to the bottom of the drywell floor pool, where the flow velocities are too low to transport this insulation over the downcomer rims into the suppression pool.

In the case of permanently installed antisweat insulation, the jacketing subjected to jet forces of a high energy line break is susceptible to being blown away along with the underlying fiberglass panels. The stainless steel jacketing is too dense to be transported to the wetwell. Loose fiberglass panels that fall to the floor float due to their low specific gravity and therefore could be carried over with the emergency core cooling water and be transported to the suppression pool. However, due to the minimal quantity of antisweat insulation provided on piping in the drywell, and the filtering effect of the physical barriers noted above, it is improbable that sufficient antisweat insulation materials would be available to plug the pump suction strainers.

In the case of stainless steel encapsulated low conductivity insulation, the steel jackets are welded around the low conductivity insulation and would therefore be expected to stay intact even if the entire assembly is blown away from the piping due to jet forces of a high energy line break. If the low conductivity insulation remained dry within the steel jackets, the assembly would have a lower specific gravity than water, thus allowing the assembly to float. However, vent holes are provided in each assembly for pressure equalization, so the low conductivity insulation would become wet, in which case the assembly would have a higher specific gravity than water and would sink. If the low conductivity insulation remained dry long enough to allow it to float to the downcomer openings, the size of most individual insulation assemblies would be too large to pass through the downcomer jet deflector assemblies. Also, the submergence of most smaller assemblies will be too deep to pass over the downcomer rims. Thus, due to the minimal quantity of low conductivity insulation provided on piping in the drywell, and the low probability of any dislodged insulation assemblies being transported to the suppression pool, it is improbable that these insulation materials would plug the pump suction strainers.

There is a potential for some quantity of fiberglass insulation to travel to the suppression pool. An evaluation was made to estimate the maximum quantity of fiberglass insulation debris that might be generated by a LOCA, the amount of such debris that might enter the suppression pool and cover the ECCS strainers, the attendant pressure losses and resulting effect on the ECCS pump NPSH margins.

In this review, no credit was taken for the protective effect of stainless steel jackets on the fiberglass insulation. The head loss due to 50% plugging of the suction strainers concurrent with minimum postaccident NPSH conditions does not cause the available NPSH to drop below that required by the RCIC and HPCI pumps. Using more realistic considerations, it has been determined that other transport mechanisms will significantly reduce the actual amount of fibrous insulation debris that could migrate to the suppression pool and cover the pump strainers.

Large capacity passive pump suction strainers have been installed on each RHR and Core Spray suction line in the suppression pool via plant modification, in response to NRC I.E. Bulletin 96-03, “Potential Plugging of Emergency Core Cooling Suction Strainers by Debris in Boiling Water Reactors”. The assumptions used in sizing these new strainers are consistent with the guidance specified in Regulatory Guidance 1.82, Revision 2, “Water Sources for Long-Term Recirculation

Cooling Following a Loss-of Coolant Accident" and NUREG/CR-6224, "Parametric Study of the Potential for BWR ECCS Strainer Blockage Due to LOCA Generated Debris" as described in PECO Energy's letter from G. A. Hunger, Jr., Director Licensing, to USNRC, dated October 6, 1997, "Request for Licensing Amendment Associated with ECCS Pump Suction Strainer Plant Modification".

It has been determined that the amount of fiberglass insulation debris generated by a LOCA jet impinging on nearby insulation will not jeopardize ECCS pump operation at LGS Units 1 & 2.

The containment cooling system is designed to withstand operating loads and loads resulting from natural phenomena. Components required to operate can be tested during normal plant operation so that reliability can be ensured. Construction codes and standards are covered in Section 5.4.7.

The containment cooling system is started manually. There are no signals that automatically initiate the system. Rather, the LPCI mode of RHR operation is automatically initiated from ECCS signals. The RHR system is realigned for containment cooling by the plant operator after the reactor vessel water level has been restored (Section 6.2.1). The RHR pumps are already operating. Containment cooling is initiated in loop A or B by manually starting the RHRSW pump; closing the heat exchanger bypass valve; opening the service water valves at the heat exchanger; closing the LPCI injection valve; and opening the pool return valve, not necessarily in this order. If a single failure has occurred that prevents system initiation, the other totally redundant system is placed into operation by following the same initiation procedure. If the operator chooses to use the containment spray to reduce containment pressure, he must close the LPCI injection valve and open the spray valves. An interlock prevents the operator from opening the drywell spray valves unless a containment high pressure signal is present.

The containment cooling system equipment is located in the reactor enclosure and protected from both internal and external floods. The equipment is located in separate compartments, the walls and doors of which are steam-tight and water-tight so that flooding due to leakage from piping in an adjacent containment cooling system or other ECCS compartment does not affect the redundant containment cooling system equipment. Flood design of the reactor enclosure is discussed in Section 3.4.

6.2.2.3 Design Evaluation

If there is a postulated LOCA, the short-term energy release from the reactor primary system is dumped to the suppression pool. Subsequent to the accident, fission product decay heat results in a continuing energy input to the pool. The containment cooling system removes this energy that is input to the primary containment system, thus resulting in acceptable suppression pool temperatures and containment pressures.

To evaluate the adequacy of the containment cooling mode of the RHR system, the following sequence of events is assumed to occur:

a. With the reactor initially operating at 3528 MWt, a LOCA occurs.

b. A LOOP occurs and one emergency diesel fails to start and remains out of service during the entire transient. This is the worst single active failure.

c. Only three LPCI pumps are activated and operated as a result of no offsite power and minimum onsite power. Section 6.3 describes the ECCS equipment.

d. No credit may be taken for manual actions within 10 minutes of a design basis accident. Analytically, it is assumed that containment heat removal begins at 10 minutes following a design basis LOCA. However, containment heat removal by activating an RHR heat exchanger for suppression pool cooling will be initiated in accordance with plant emergency operating procedures based on plant conditions. Once containment cooling has been established, no further operator actions are required.

When calculating the long-term post-LOCA pool temperature transient, it is assumed that the initial suppression pool temperature and the RHRSW temperature are at their maximum values. This assumption maximizes the heat sink temperature to which the containment heat is rejected and thus maximizes the containment temperature. All heat sources in the containment are considered with no credit taken for any heat losses other than through the RHR heat exchanger. These heat sources are discussed in Section 6.2.1.3. In addition, the RHR heat exchanger is assumed to be in a fully fouled condition at the time the accident occurs. This conservatively minimizes the heat exchanger heat removal capacity.

Figure 6.2-10 shows the actual heat removal rate of the RHR heat exchanger. The resultant suppression pool temperature transient is described in Section 6.2.1.1.3.3.1 and is shown in Figure 6.2-9. Even with the degraded conditions outlined above, the maximum suppression pool temperature is maintained below the design limit of 220°F.

The conservative evaluation procedure described above clearly demonstrates that the RHR system in the containment cooling mode meets its design objective of limiting the post-LOCA containment temperature transients safely.

6.2.2.4 Tests and Inspections

The Suppression Pool floor and low pressure ECCS (RHR and Core Spray) suction strainers shall be visually inspected for sludge accumulation and foreign material. The visual inspection allows use of a remote camera in lieu of divers. The interval of these inspections shall be every other refueling outage.

Preoperational tests are performed to verify individual component operation, individual logic element operation, and system operation up to the drywell spray spargers. A sample of the sparger nozzles is bench-tested for flow rate versus pressure drop to evaluate the original hydraulic calculations. Finally, the spargers are tested by air to verify that all nozzles are clear.

The preoperational test program of the containment cooling system is described in Chapter 14.

A design flow functional test of the RHR pumps is performed for each pump during normal plant operation by taking suction from and returning to the suppression pool. The discharge valves to the reactor recirculation system loops remain closed during this test, and reactor operation is undisturbed.

An operational test of the discharge valves is performed by shutting the downstream valve after it has been satisfactorily tested, thereby establishing the RCPB at the downstream valve, and then operating the upstream valve. The discharge valves to the drywell spray headers are checked in a similar manner by operating the upstream and downstream valves individually. All these valves can

be actuated from the control room by using remote manual switches. Control system design provides automatic return from the test to the operating mode if LPCI initiation is required during testing.

The surveillance frequency for testing and inspection is discussed in Chapter 16.

6.2.2.5 Instrumentation Requirements

The containment spray and suppression pool cooling modes of the RHR system are manually initiated from the control room. Once initiated, containment cooling performance is monitored by suppression pool temperature, flow, and containment pressure instrumentation. Details of the instrumentation are provided in Section 7.3.1.

6.2.3 SECONDARY CONTAINMENT FUNCTIONAL DESIGN

The secondary containment consists of three distinct isolatable zones. Zones I and II are the Unit 1 and Unit 2 reactor enclosures, respectively. Zone III is the common refueling area. Each zone has an independent normal ventilation system which is capable of providing secondary containment zone isolation as required.

Each reactor enclosure (Zones I or II) completely encloses and provides secondary containment for its corresponding primary containment and reactor auxiliary or service equipment, including the RCIC system, RWCU system, SLCS, CRD system equipment, the ECCS, and electrical equipment components.

The common refueling area (Zone III) completely encloses and provides secondary containment for the refueling servicing equipment and spent fuel storage facilities for Units 1 and 2.

When a unit's primary containment is open, as it is during the refueling period, the associated reactor enclosure and common refueling area provide primary containment for the unit being refueled.

The ability to procedurally combine each of the reactor enclosure secondary containment zones to the common refueling area secondary containment zone exists. The combining of the associated isolation zones is accomplished via an interlock switch located on the auxiliary equipment room panels. Table 6.2-29 identifies the associated secondary containment ventilation system automatic isolation valves that are required for the combined zone alignment.

6.2.3.1 Design Bases

a. The conditions that could exist following a LOCA or fuel handling accident require the establishment of a method of controlling any fission products that may leak into the secondary containment.

b. The functional capability of the ventilation system to maintain negative pressure in the secondary containment with respect to the outdoors is discussed in Sections 6.5.1.1 and 9.4.2.

c. The seismic design, leak-tightness, and internal and external design pressures of the secondary containment structure are discussed in Section 6.2.3.2 and Chapter 3.

d. The surveillance requirements for periodic inspection and functional testing of the secondary containment structure is discussed in the Technical Specifications.

6.2.3.2 System Design

6.2.3.2.1 Secondary Containment Design

The secondary containment is designed and constructed in accordance with the design criteria outlined in Chapter 3. All of the major structural walls are constructed of reinforced concrete. All of the major structural floor slabs and roof slabs are constructed of reinforced concrete supported by structural steel framing.

The reactor enclosure secondary containment (Zones I and II) are designed to limit the inleakage to 200% of their zone free volume per day, and the refueling area secondary containment (Zone III) is designed to limit the inleakage to 50% of its zone free volume per day. These inleakage rates are based on a negative interior pressure of 0.25 in wg, while operating the SGTS. Following a LOCA the affected zone is maintained at this negative pressure by operation of the SGTS. The secondary containment zones are identified in Figures 6.2-27 through 6.2-35.

An analysis of the post-LOCA pressure transient in the Unit 1/2 reactor enclosure secondary containment was performed (Figure 6.2-52). The length of time following isolation signal initiation of the SGTS that the pressure in the secondary containment would exceed -0.25 in wg. is 15.5 minutes based on drawing down both reactor enclosures and the common refueling area simultaneously.

In addition to the pressure transient analysis, a detailed review has been performed to identify potential leakage paths from either the primary containment or the secondary containment to the common refueling area. This review resulted in the following changes which ensure that no leakage paths exits:

a. A vent path from the reactor well to the reactor enclosure was added. When blind flanges are attached, the vent path will be through the associated opened drain lines or through a 1.5 inch hole in the blind flange.

b. Normally closed valves on the reactor well skimmer drain lines were added.

c. Provisions have been made to ensure that there is no flow path through the drain system between the refueling area and the reactor enclosure secondary containment.

Periodic tests are performed in accordance with the plant Technical Specifications to verify that the reactor enclosure secondary containment inleakage is less than 200% of its free volume per day at a negative interior pressure of 0.25 in wg.

The time line of events for actuating the SGTS is as follows:

Event	Time (sec)
Start of accident	0
Signal to start diesel	3
Diesel ready to load	13
Apply power to 480 V block 1 load	16
SGTS fans at rated speed	18

A maximum SGTS flow rate of 2800 cfm from a single reactor enclosure zone was used for the drawdown analysis.

The guidelines stated in the SRP 6.2.3 have been followed in calculating the drawdown time as noted:

a.

1. The heat transfer coefficients found in BTP CSB 6-1 apply to an atmosphere with high-energy blowdown where condensation on the primary containment surface is expected. Because the drawdown analysis was only 15.5 minutes long, the primary containment heat load was calculated as the steady-state load during normal operation when there are no condensation effects. This is accurate because LOCA conditions inside the primary containment will not affect the exterior surface temperature of the 6 foot containment wall significantly in 15.5 minutes. For steady-state heat load a conservative value was assumed.

2. Steady-state conduction and convection was calculated.

3. Radiant heat transfer was considered.

b. Adiabatic boundary conditions were used.

c. There will be negligible expansion of the 6 foot thick primary containment concrete walls in 15.5 minutes.

d. Inleakage was considered.

e. No credit was taken for outleakage.

f. The analysis was based on the assumptions and delays indicated in the acceptance criteria.

g. Heat loads generated within the secondary containment were considered.

h. Fan performance characteristics were considered.

Information that demonstrates the external design pressure of the secondary containment structure ensures an adequate margin above the maximum expected external pressure for wind loadings, tornado loadings, and explosion loadings. This information is provided in Sections 3.3 and 2.2.3.

The openings provided for gaining access to the secondary containment are listed in Table 6.2-13, and are shown in Figures 6.2-27 through 6.2-33.

Personnel Access Doors:

At each secondary containment personnel access opening there are two doors, which are designated the inner door and the outer door. Each door is equipped with a door position switch to provide monitoring. The monitoring circuitry consists of local indicating lights, local audible alarms, and control room annunciator lights and alarms. The monitoring operation is as follows:

a. Both doors closed - the blue indicating lights located on both sides above each door are de-energized

b. One door opened (either inner or outer) - the blue indicating lights above the door that is still closed are energized to warn against opening. The blue indicating lights above the opened door are still de-energized.

c. Both doors opened - the blue indicating lights above each door are energized; an instantaneous audible local alarm is energized; a time delay relay is energized and, after a preset time, it energizes a control room annunciator to identify that secondary containment access has been breached.

Closure of one of the doors returns the system condition to the same status as in paragraph B, above.

Equipment Access Doors:

All equipment access doors are kept locked. Each door is equipped with a door position switch to provide constant monitoring. The monitoring circuitry consists of a blue light indication on both sides of each door; instantaneous audible local alarm; and time delayed alarm in the main control room. The monitoring operation is the same as for the Personnel Access Doors described above.

Entrances to the reactor enclosure are provided with air locks for separation. Access doors between reactor enclosure ventilation zones are provided with airlocks.

The railroad access shaft, located between Unit 1 and Unit 2, is accessible through airlocks to the reactor enclosures and through the refueling floor ventilation duct-work and access hatch to the refueling floor. The railroad access door position is constantly monitored and alarmed (in the plant security system), under the requirements defined in the Physical Security Plan. Administrative procedures require that the access shaft outside door be closed and locked unless the access shaft is sealed closed from the refueling area and the ventilation duct-work is blocked whenever the refueling area secondary containment is required to be maintained.

Each door and section of the hatch is equipped with a position switch to provide constant monitoring. The monitoring circuitry consists of a blue light indication on both sides of the railroad access door and the top of the refueling floor access hatch; instantaneous audible local alarm; and time delayed alarm in the main control room. The monitoring operation is the same as for the Personnel Access Doors described above.

The boundaries of the secondary containment are shown in Figures 6.2-27 through 6.2-35.

The secondary containment design data are in Table 6.2-14.

6.2.3.2.2 Secondary Containment Isolation System

Isolation dampers and the plant protection signals that activate the secondary containment isolation system are described in Section 9.4.2.1.3.

6.2.3.2.3 Containment Bypass Leakage

Upon receipt of a reactor enclosure isolation signal, the RERS and the SGTS are automatically activated and begin to process all air flow streams from the reactor enclosure ventilation system. Therefore, if a LOCA occurs, radioactivity that exfiltrates the steel-lined primary containment or piping systems containing radioactive fluids is collected and passed through the RERS and SGTS as described in Section 6.5.

The potential paths by which leakage from the primary containment can bypass the areas serviced by the SGTS have been evaluated. Table 6.2-15 identifies all primary containment penetrations, the termination region of all lines penetrating primary containment, and the bypass leakage barriers in each line. It has been determined that no potential bypass leakage paths exist except for the feedwater line following a feedwater line break inside containment and the TIP purge nitrogen supply line. No significant amounts of radioactivity will be released to the environment in either case, as discussed below.

Leakage through the containment isolation valves of the TIP purge line could be released from a break or equipment failure into the reactor enclosure, radwaste enclosure, or outdoors. Leakage into the reactor enclosure would not constitute a bypass leakage path because the reactor enclosure is serviced by the SGTS. Any leakage into the radwaste enclosure would not result in a significant release of radioactivity because of plateout, deposition, and transport delay within the TIP purge piping. The long lines within the reactor enclosure (>240 feet of 1 inch pipe and >220 feet of 6 inch pipe) and the presence of numerous valves in these lines (2 containment isolation valves, a ¼ inch check valve, a ¼ inch solenoid valve, a ¼ inch metering valve, a 1 inch check valve, and a 1 inch globe valve) provide a long and tortuous route between the primary containment and the radwaste enclosure. Any leakage through the reactor enclosure and radwaste enclosure piping would be into the liquid nitrogen facility (tanks, vaporizers, control valves, etc.) located adjacent to the radwaste enclosure. The liquid nitrogen facility maintains system pressure at 50 psig.

A water seal cannot be maintained in the broken feedwater line by the feedwater fill system (Section 6.2.3.2.3.2) for the case of a feedwater line break inside containment. For this case, containment leakage may travel past the broken feedwater line's containment isolation valves into the portion of the feedwater line located in the turbine enclosure. However, a water seal in this portion of the feedwater line would be maintained by water from the CST as discussed in Section 6.2.3.2.3.1.

When designating the termination region, if either the system line that penetrates primary containment or any branch lines connecting to it penetrate the reactor enclosure, the termination region is listed in Table 6.2-15 as outside reactor enclosure. The types of bypass leakage barriers employed by these lines are:

1. Redundant primary containment isolation valves

2. Closed piping system inside primary containment

3. A water seal maintained for 30 days following a LOCA

4. The line beyond the outboard primary containment isolation valve is vented to the reactor enclosure by use of a vent line located upstream of the two block valves.

5. A MSIV alternate drain pathway is provided.

6. The line contains a temporary spool piece that is removed during normal operation and replaced by blind flanges so that any leakage through the flange is into the reactor enclosure.

7. A closed seismic Category I piping system outside primary containment.

8. The line contains a spectacle flange with the blind side installed during normal operation. Any leakage through the flange will be into the reactor enclosure.

9. The line contains two spring loaded check valves and two manual stop valves.

Type 1 and Type 2 leakage barriers are considered to limit but not eliminate bypass leakage. Leakage barriers of Type 3 through Type 9 are considered to effectively eliminate any bypass leakage.

Leakage from those lines terminating in the reactor enclosure is collected during the LOCA because the reactor enclosure is restored to and maintained at subatmospheric pressure and all exhaust is processed by the RERS and SGTS during these modes (Section 6.5). Therefore, lines terminating within the reactor enclosure are not considered potential bypass leakage paths.

Lines penetrating primary containment are isolated following a LOCA as described in Section 6.2.4. All containment isolation valves and penetrations are designed to seismic Category I requirements.

The primary containment and penetration leakage is monitored during periodic tests as discussed in Section 6.2.6. Those penetrations for which credit is taken for water seals as a means of eliminating bypass leakage (Table 6.2-15) are preoperationally leak tested with water and Technical Specification leakage rates are given as water leak rates.

6.2.3.2.3.1 Water Seals

In each case where water seals are used to eliminate the potential of reactor enclosure bypass leakage, a 30 day water seal is assured because either a loop seal is present or the water for the seal is provided from a large reservoir. The water seals for all of these lines will be maintained at a pressure greater than the peak containment accident pressure. Each of the water seals listed in Table 6.2-15 is discussed below (some penetrations may be listed more than once due to the presence of multiple types of water seals).

a. Penetrations 9A, 9B, and 44:

   The feedwater fill system (Section 6.2.3.2.3.2) is used to maintain a water seal in the lines downstream of these penetrations. The feedwater fill system cannot maintain a water seal in the feedwater lines (penetrations 9A and 9B) following a feedwater line break inside containment. However, for this case, a water seal will be maintained in the piping and equipment between the CST and the feedwater penetrations because:

   1. The elevation of the primary containment penetrations is 287 ft.

   2. The elevation of the minimum CST water level is 246 ft.

   3. The low point of the makeup water line is at elevation 220 ft.

   Therefore, the water seal will be maintained in that portion of the piping system below el 246'. This water seal will be able to withstand the containment pressure resulting from a feedwater line break as discussed below.

Immediately after the line break, when containment pressure will be at its peak, the feedwater line will still have a pressure greater than the pressure in primary containment. The feedwater will flash into steam at the break until the line pressure matches the containment pressure, thus preventing any containment atmosphere from entering the line during this period. In addition, there are several valves in the feedwater line between the primary containment and the water seal. A pressure decrease will occur across each valve, reducing the pressure that the water seal will encounter. Figures 6.2-3 and 6.2-7 show the primary containment pressure transient following a recirculation line break. These figures show that the maximum long-term pressure post-LOCA is approximately 17 psig. The difference in elevation between the lowest point of the water seal and the minimum CST water level indicates a head of 20 psig, which is greater than the pressure that the primary containment will exert on the water seal.

The piping and equipment that comprise this potential bypass leakage flow path is continuously inspected during normal operation when pressures are more than ten times greater than post-LOCA pressures. Even considering liquid leakage from the components in the water seal, the volume of water contained in the CST is sufficiently large to ensure that a water seal is maintained for at least 30 days.

b. Penetrations 204A, 204B, 207A, 207B, 208B, 210, 212, 215, 216, 217, 226A, 226B, 235, 236, 238, 239, and 240:

The lines associated with these penetrations all penetrate the wetwell above the suppression pool water level and terminate at least 4 feet below the minimum suppression pool water level. A 30 day water seal is therefore assured on the submerged portion of line.

c. Penetrations 13A, 13B, 16A, 16B, 17, 39A, 39B, 45A-D, 205A, and 205B:

Piping connected to these penetrations is normally full of water and will be kept full after a LOCA due to operation of the ECCS and/or safeguard piping fill system. The suppression pool is the water source for the ECCS and fill system, and therefore a 30 day water supply is assured.

d. Penetrations 203A-D, 206A-D, 209, 214, and 237:

The lines associated with these penetrations all penetrate the wetwell at least 11 feet below the minimum water level of the suppression pool, and therefore a 30 day water seal is assured.

e. Penetrations 231A and 231B:

The line to the containment isolation valves from the drywell floor drain sump is maintained full of water by an elevation difference between the sump and the valves. The line to the containment isolation valves from the drywell equipment drain tank is maintained full of water by an elevation difference between the tank and the valves.

f. Penetrations 10, 11, 12, 44, 228D, and 241:

Lines associated with these penetrations that pass through the secondary containment boundary and take credit for water seals are provided with loop seals inside secondary containment, which eliminates the possibility of bypass leakage. The HPCI and RCIC steam supply line connections to Auxiliary Steam contain spectacle flanges. After testing, the blind portion of the spectacle flange shall be installed. These spectacle flanges are shown on drawing M-55 (lines 4" GBD-137 and GBD-237) and on drawing M-50 (lines 3" GBD-136 and GBD-236).

g. Penetration 14:

The minimum piping height inside primary containment of the RWCU supply line that branches off the recirculation loop is at el 267'. The primary containment penetration is at el 297' and the RPV penetration is at el 280'. This elevation difference ensures that a water seal is maintained in the line from the RPV to the containment isolation valves. The RWCU supply branch line that connects to the bottom of the vessel is normally full of water, and the water will be maintained in this line because it connects directly to, and below, the vessel.

h. Penetrations 37A-D and 38A-D:

The CRD insert and withdraw lines are normally full of water. A water seal will be maintained in these lines after a LOCA due to the elevation difference between the containment penetrations (el 265') and the connections to the control rod drives (el 215').

i. Penetrations 23, 24, 53, 54, 55, and 56:

Both the drywell chilled water system and the RECW system have a system vent in the refueling area. A 30 day water seal is provided between the system vent and the containment penetrations. These systems are normally full of water and are inspected during normal operation, when system pressure is greater than post-LOCA containment pressure, to ensure that leakage is minimized. These systems have an interconnecting line between them which decreases the possibility of depleting their water seals. The systems each contain a head tank with a water-retaining boundary qualified to LOCA (hydrodynamic) loads. These tanks increase the system water inventory and maintain the head of water in the system piping greater than the maximum containment pressure following a LOCA.

j. Penetration 61:

The recirculation pump seal purge lines are vented to secondary containment by use of vent lines located before two block valves and the secondary containment (drawings M-43 and M-46). The normally open block valves (HV127 and HV128) receive an automatic containment isolation signal to close, which is shown as Reference 18 on drawing M-46. It is not necessary for the containment isolation signal to also automatically open the (normally closed) vent valves. The seal lines are normally filled with water, which will spill into secondary containment when the vent valves open. To preclude the possibility of this happening in the event of a false LOCA, the vent valves will be manually actuated to open when the operator has verified that isolation and venting of these lines is required. The water in the lines will provide a temporary seal to prevent bypass leakage until the vent valves are opened.

6.2.3.2.3.2 Feedwater Fill System

The feedwater fill system prevents the release of fission products through the feedwater containment isolation valves after a LOCA by providing a water seal downstream of the valves.

6.2.3.2.3.2.1 Safety Design Bases

The feedwater fill system is designed with sufficient capacity and capability to prevent leakage through the feedwater lines under the conditions associated with the entire spectrum of LOCAs except for a feedwater line break inside containment.

The feedwater fill system conforms to seismic Category I requirements. Quality group classifications are shown in Table 3.2-1, Item XI.A. The system meets the intent of Regulatory Guide 1.96, where applicable.

The feedwater fill system is capable of performing its safety function considering the effects resulting from a LOCA, including missiles that may result from equipment failures, dynamic effects associated with pipe whip and jet forces, and normal operating and accident-caused local environmental conditions consistent with the design basis event. Furthermore, any portion of the feedwater fill system that is quality Group A and is located outside the primary containment structure is protected from missiles, pipe whip, and jet force effects originating outside the containment so that containment integrity is maintained.

The feedwater fill system is capable of performing its safety function following a LOCA and an assumed single active failure.

The feedwater fill system is designed so that effects resulting from a single active component failure do not affect the integrity or operability of the feedwater lines or the feedwater containment isolation valves.

The feedwater fill system is capable of performing its safety function following a LOOP coincident with a postulated design basis LOCA.

The feedwater fill system is designed to prevent leakage from the feedwater lines consistent with maintaining containment integrity for up to 30 days.

The feedwater fill system is manually actuated and is not required to be actuated sooner than 30 minutes after a LOCA.

The feedwater fill system, including instrumentation and circuits necessary for the functioning of the system, is designed in accordance with standards applicable to an ESF.

The plant is designed to permit testing of the operability of the feedwater fill system controls and actuating devices during power operation, to the extent practicable, and to permit testing of the complete functioning of the system during plant shutdowns.

6.2.3.2.3.2.2 System Description

The feedwater fill system is a subsystem of the safeguard piping fill system. The safeguard piping fill pumps provide suppression pool water as the water seal source for the feedwater lines (Section

6.3.2.2.6 and drawing M-52). The feedwater fill system consists of two fill trains, one from each fill pump. Each train is routed to both feedwater lines (drawing M-41).

Following a LOCA, the feedwater fill system is manually initiated from the control room. A water seal is provided by the fill system in both feedwater lines for all line breaks other than a feedwater line break inside containment. For this case, the feedwater fill system can be isolated from the broken feedwater line so that a water seal can be maintained in the intact feedwater line. A water seal inside the broken feedwater line cannot be maintained by the fill system for the case of a feedwater line break inside containment because the water escapes out the broken pipe into primary containment.

The sealing water to the valves eventually fills the feedwater lines up to the reactor vessel, and the water returns to the suppression pool through the LOCA break. Because the source of sealing water is the suppression pool, a 30 day water supply is assured. Operation of the feedwater fill system will not affect the function of the suppression pool because the seal water is eventually returned to the pool when the drywell is flooded back through the downcomers.

6.2.3.2.3.2.3 Safety Evaluation

The feedwater fill system is designed to prevent the release of radioactivity through the feedwater line isolation valves by providing a continuous flow of water through the feedwater lines following a LOOP coincident with the postulated design basis LOCA. The two redundant fill trains are physically separated, except where the lines are interconnected, to minimize the exposure to missiles and to the effects of pipe whip or jet impingement from high energy line breaks.

The feedwater fill system is seismic Category I and is capable of performing its intended function following an active component failure. Each fill train is powered from a different division of the Class 1E power supply. Double series isolation valves are provided to ensure that no single active failure will affect the integrity of the feedwater lines.

Feedwater line pressure is indicated in the control room so that the operator can determine if there has been a feedwater line break inside containment. If so, the operator can isolate the system from the broken line and still provide fill system water to the intact line.

6.2.3.2.3.2.4 Instrumentation and Controls

The instrumentation necessary for control and status indication of the feedwater fill system is classified as essential and, as such, is designed and qualified in accordance with applicable IEEE standards to function under seismic Category I and LOCA environmental loading conditions appropriate to its installation, with the control circuits designed to satisfy the mechanical and electrical separation criteria. Section 7.6 gives a control and instrumentation description.

6.2.3.2.3.2.5 Inspection and Testing

Preoperational tests for the safeguard piping fill system are discussed in Chapter 14. During plant operation, valves, piping, instrumentation, electrical circuits, and other components outside the steam tunnel can be inspected visually at any time. Complete system functional testing or isolation valve testing from fully closed-to-open and the return open-to-closed position is performed during reactor shutdown.

6.2.3.3 Design Evaluation

The design evaluation of the secondary containment ventilation systems are given in Sections 6.5.1 and 9.4.2. The high energy lines within the secondary containment are identified and pipe ruptures analyzed in Section 3.6. The leak-off system on the nitrogen purge lines has two outboard block valves in series downstream of the leak-off vent valves and the secondary containment boundary. The liquid nitrogen facility is located outside of secondary containment. Therefore, a failure of one of the outboard block valves does not prevent a negative pressure from being maintained in the secondary containment structure or result in leakage from the primary containment across the inboard valve to the environment.

6.2.3.4 Tests and Inspections

The program for initial performance testing is described in Chapter 14. The program for periodic functional testing of the secondary containment structures including SGTS drawdown time and the secondary containment isolation system and system components is described in Chapter 16. The leak rate testing program and provisions are discussed in Section 6.5.1, as part of the SGTS tests.

6.2.3.5 Instrumentation Requirements

The control systems to be employed for the actuation of the reactor enclosure ESF air handling systems are described in Section 7.3.

The control and monitoring instrumentation for the above systems is discussed in Sections 6.5.1 and 9.4.2. Design details and instrumentation logic are discussed in Section 7.3.

6.2.4 CONTAINMENT ISOLATION SYSTEM

The containment isolation system is designed to prevent or limit the release of radioactive materials that may result from postulated accidents. This is accomplished by providing isolation barriers in all fluid lines that penetrate primary containment.

6.2.4.1 Design Bases

a. The containment isolation system is designed to allow the normal or emergency passage of fluids through the containment boundary while preserving the ability of the boundary to prevent or limit the escape of radioactive materials that can result from postulated accidents.

b. The containment isolation system is designed to either automatically isolate fluid penetrations or provide the capability for remote manual isolation from the control room.

c. The arrangement of containment isolation valves for fluid systems that penetrate the primary containment conforms to GDC 54, 55, 56, and 57 to the greatest extent practicable.

d. Fluid instrument lines that penetrate primary containment conform to the isolation criteria of Regulatory Guide 1.11 to the greatest extent practicable.

e. Containment isolation provisions are designed to withstand the most severe natural phenomenon or site-related event (e.g., earthquake, tornado, wind, flood, or transportation accident) without impairing their functions.

f. The containment isolation system is designed with provisions for periodic operability and leak rate testing.

g. Valve closure times are selected to limit the release of containment atmosphere to the environs, to mitigate offsite radiological consequences, and to ensure that ECCS effectiveness is not degraded.

h. Design provisions are made to detect possible leakage from lines provided with remote manually controlled isolation valves.

i. Isolation valves, actuators, and controls are protected against loss of functional capability from missiles and accident environments for which they are designed.

j. Redundancy and physical separation are provided in the electrical and mechanical design to ensure that no single failure in the containment isolation system can prevent the system from performing its intended function (except as described in this section).

k. The design of the control systems for automatic containment isolation valves is such that resetting the isolation signal does not result in the automatic reopening of containment isolation valves (except as described in this section).

6.2.4.2 System Design

Table 6.2-17 lists the fluid system and instrument line containment penetrations and presents design information about each. Accompanying this table is Figure 6.2-36, which consists of diagrams for the various isolation valve arrangements. Cross references are provided between the diagrams and the table.

The plant protection signals and instrumentation that initiates containment isolation are discussed in Section 7.3.1.1.2.

Evaluation of the containment isolation system with respect to the following areas is discussed in separate sections as indicated:

a.	Code class and seismic design	Section 3.2
b.	Missile protection	Section 3.5
c.	Protection against dynamic effects associated with the postulated rupture of piping	Section 3.6
d.	Environmental design	Section 3.11

Debris transported to the suppression pool by the emergency core cooling water is prevented from entering the ECCS suction lines by suction strainers. The suction strainers are described in Section 6.2.2.

Assurance of the operability of valves and valve operators in the containment atmosphere under normal plant operating conditions and postulated accident conditions is discussed in Section 3.9.3.

Provisions for detecting leakage from systems connected to the RCPB which are provided with manual isolation valves are discussed in Section 5.2.5.

The design provisions for testing the operability of the isolation valves and the leakage rate of the containment isolation barriers are discussed in Section 6.2.6.

An alternate drain pathway is provided for the MSIVs, and is discussed in Section 6.7. A seismic Category I fill system provides a water seal for the feedwater lines, as discussed in Section 6.2.3.2.3.

Containment isolation valve closure times are selected to ensure rapid isolation of the containment following postulated accidents. The isolation valves, in lines that provide an open path from the containment to the environs, have closure times that limit the release of containment radioactivity to the environs to below 10CFR50.67 dose limits, mitigate the offsite radiological consequences, and ensure that ECCS effectiveness is not degraded. These valve closure times are identified with a double asterisk in Table 6.2-17. The isolation valves for lines in which HELBs can occur have closure times that limit the resultant pressure and temperature transients as well as the radiological consequences. These valve closure times are identified with a single asterisk in Table 6.2-17.

All of the isolation valve closure times listed in Table 6.2-17 are the actual closure times that the isolation valves were purchased with, which in all cases are equal to or lower than the closure times necessary to meet the aforementioned design requirements. The given valve closure times are the maximum time it takes for a valve to move to its fully closed position after power has reached the operator assembly. Those closure times which are required to be met to satisfy isolation valve closure time design requirements are identified by a single or double asterisk in Table 6.2-17.

The essential/nonessential classification of containment isolation valves, as listed in Table 6.2-17, was based on the following: those systems identified as essential are regarded as indispensable or are backup systems in the event of an accident; nonessential systems have been judged to not be required after an accident. The classification of essential and nonessential systems is given in Table 6.2-27.

Isolation valves are designed to be operable under environmental conditions such as maximum differential pressures, seismic occurrences, steam atmosphere, high temperature, and high humidity. The normal and accident environmental conditions are described in Section 3.11.

Refer to Table 6.2-17 for isolation valve power supplies.

Motor-operated isolation valves remain in their last position upon failure of electrical power to the motor operator. Air operated containment isolation valves are spring-loaded to close upon loss of air or electrical power.

The design of the isolation valve system gives consideration to the possible adverse effects of sudden isolation valve closure when the plant systems are functioning under normal operation.

Reopening of the containment isolation valves requires deliberate operator action. The HPCI and RCIC steam line isolation valves are exceptions as discussed in Section 7.1.2.11. Control systems for the automatic containment isolation valves are discussed in Section 7.3.1.1.2.

The LGS containment purge valves have been designed to function if a LOCA should occur while the purge valves were open. The valve manufacturer has completed an extensive program of tests

and analyses to demonstrate the operability of the valves in accordance with all published NRC guidelines and criteria. The following is a brief summary of the factors addressed in the valve operability qualification report (Reference 6.2-8):

a. Valves are supplied in accordance with ASME Section III, Class 2 requirements

b. Finite-element analyses have been used to determine valve component stress levels for limiting combinations of loads

c. The impact of dynamic loadings is addressed by analysis and static load testing

d. All valves are located outside containment, thus eliminating concern over the effects of containment pressure on pneumatic operator performance

e. Air operators are equipped with springs to facilitate valve closure; accumulators or other pneumatic systems are not used for valve closure or sealing

f. Valve dynamic torque coefficients have been determined by reduced-scale and full-scale testing

g. The effects of installation geometry and arrangement have been fully considered

h. Containment pressure has been conservatively assumed to be constant at its maximum pressure for all valve angles

i. Back pressure caused by flow through downstream piping has been conservatively neglected

j. Elastomeric materials are not used for valve seating surfaces

k. Valve operators and pilot solenoids have been qualified to IEEE 323 (1974) and NUREG-0588 Category I requirements

l. Motor operator performance has been demonstrated at minimum available voltage levels

m. Motor operators are equipped with hand wheels which automatically disengage upon electric activation

6.2.4.3 Design Evaluation

The main objective of the containment isolation system is to provide protection by limiting release to the environment of radioactive materials. This is accomplished by isolation of system lines penetrating the primary containment. Redundancy is provided so that the active failure of any single valve or component does not prevent containment isolation.

The arrangements of isolation valves are described in Table 6.2-17 and Figure 6.2-36. In general, isolation valves have redundancy in the mode of actuation as indicated in Table 6.2-17. A program of testing, described in Section 6.2.4.4, is maintained to ensure valve operability and leak-tightness.

The design specifications require each isolation valve to be operable under the most severe environmental conditions that it might experience. Protection from potential missiles is discussed in Section 3.5.

Provisions for administrative control of the proper position of all nonpowered isolation valves, including valves in test, vent, drain, and similar types of branch lines that serve as containment isolation barriers, are maintained. The test taps, vents, drains, and similar types of branch lines that constitute containment isolation barriers are equipped with manually closed isolation valves.

Administrative controls will ensure that the valves are locked closed after use.

All power-operated isolation valves have position indicators in the control room. Discussion of instrumentation and controls for the isolation valves is included in Chapter 7.

6.2.4.3.1 Evaluation Against General Design Criteria

6.2.4.3.1.1 Evaluation Against GDC 54

All piping systems penetrating containment, other than instrument lines, are designed in accordance with GDC 54.

6.2.4.3.1.2 Evaluation Against GDC 55

GDC 55 requires that lines which penetrate the primary containment and form a part of the RCPB must have two isolation valves; one inside the containment and one outside, unless it can be demonstrated that the containment isolation provisions for a specific class of lines are acceptable on some other basis.

The RCPB, as defined in 10CFR50, Section 50.2 (v), consists of the RPV, pressure-retaining appurtenances attached to the vessel, and valves and pipes that extend from the RPV up to and including the outermost isolation valve.

6.2.4.3.1.2.1 Influent Lines

All influent lines that penetrate the primary containment and connect directly to the RCPB are equipped with at least two isolation valves, one inside the drywell, and the other outside the drywell and as close to the external side of the containment as practicable.

6.2.4.3.1.2.1.1 Feedwater Line

The feedwater lines are part of the RCPB as they penetrate the drywell to connect with the RPV. Each of the two feedwater penetrations is provided with a series arrangement of three isolation valves:

a. A check valve is provided inside the drywell as close to the containment wall as practicable. For a worst case break of a feedwater line inside containment, it would be impossible to ensure the operability of the inboard check valve due to pipe whip forces.

b. A spring assisted check valve is provided outside the drywell as close to the containment wall as practicable. The spring forces the valve flapper in the closed

direction, thus providing added assurance of valve seating in the event of low pressure in the supply piping. The spring will not prevent flow in the downstream (toward the vessel) direction but does create some flow restriction. An air operator is provided with the check valve assembly. This air operator is normally pressurized, thus compressing the spring and reducing the flow restriction.

c. A third check valve is provided in the feedwater line outboard of the above described spring assisted check valve. The function of these valves is to:

1. Prevent HPCI, RCIC, and RWCU water from flowing upstream in the feedwater line, thus ensuring flow into the reactor vessel.

2. Provide isolation in the event of a feedwater line break upstream of this valve.

This third check valve includes a motor operator to seal the disc closed for long-term leakage control.

Additional isolation valves are provided on each of the lines connecting to the feedwater lines inboard of the check valve :

1. MOVs are provided on the HPCI, RCIC, and long path recirculation lines.

2. A spring assisted check valve is provided on the RWCU supply line. This valve is of a design similar to the outboard spring assisted feedwater check valves described above. This RWCU check valve is spring assisted to seal the disc closed for long-term leakage control.

In the Limerick SER Section 6.2.4, licensee committed to administrative procedures that will require isolation of the main feedwater, RWCU, RCIC, and HPCI system lines following an accident if these systems are not providing reactor coolant makeup. The NRC included this commitment in the SER to satisfy SRP 6.2.4.6.b criteria. Instead of using a leakage detection system in conjunction with a remote manual containment isolation valve, to satisfy SRP criteria, these valves would be procedurally controlled and remotely closed from the control room to provide long term leakage protection after a postulated LOCA to satisfy SRP criteria.

Plant procedures will require remote manual closure of the remote manual containment isolation valves in the main feedwater and RWCU systems, if reactor coolant makeup is no longer required. The containment isolation valves in the RCIC and HPCI system automatically reposition closed, if reactor coolant makeup is no longer required from these systems. Therefore, plant procedures will not be required to remote manually close the RCIC and HPCI containment isolation valves.

Limerick SER Section 6.2.4 also states that a remote-manual motor-operated valve upstream of the air-operated check valve on the RWCU branch line that can also be utilized to isolate this line. This non-safety related remote-manual motor-operated valve upstream of the air-operated check valve is not capable of, or required to support a safety related long-term leakage control function as described in the SER.

6.2.4.3.1.2.1.2 Core Spray (CS) Loop B

The CS loop B line penetrates the drywell to inject directly into the RPV. Isolation is provided by two valves in the CS line, a pneumatic testable check valve inside the containment, and a spring assisted check valve outside the containment, with positions of both indicated in the main control room. The

core spray loop B line is also provided with a normally closed pneumatic operated globe valve which bypasses the inboard isolation valve for equalization during testing.

Although not a containment isolation valve, a MOV is provided outboard of the spring assisted check valve to provide isolation of this flow path for long-term leakage control.

One branch of the HPCI line connects to the CS loop B upstream of the outboard spring assisted check valve. Although not a containment isolation valve, the HPCI line also contains a MOV outboard of the spring assisted check valve to provide isolation of this flow path for long-term leakage control.

6.2.4.3.1.2.1.3 LPCI and CS Loop A

The LPCI lines and CS loop A line are provided with remote manually controlled gate valves outside and pneumatic testable check valves inside containment. Both types of valves are normally closed with the gate valves receiving an automatic signal to open at the appropriate time. The check valves are located as close as practicable to the RPV. The normally closed check valves limit containment pressurization if there is a pipe rupture between the check valve and containment wall. The core spray loop A line and the LPCI lines are also each provided with a normally closed pneumatic operated globe valve which bypasses the inboard isolation valve for testing purposes.

6.2.4.3.1.2.1.4 Deleted

6.2.4.3.1.2.1.5 Recirculation Pump Seal Purge Line

The recirculation pump seal purge line extends from the CRD supply line outside primary containment, penetrates primary containment through an excess flow check valve outside and a check valve inside containment, and connects to the recirculation pump seal housing. The 1 inch recirculation pump seal purge line is Quality Group Classification A from the pump up to and including the excess flow check valve outside containment. Should this line be postulated to fail and either one of the check valves is assumed to fail open, the flow rate through a broken line outside containment is calculated to be substantially less than that permitted for a broken instrument line. Therefore, the two check valves in series provide sufficient isolation capability for the postulated failure of this line.

6.2.4.3.1.2.1.6 Standby Liquid Control System Lines

The SLCS line penetrates the drywell and connects to the Core Spray loop B line. In addition to a simple check valve inside the drywell, a globe stop-check valve is located outside the drywell. Since the SLCS line is a normally closed, nonflowing line, rupture of this line is of extremely remote probability. The globe stop check includes a motor operator to seal the valve closed for long-term leakage control.

6.2.4.3.1.2.1.7 RWCU System

The RWCU pumps, heat exchangers, and filter/demineralizers are located outside the drywell. The return line branches into three separate lines outside the drywell. One line connects to the RCIC line that connects to the B feedwater line penetrating the drywell and injecting directly into the RPV. The second branch connects directly to the A feedwater line that penetrates the drywell and injects directly into the RPV.

Isolation of both these lines is provided by the feedwater system check valves inside and outside the containment and a spring assisted check valve in the connecting RWCU return line.

Following a LOCA, it is desirable to maintain reactor coolant makeup. For this reason, the above remote manual containment isolation valves are not provided with automatic isolation signals. However, plant procedures will require remote manual closure of the remote manual containment isolation valves, if reactor coolant makeup is no longer required.

The third line penetrates the drywell and then connects to the A feedwater line that injects directly into the RPV. This line is only used during outages. Isolation is provided by one locked closed globe valve inside containment and one locked closed globe valve outside containment. A 3/4 inch relief valve is provided outside containment between the two isolation valves for thermal relief.

6.2.4.3.1.2.1.8 RCIC Line

The RCIC line connects to the B feedwater line outside containment that penetrates the drywell to inject directly into the RPV. The feedwater line has a check valve both inside and outside the drywell. In addition to these two isolation valves, a motor- operated gate valve is located in the RCIC line that is normally closed and receives an automatic signal to open. Following a LOCA, plant procedures will require remote manual closure of this isolation valve unless RCIC is providing reactor coolant makeup.

6.2.4.3.1.2.1.9 RHR Shutdown Cooling Return

Each RHR shutdown cooling return line penetrates primary containment and discharges into a recirculation pump discharge line that injects directly into the RPV. Isolation is provided by an automatically actuated motor-operated globe valve outside containment and a pneumatic testable check valve and a spring-assist check valve inside containment. A normally closed pneumatic operated globe valve is provided which bypasses the inboard isolation testable check valve for equalization during testing. To increase the reliability of RHR shutdown cooling mode during refueling outages, the automatic isolation function of the RHR shutdown cooling mode return motor-operated valves is typically bypassed provided that automatic isolation is not required by the Technical Specifications or Technical Requirements Manual and the reactor cavity is flooded up. Manual isolation capability is retained.

6.2.4.3.1.2.2 Effluent Lines

Effluent lines that form part of the RCPB and penetrate containment are equipped with at least two isolation valves; one inside the drywell and the other outside, located as close to the containment as practicable or justified on an alternate basis.

6.2.4.3.1.2.2.1 Main Steam, RCIC and HPCI Steam Lines, and RHR Shutdown Cooling Supply Line

The main steam lines extend from the RPV to the main turbine and condenser system, and penetrate the primary containment. For these lines, isolation is provided by automatically actuated globe valves, one inside the containment and one just outside the containment. The MSIVs are spring-loaded, pneumatic, piston- operated globe valves designed to fail closed on loss of pneumatic pressure or loss of power to the solenoid-operated pilot valves. Each valve has two independent pilot valves supplied from independent power sources. Each MSIV has an accumulator to assist in its closure upon loss of normal supply. The springs and accumulator provide a local stored energy source dedicated to closure of an MSIV under all conditions which requires MSIV closure.

The main steam line drain connects to the main steam lines inside containment and extends through containment to the condenser. This line is provided with motor-operated gate valves inside and

outside containment that receive an automatic isolation signal to close when the reactor water level drops below Level 1.

The RCIC turbine steam supply line from main steam line B is provided with two motor-operated, normally open globe valves, one inside and one outside the containment. These valves are closed on receipt of an RCIC isolation signal. The HPCI system turbine steam supply line from main steam line C is provided with motor-operated, normally open globe valves, one inside and one outside containment. These valves are closed on receipt of a HPCI isolation signal.

The RCIC and HPCI steam lines are each also provided with a normally closed motor-operated globe valve that bypasses the outboard isolation valve for steam supply line warmup purposes only. The valve in the RCIC steam line is closed upon receipt of an RCIC isolation signal, and the HPCI steam line valve is closed upon receipt of an HPCI isolation signal. The isolation signals are considered adequate because there is no consequence if the valves open or leak while the system is in operation and appropriate isolation signals are provided to secure the line when system isolation is required.

The RHR shutdown cooling supply line is provided with motor- operated gate valves, one inside and one outside containment, that receive an automatic isolation signal when isolation is required. To increase the reliability of RHR shutdown cooling mode during refueling outages, the automatic isolation function of the RHR shutdown cooling mode supply motor-operated valves is typically bypassed provided that automatic isolation is not required by the Technical Specifications or Technical Requirements Manual and the reactor cavity is flooded up. Manual isolation capability is retained.

6.2.4.3.1.2.2.2 Main Steam and Recirculation System Sample Lines

Sample lines from the main steam and recirculation lines penetrate the primary containment. These lines are provided with air operated globe valves, one inside and one outside containment, that receive an automatic isolation signal if there is an accident, or fail closed on loss of air or electrical power.

6.2.4.3.1.2.3 CRD Lines

The CRD system has multiple lines, the insert and withdraw lines, that penetrate primary containment.

The classification of these lines is Quality Group B, and they are designed in accordance with ASME Section III, Class 2. The basis on which the CRD insert and withdraw lines are designed is commensurate with the safety importance of maintaining the pressure integrity of these lines.

The CRD insert and withdrawal lines are not provided with automatic containment isolation valves in order to maximize the reliability of the scram function. A ball check valve located in the CRD flange housing automatically seals the insert line in the event of a line break. The insert and withdrawal lines terminate in HCUs which contain multiple valves (manual, solenoid, air operated, and check valves) to control CRD movement, and limit leakage. The isolation function is provided by two redundant simple check valves outboard of the HCUs on each main water header (charging, cooling, drive and exhaust). All automatic valves in the HCUs are normally closed and are open only during rod movement. Because the scram valves in the HCU are normally open after a scram, the scram discharge volume is provided with redundant automatic vent and drain valves.

6.2.4.3.1.2.4 Conclusion on GDC 55

In order to ensure protection against the consequences of accidents involving the release of radioactive material, pipes that form the RCPB are shown to provide adequate isolation capabilities on a case-by-case basis. In all cases, a minimum of two barriers are shown to limit the release of radioactive materials.

The pressure-retaining components that comprise the RCPB are designed to meet other appropriate requirements that limit the probability or consequences of an accidental pipe rupture. The quality requirements for these components ensure that they are designed, fabricated, and tested to the highest quality standards of all reactor plant components. The classification of components that comprise the RCPB are designed in accordance with ASME Section III, Class 1, with the exception of the CRD insert and withdrawal lines as discussed in Section 6.2.4.3.1.2.3 above.

It is therefore concluded that the design of piping systems that comprise the RCPB and penetrate containment either meet the explicit requirements of, or are acceptable alternatives to the explicit requirements of GDC 55.

6.2.4.3.1.3 Evaluation Against GDC 56

GDC 56 requires that lines which penetrate the containment and communicate with the containment interior must have two isolation valves; one inside the containment and one outside, unless it can be demonstrated that the containment isolation provisions for a specific class of lines are acceptable on some other basis.

6.2.4.3.1.3.1 Influent and Effluent Lines to Suppression Pool

Typically, lines which connect directly to the suppression pool are provided with a single remote manual or automatic isolation valve. These valves are attached to lines which are an extension of the containment and are enclosed in a pump-room adjacent to the containment which has provisions for environmental control of any fluid leakage. The lines to the suppression pool are always submerged so no containment atmosphere can impinge upon the valves.

The systems which the lines from the suppression pool connect to outside containment are closed systems meeting the appropriate requirements of closed systems, except for the suppression pool cleanup line and the RCIC vacuum pump discharge line. Both of these lines have redundant containment isolation valves.

The valves provide a barrier outside containment to prevent loss of suppression pool water should a leak develop downstream of the valves in the lines from the suppression pool. (The valves are either remotely closed from the control room or automatically closed to accomplish this. Leak detection is provided for the lines outside containment so that the operator can determine which valve is to be closed.) Should a leak develop outside containment, the fluid will be contained within compartments that have provisions for the environmental control of any fluid leakage. The configuration of the connection of the lines to the suppression pool assures that the connections are always submerged, and prevents escape of containment atmosphere.

6.2.4.3.1.3.1.1 CS, HPCI, and RHR Test Lines and Minimum Flow Bypass Lines

The CS, HPCI, and RHR test and minimum flow bypass lines have isolation capabilities commensurate with the importance to safety of isolating these lines.

The RHR pump test lines connect to the associated minimum flow bypass lines outside primary containment and penetrate containment through normally open, remote manually controlled gate valves located directly on the containment. This reduces the number of penetrations through the primary containment, thus minimizing the potential pathways for radioactive material release.

The CS pump test lines have a normally closed, motor-operated globe valve located directly on the containment that receives an automatic isolation signal if there is an accident. The CS minimum flow bypass lines have a normally open motor-operated globe valve that receives an automatic isolation signal when adequate flow is established in the pump discharge lines.

The HPCI pump test line has a normally closed motor-operated gate valve located directly on the containment that receives an automatic isolation signal if there is an accident. The minimum flow bypass line has a normally closed motor-operated globe valve located directly on the containment that receives an automatic isolation signal when adequate flow is established in the pump discharge lines.

The CS, HPCI and RHR pump test and minimum flow bypass lines discharge below the surface of the suppression pool. Thus the lines are not directly open to the containment atmosphere.

6.2.4.3.1.3.1.2 RCIC Turbine Exhaust, Vacuum Pump Discharge, and RCIC Pump Minimum Flow Bypass Lines

The lines that penetrate the containment and discharge to the suppression pool are equipped with a remote manually actuated valve. The RCIC turbine exhaust isolation valve is a normally open motor-operated gate valve. The vacuum pump discharge isolation valve is a normally open globe stop-check valve. The RCIC pump minimum flow bypass isolation valve is a normally closed motor-operated globe valve. In addition, there is a check valve upstream of each valve that provides positive actuation for immediate isolation if there is a break upstream of this valve. The gate valve in the RCIC turbine exhaust is designed to be key-locked open in the control room and interlocked to preclude opening of the inlet steam valve to the turbine when the turbine exhaust valve is not in a fully open position. The RCIC vacuum pump discharge line is also normally key-locked open but has no requirement for interlocking with the steam inlet to the turbine. The RCIC vacuum pump discharge line is provided with a stop-check valve at the containment to automatically prevent flow out of the containment. This valve functions as both a check valve and a remote manually actuated globe valve. A remote manually actuated motor operator ensures the long-term positive closure of the stop-check valve. This arrangement ensures that the essential RCIC pump-turbine will be ready to operate in the event of a reactor vessel isolation occurrence accompanied by loss of feedwater flow. The RCIC pump minimum flow bypass line is isolated by a normally closed remote manually actuated valve that is automatically isolated when adequate flow is obtained in the pump discharge line, with a check valve installed upstream. These lines discharge below the surface of the suppression pool. Thus, the lines are not directly open to containment atmosphere.

6.2.4.3.1.3.1.3 RHR Heat Exchanger Vent Lines and Relief Valve Discharge Lines

The Unit 2 RHR heat exchanger vent lines discharge to the suppression chamber via relief valve discharge lines and are provided with two normally closed, remotely controlled motor-operated globe valves. The inboard valves receive an automatic isolation signal if there is a LOCA. The Unit 1 and Unit 2 relief valve discharge lines are isolated by the relief valves themselves in a fashion similar to a check valve, and the relief setting on these valves is more than 1.5 times the containment design pressure. The lines discharge below the surface of the suppression pool. Thus, the lines are not directly open to containment atmosphere.

6.2.4.3.1.3.1.4 HPCI Turbine Exhaust Line

The HPCI turbine exhaust line that penetrates the primary containment and discharges to the suppression pool is equipped with a remote manually operated gate valve located directly on the containment. In addition, there is a stop-check upstream of the gate valve that provides positive actuation for immediate isolation if there is a break upstream of this valve. The gate valve is designed to be key-locked open and interlocked to preclude opening of the inlet steam valve to the turbine while the turbine exhaust valve is not fully open. This line discharges below the surface of the suppression pool. Thus, the line is not directly open to containment atmosphere.

6.2.4.3.1.3.1.5 RHR, RCIC, CS, and HPCI Pump Suction Lines

The RHR, RCIC, CS, and HPCI suction lines contain motor-operated, remote manually actuated gate valves that provide assurance of isolating these lines if there is a break. These valves also provide long-term leakage control. In addition, the suction piping from the suppression chamber is considered an extension of containment since it must be available for long-term usage following a design basis LOCA, and as such, is designed to the same quality standards as the containment. System reliability is greater with only one isolation valve in the line because the ECCS pumps must have the capability to take suction from the suppression pool in order to mitigate the consequences of an accident. The RHR suction lines are also provided with a relief valve that discharges back into the suppression pool through the suction line penetration. The relief valve discharge lines are isolated by the relief valves themselves in a fashion similar to a check valve.

6.2.4.3.1.3.1.6 Suppression Pool Cleanup Line

The suppression pool cleanup line is isolated by two normally closed motor-operated gate valves that close on receipt of a containment isolation signal and a relief valve (PSV-52-127) whose setting is more than 1.5 times the containment design pressure.

6.2.4.3.1.3.2 Influent and Effluent Lines from Drywell and Suppression Pool Free Volume

6.2.4.3.1.3.2.1 Containment Atmosphere Sampling Lines

The sampling system lines that penetrate the containment and connect to the drywell and suppression chamber air volume are equipped with two normally open solenoid-operated isolation valves in series, located outside and as close to the containment as possible. These valves ensure isolation of these lines if there is a break; they also provide long-term leakage control. In addition, the piping is considered an extension of the containment boundary since it must be available for long-term usage following a design basis LOCA, and, as such, is designed to the same quality standards as the primary containment. The following containment atmosphere sampling isolation valves have ganged controls for reopening:

a. Inboard drywell sample and return isolation valves SV-132, SV-134, and SV-150 are ganged on HS-132

b. Inboard suppression pool sample and return valves SV-183 and SV-191 are ganged on HS-183

c. Outboard drywell sample and return isolation valves SV-141, SV-142, SV-143, SV-144, SV-145, and SV-159 are ganged on HS-153

d. Outboard suppression pool sample and return isolation valves SV-184, SV-185, SV-186, SV-190, and SV-195 are ganged on HS-187.

6.2.4.3.1.3.2.2 Drywell Equipment and Floor Drain Lines

The drywell equipment and floor drain lines are each provided with two air operated spring-closed valves located outside the primary containment. One of these valves is normally open and one normally closed. The inner valve (normally open) is located directly on the containment. Both valves are automatically closed upon receipt of a containment isolation signal.

6.2.4.3.1.3.2.3 Containment Purge and Hydrogen Recombiner Lines

The high volume purge lines for the drywell and suppression chamber are each provided with two isolation valves located outside the primary containment. The inboard valve in each line is a normally closed, air operated butterfly valve located as close as practical to the primary containment penetration. The outboard valve in each line is a normally closed, motor-operated butterfly valve. A nonsafety-related north stack effluent high radiation isolation signal is also provided for the containment purge valves (HV-104, 109, 114, 115, 112, 121, 124, 123, 131, 135, 147). A description of the type and the arrangement of containment isolation valves used in the low volume purge exhaust lines is provided in Section 9.4.5.1.2. Each of these valves receives automatic isolation signals.

The hydrogen recombiner lines connect to the high volume purge lines between the containment penetration and the inboard isolation valve. Each of the recombiner lines is provided with two normally closed MOVs that can be manually actuated from the control room. These isolation valves each receive automatic isolation signals. For operation of the recombiners after a LOCA, the isolation signals to these valves are overridden by using key-locked bypass switches. All four isolation valves on each recombiner train are powered from the same channel of electrical power in order to minimize the impact on system reliability.

The ESF recombiner system (Section 6.2.5) is designed as a closed system outside containment in addition to the isolation valves described above. The containment isolation provisions for the recombiner lines meet all of the relevant design criteria in Regulatory Guide 1.141, ANSI N-271, and SRP 6.2.4, as described below:

a. The closed system does not communicate with either the secondary containment atmosphere or the environment.

b. The closed system has been designed, fabricated, installed, and stamped in accordance with ASME Section III, Class 2 requirements.

c. The closed system has a design temperature and pressure at least equal to the containment design conditions. The design temperatures and pressures are as follows:

    1. Nonoperating modes: 55 psig / 340°F for stainless steel and carbon steel components

    2. Operating conditions: stainless steel components (30 psig / 1400°F)

d. The closed system is designed as seismic Category I.

e. The system is designed to withstand the loads and environmental conditions accompanying a LOCA.

f. High energy and moderate energy pipe break effects will not affect hydrogen recombiner system continuity when the closed system is needed for containment isolation (Section 3.6.2).

g. The recombiner system is designed to be leak-tight and will be periodically leak tested at the containment peak accident pressure.

h. Any leakage from the system will be confined within the secondary containment and will be diluted and filtered prior to release.

i. The closed system is protected from missiles (Section 3.5).

The high volume purge lines are provided with debris screens located at the point where each purge line terminates inside the primary containment. The debris screens are designated as seismic Category I and are designed to withstand the maximum differential pressure across the screen that could result from a LOCA.

6.2.4.3.1.3.2.4 RCIC and HPCI Turbine Exhaust Vacuum Breaker Lines

These lines are provided with two normally open motor-operated remote manually actuated gate valves. The valves are automatically closed on receipt of an RCIC or HPCI isolation signal.

6.2.4.3.1.3.2.5 Traversing Incore Probe

The TIP system purge line is equipped with a normally open air operated globe valve outside containment and a check valve inside containment. The TIP system purge line air operated valve is normally open in order to provide a continuous supply of dry gas to the indexing mechanisms. Upon receipt of a containment isolation signal, the TIP system purge line AOV is automatically closed. TIP drive cables are normally retracted except during calibration of the power range neutron detectors or when an actual TIP mapping operation is in progress. Under normal operating conditions, the TIP system guide tubes do not communicate with the containment atmosphere because purge air supplied to the box surrounding the indexing mechanism effectively precludes such communication. However, following a LOCA or containment pressurizing event, a check valve on the box will open resulting in direct communication between the containment atmosphere and the TIP guide tubes. Because the TIP system lines can be considered instrument lines, the isolation provisions for the TIP system are described in the evaluation of compliance with Regulatory Guide 1.11, Section 6.2.4.3.1.5.

6.2.4.3.1.3.2.6 Containment Spray

The containment spray lines are provided with two normally closed, remote manually operated isolation valves outside the containment. The inner isolation valve is located directly on the containment.

6.2.4.3.1.3.2.7 Suppression Pool Spray

The suppression pool spray lines are provided with normally closed isolation valves outside containment, located directly on the containment. The valves automatically close upon receipt of an isolation signal. The external pipe, designed to Quality Group B and seismic Category I requirements, provides the second isolation barrier. Because of the desired use of this system after a LOCA, the system reliability is greater with only one isolation valve in the line.

6.2.4.3.1.3.2.8 Drywell Radiation Sampling Lines

The sampling system lines that penetrate the containment and connect to the drywell and suppression chamber air volume are equipped with two normally open solenoid-operated isolation valves in series, located outside and as close to the containment as possible. These valves ensure isolation of these lines if there should be a break; they also provide long-term leakage control.

In addition, the piping is considered an extension of the containment boundary and, as such, is designed to the same quality standards as the primary containment. The drywell radiation sampling isolation valves have ganged controls for reopening. Inboard sample and return isolation valves SV-190A and SV-190C are ganged on HS-190A. Outboard sample and return isolation valves SV-190B and SV-190D are ganged on HS-190B.

6.2.4.3.1.3.2.9 Primary Containment Instrument Gas

The influent lines are provided with a normally open power-operated globe valve outside the containment and a check valve inside the containment. MOVs are used on the influent lines that contain the ADS gas supply. These are essential lines that provide a long-term backup to the ADS accumulators inside containment. The valves on these essential lines are remote manually operated and automatically isolate only when flow out of containment through these lines would be possible (i.e., low differential pressure between the containment and the instrument gas line). The remaining influent lines are nonessential lines that use AOVs that are automatically closed on receipt of a containment isolation signal. The effluent line is provided with a normally open air operated globe valve outside and a motor-operated globe valve inside the containment that close automatically on receipt of a containment isolation signal.

6.2.4.3.1.3.2.10 Reactor Enclosure Cooling Water

Each influent and effluent line is provided with two gate valves located outside containment. The inboard valves are motor- operated. The outboard valves on the ESW intertie lines are locked closed and the motor operators are not connected to any power supply. The outboard valves on the RECW lines (HV-108 and HV-111) are motor-operated and their controls are ganged on HS-108. Each of the MOVs can be remote manually closed from the control room. Automatic, diverse isolation signals are also provided to these valves. In addition, the containment isolation signals to these valves can be overridden by using key-locked bypass switches.

6.2.4.3.1.3.2.11 Drywell Chilled Water

Each influent and effluent line is provided with two motor-operated gate valves located outside containment. The controls for these valves are ganged as follows:

a. Loop A inboard influent and effluent isolation valves HV-128 and HV-129 are ganged on HS-128.

b. Loop B inboard influent and effluent isolation valves HV-122 and HV-123 are ganged on HS-122.

c. Loop A outboard influent and effluent isolation valves HV-120A, 121A, 124A and 125A are ganged on HSS-121A.

d. Loop B outboard influent and effluent isolation valves HV-120B, 121B, 124B and 125B are ganged on HSS-121B.

The inboard valves are provided with automatic isolation signals as indicated in Table 6.2-17. The outboard isolation valves are normally aligned to the drywell chilled water system. Outboard valves HV-120A, HV-120B, HV-121A and HV-121B are provided with diverse, automatic isolation signals. In addition, the containment isolation signals to these valves can be overridden by using key-locked bypass switches. The other outboard isolation valves, HV-124A, HV-124B, HV-125A, and HV-125B were motor operated valves converted to normally closed passive manual valves using the existing actuator. These valves may be aligned to the RECW system as allowed by the Primary Containment Isolation Valve Technical Specification LCO/Action requirements. These valves have administrative controls because they are passive locked closed manual valves with the associated breakers locked open when primary containment integrity is required.

6.2.4.3.1.3.3 Conclusion on GDC 56

In order to ensure protection against the consequences of accidents involving release of significant amounts of radioactive materials, pipes that penetrate the containment have been demonstrated to provide isolation capabilities on a case-by-case basis in accordance with GDC 56.

In addition to meeting isolation requirements, the pressure- retaining components of these systems are designed to the same quality standards equivalent to those used for the primary containment.

6.2.4.3.1.4 Evaluation Against GDC 57

This GDC was not used in the design of containment penetrations for LGS.

6.2.4.3.1.5 Evaluation Against Regulatory Guide 1.11

Instrument lines that penetrate the containment from the RCPB conform to Regulatory Guide 1.11 in that they are equipped with a restricting orifice located inside the drywell and an EFCV located outside and as close as practicable to the containment. Should an instrument line that forms part of the reactor pressure boundary develop a leak outside the containment, a flow rate that results in a differential pressure across the valve of 3-10 psi causes the EFCV to close automatically. Should an EFCV fail to close when required, the main flow path through the valve has a resistance to flow at least equivalent to a sharp-edged orifice of 0.375 inch diameter. Valve position indication is provided in the reactor enclosure. Those instrument lines that do not connect to the RCPB conform to Regulatory Guide 1.11 in that they are either equipped with an EFCV or an isolation valve capable of remote operation from the control room, and are sized or orificed to meet the criteria outlined in Regulatory Guide 1.11. The drywell pressure, suppression pool level, suppression chamber pressure, and drywell sump level instrument lines are:

a. Provided with isolation valves capable of remote operation from the control room.

b. Q-listed, as discussed in Section 3.2.

c. Designed to seismic Category I standards.

d. Designed to withstand containment design pressure and temperature.

e. Terminate in the reactor enclosure, which is served by the SGTS.

The status of the isolation valves capable of remote operation from the control room is indicated in the control room.

The TIP system lines as shown in drawing M-59 and described below are considered instrument lines because:

a. they function as instrument lines or support the operation of instrument lines, and

b. they are small diameter lines.

TIP system isolation valves are provided on each guide tube immediately outside the containment. Dual barrier protection is provided by a solenoid-operated ball valve and an explosive actuated cable shearing valve. The ball valve is closed except when a TIP is inserted. These valves prevent loss of reactor coolant in the event that an incore guide tube ruptures inside the reactor vessel and prevents the escape of primary containment atmosphere.

The guide tube ball valve solenoid is normally de-energized and the valve is in the closed position. When the TIP starts forward, the valve solenoid is energized and the valve is held open against its spring. As the valve opens, it actuates a set of contacts which provide position indication at the TIP control panel and a permissive signal for TIP motion. Upon receipt of a containment isolation signal (reactor low water level or high drywell pressure), the TIP drive mechanism is signalled to retract the TIP. As the TIP is withdrawn into its shield chamber outside containment, a position switch signals the ball valve to close.

The shear valve is provided as a backup in the event that a TIP cannot be retracted or a ball valve sticks open when containment isolation is required. In this event, the shear valve would be operated from the control room to cut the cable and seal the guide tube. Continuity of the shear valve squib firing circuits is continuously monitored by front panel indicator lights in the control room.

The guidelines of Regulatory Guide 1.11, section 1.b are met for the TIP system as discussed below.

An analysis of the maximum leakage rate from the TIP system and the offsite radiological effects under normal reactor operating conditions was performed. The analysis conservatively assumed that all TIP system lines suffered guillotine breaks just outside the containment boundary. Specific activity inside the primary containment was assumed to be at the maximum Technical Specification limit for iodine in the primary coolant. (This is an extreme conservatism because a primary coolant rather than drywell atmosphere source term was assumed.) To characterize maximum flow through the TIP system lines, the drywell was assumed to be at its maximum normal pressure (2.0 psig) and normal temperature (135°F ①). It was also conservatively assumed that all TIP probes are fully retracted. Under these conditions, total flow from the TIP system lines would be only 0.105 lb_m/sec as compared to 2.2 lb_m/sec for an instrument line which penetrates the reactor primary coolant

boundary. The corresponding 24 hour site boundary dose for this flow rate (using worst case average annual meteorology) would be less than 0.03 rem thyroid. The conservatively calculated leak rate is extremely low and the offsite dose is a small fraction of 10CFR50.67 limits.

The TIP guide tubes are equipped with dual isolation valves located as close to containment as practical; a solenoid-actuated ball valve and an explosively actuated shear valve acting in series. The ball valves are normally de-energized (in a closed position). Consequently, during normal operation, the containment isolation function for the TIP system is accomplished without the need for any action. Therefore, requirement of Regulatory Guide 1.11, section 1.C.1 is met. In the unlikely event of a LOCA while the TIP system is in operation, containment isolation is automatically accomplished as follows. Upon receipt of a containment isolation signal (reactor low water level or high drywell pressure), the TIP drive mechanism is automatically signaled to retract the TIP. As the TIP is withdrawn into its shield chamber, a position switch signals the ball valve to close. All TIP line ball valves open against a spring and will close on loss of power. The cable shearing valves are equipped with redundant explosive actuating devices increasing the isolation reliability of the system and are remote manually operated from the control room. The ball and shear valves are instrumented to indicate position (i.e., open or closed).

Accidental closure of the TIP line isolation valves does not create a safety hazard, nor is the TIP system required to operate during an accident to mitigate the consequences of that accident. Therefore, the isolation provisions of the TIP system comply with the requirements of Regulatory Guide 1.11, section 1.C.2. When the TIP starts forward, the ball valve solenoid is energized and the valve is held open against its spring. This satisfies the requirement of section 1.C.3, and therefore satisfies all the requirements of Regulatory Guide 1.11, section 1.C.

The design of the TIP isolation system is commensurate with the importance to safety of isolating that system. It recognizes that the TIP system design is such that the TIP guide tube isolation ball valve is normally closed. Typically, a TIP scan requires insertion of the TIP probes into the reactor vessel for a period of approximately 4 hours per month. Over a one year period, this amounts to a total of 120 hours per year, or less than 2% of the time.

① This evaluation bounds the effects of operating at a normal temperature of 150°F, since total mass flow would be reduced.

Because of the normally closed state of the TIP ball valves, the probability of a release of radioactivity through the TIP guide tubes following a LOCA is extremely low. Even in the event of a LOCA, the TIP system design will reliably provide automatic isolation of any open TIP guide tubes by providing for automatic retraction of the TIP cable followed by automatic closure of the TIP ball valve. Should the ball valve fail to automatically close, that condition would be indicated to the operator in the control room. The operator could then manually actuate the shear valve in the control room to isolate that line.

The design of the TIP system isolation provisions is based on the low probability that the system will be called upon to isolate the containment following a significant fission product release to the containment atmosphere. Consequently, the power supplies and the controls for the TIP isolation valves are not safety-grade. However, the overall system reliability for isolation is high because: (1) the ball and shear valves are powered from separate power supplies, (2) the shear valves are powered from an onsite dc power source, (3) the ball, shear, and purge check valves, and the line from the containment to the outermost isolation valve are mechanically safety-grade, (4) upon loss of power the ball valves close, and (5) the TIP system receives automatic LOCA signals to retract and isolate.

In considering the potential magnitude of a fission product release through the TIP guide tubes as a result of a design basis LOCA event, it is appropriate to consider the event probability. There are several sequences of events which could lead to a fission product release through the TIP guide tubes. Any sequence which leads to a release must involve: (1) a design basis LOCA, and (2) a degraded core. The probability of this combination of events alone is on the order of 10^{-7} per reactor year. Additional failure(s) in the TIP isolation system have to be assumed for the release through the TIP guide tubes to occur. These failures would involve the ball and shear valves not closing as designed for various reasons such as a hot short causing the ball valves to fail open and the shear valve not closing after the cable is retracted. The inclusion of the additional failures would lower the probability of occurrence of the event by several orders of magnitude below the 10^{-7} per reactor year figure discussed above. This analysis assumes the proper functioning of nonsafety-grade power supplies and circuits for the TIP isolation valves in determining overall system reliability. The low probability of a fission product release to the environment through the TIP guide tubes demonstrates the adequacy of the current TIP isolation system design basis.

Although the above discussion indicates an extremely low likelihood of a fission product release through the TIP guide tubes or purge lines, the consequence of that release has been evaluated for the most probable event. That event would involve the failure of all five TIP guide tubes to isolate following a degraded core event. In this instance, the TIP probe substantially reduces the flow area in the TIP guide tube which provides a pathway for fission product release unless some other unlikely event (i.e., earthquake) were to occur at the same time and cause further equipment failures. The pathway for an atmospheric fission product release would be through the check valve in the indexer box (open due to a positive internal containment pressure), down the long and narrow annulus between the TIP probe/cable assembly and the guide tube, and out through the end of the guide tube located in the reactor enclosure. The probe/cable assembly are never completely withdrawn from the guide tube, so the annular flow restriction is maintained. For the radiological analysis, Regulatory Guide 1.183 source terms and accident meteorology were assumed.

The results of the radiological evaluation show that the site boundary and low population zone doses for this limiting event using Regulatory Guide 1.183 assumptions are below 10CFR50.67 limits.

The low probability of fission product release and the results of the radiological evaluation satisfy the intent of Regulatory Guide 1.11, section 1.d.

6.2.4.3.1.6 Evaluation Against Regulatory Guide 1.141

The containment isolation system conforms to Regulatory Guide 1.141 except as discussed below:

> Section 3.6.4 Single Valve and Closed System Both Outside Containment...
>
> The single valve and piping between the containment and the valve shall be enclosed in a protective leak-tight or controlled leakage housing to prevent leakage to the atmosphere.

LGS Design:

For systems that fall into this category except for the ECCS pump suction lines, the single valve outside primary containment is not enclosed in a protective leak-tight or controlled leakage housing. Moderate energy lines that fall into this category do not connect to the RCPB and are not postulated to break concurrent with a LOCA. Therefore, neither reactor coolant nor post-LOCA containment atmosphere are released. However, any leakage is contained within the secondary containment

and is diluted and filtered prior to release. The ECCS pump suction isolation valves are enclosed in pump rooms adjacent to the containment that have provisions for the environmental control of any fluid leakage.

The existing isolation provisions for the above lines meet the criteria set forth by ANSI N271 (1976). These isolation provisions consist of a line submerged in the suppression pool (except for the suppression pool spray line) and a valve outside containment. In addition, a closed system is provided as another containment isolation barrier. For each of the lines, the closed system outside containment is protected from missiles, designed to seismic Category I standards, classified safety class 2, and is designed to the temperature and pressure conditions that the system will encounter after an accident. Justification for the design of the valve nearest containment and any piping between containment and the valve is provided in the following discussion.

> Section 3.6.5 Two Valves Outside Containment...
>
> The valve nearest the containment wall and piping between the containment and that valve shall be enclosed in a protective leak-tight or controlled leakage housing to prevent leakage to the atmosphere.

LGS Design:

The lines listed below, which have containment isolation provisions that consist of two valves in series located outside primary containment, are moderate energy lines that do not connect to the RCPB. These lines are not postulated to experience a guillotine break. Locating the valves on these lines outside the primary containment is more practical than locating the valves inside containment because of the adverse environment that is experienced when most of the valves may be needed (post-LOCA) and because this location allows inspections and maintenance to be performed on these valves during normal operation. The existing isolation provisions for all these lines meet the criteria set forth by ANSI N271 (1976).

The design of the valve nearest containment and any piping between the containment and the valve, for the following penetrations, is discussed below:

Penetration	Line	Valve
X-25	Drywell purge supply	122
X-26	Drywell purge exhaust	113
X-28A	Drywell $H_2/0_2$ sample	134, 132
X-28B	Drywell $H_2/0_2$ sample	133
X-39A,B	Containment Spray	F021A,B
X-35C-G	TIP Drive	140A-E, 141A-E
X-40G	ILRT data acquisition	1057, 1071
X-117B	Drywell radiation sampling	190A,B, 190C,D

X-62	$H_2/0_2$ sample return; drywell purge makeup	150
X-201A	Suppression pool purge supply	125
X-202	Suppression pool purge exhaust	103
X-203A,B,C,D	RHR pump suction	F004A,B,C,D
X-204A,B	RHR pump test and minimum flow	125A,B
X-205A,B	Suppression pool spray	F027A,B
X-206A,B,C,D	CS pump suction	F001A,B,C,D
X-207A,B	CS pump test and flush	F015A,B
X-208B	CS pump minimum flow	F031B
X-209	HPCI pump suction	F042
X-210	HPCI turbine exhaust	F072
X-212	HPCI pump test and flush	F071
X-214	RCIC pump suction	F031
X-215	RCIC turbine exhaust	F060
X-216	RCIC minimum flow	F019
X-217	RCIC vacuum pump discharge	F002
X-220A	$H_2/0_2$ sample return; wetwell purge makeup	190
X-221A	Wetwell $H_2/0_2$ sample	181
X-221B	Wetwell $H_2/0_2$ sample	183
X-226A,B	RHR minimum flow	105A,B
X-227	ILRT data acquisition	1073
X-228D	HPCI vacuum relief	F095
X-231A,B	Drywell sump drains	110, 130
X-235	CS pump minimum flow	F031A
X-236	HPCI pump minimum flow	F012

X-238	RHR relief valve discharge	106B
X-239	RHR relief valve discharge	106A
X-241	RCIC vacuum relief	F084

These moderate energy lines are not postulated to break concurrent with a LOCA. Therefore, neither reactor coolant nor post-LOCA containment atmosphere are released. Analyses have been performed to ensure that the effects of postulated moderate energy line breaks will not prevent the safe shutdown of the plant. The results of these analyses are provided in Section 3.6.1.2.

Section 4.4.2 Method of Valve Actuation...

It should not be possible for remote manual operation to override the automatic isolation signal until the sequence of automatic events following a isolation signal is completed...

LGS Design:

This guideline is met for all remote manually operable valves with the exception of valves in systems that must be operated after an accident and that have been provided with a key-locked override switch for this purpose.

Section 5.3.2 - Leakage Rate Testing

Provisions and Methods. Provisions shall be made for leakage rate testing of containment isolation valves.

LGS Design:

Individual leakage rate tests are performed for containment isolation valves as indicated in Table 6.2-25.

6.2.4.3.2 Failure Mode and Effects Analyses

A single failure can be defined as a failure of some component in any safety system that results in a loss or degradation of the system's capability to perform its safety function. Active components are defined as components that must perform a mechanical motion during the course of accomplishing a system safety function. 10CFR50, Appendix A requires that electrical systems be designed against passive single failures as well as active single failures. Section 3.1 describes the implementation of these requirements as well as GDC 17, 21, 35, 41, 44, 54, 55, and 56.

In single failure analysis of electrical systems, no distinction is made between mechanically active or passive components; all fluid system components, such as valves, are considered electrically active whether or not mechanical action is required.

6.2.4.4 Tests and Inspections

The containment isolation system undergoes periodic testing during reactor operation. The functional capabilities of power-operated isolation valves are remotely tested manually from the main control room. During all modes of manual MOV operation using the handswitch from the main control room, a "dead zone" is present for a portion of the valve travel. The "dead zone" is present when the valve is not fully closed and green light only indication exists. If the valve is stopped in the "dead

zone", operator action is required to restart the valve. By observing position indicators and changes in the affected system operation, the closing ability of a particular isolation valve is demonstrated.

A discussion of testing and inspection pertaining to isolation valves is provided in Section 6.2.1.6 and in Chapter 16. Table 6.2-17 lists all isolation valves.

Instruments are periodically tested and inspected. Test and/or calibration points are supplied with each instrument.

EFCVs are periodically tested to verify proper operation. As these valves are outside the containment and accessible, periodic visual inspection is performed in addition to the operational check.

Leak rate testing for the containment isolation system is discussed in Section 6.2.6.

6.2.5 COMBUSTIBLE GAS CONTROL IN CONTAINMENT

Limerick license amendment numbers 173/135 for Unit 1 and 2, respectively approved the removal of the hydrogen recombiner and hydrogen and oxygen monitoring controls from Technical Specifications. The following items were committed to as part of license amendment numbers 173/135.

1. Limerick will maintain the hydrogen monitors within the Emergency and Operating procedures and the Maintenance Program.

2. Limerick will maintain the oxygen monitors within the Emergency and Operating Procedures and the Maintenance Program.

The revised Technical Specifications are based on the NRC revision to 10CFR50.44 (Combustible gas control for nuclear power reactors), which eliminated the design basis LOCA hydrogen release based on risk significance; eliminated the requirements for hydrogen control systems to mitigate such releases; and maintained the requirements for containment inerting, containment atmosphere mixing, monitoring of oxygen to verify the status of the inert containment, and monitoring of hydrogen for diagnosing beyond design basis accidents. Based on the revised rule removing the design basis requirements for beyond design basis accidents, the hydrogen recombiners can be eliminated in the future and the H2/O2 analyzers are downgraded to non-safety related and non-redundant. However, the recombiners and analyzers are currently being maintained as described in the UFSAR, except for removal of the system requirements from the Technical Specifications. The analyzer system requirements removed from the Technical Specifications have been transferred to the Technical Requirements Manual (TRM).

Following a postulated LOCA, hydrogen gas may be generated within the primary containment as a result of the following processes:

a. Metal-water reaction involving the Zircaloy fuel cladding and the reactor coolant

b. Radiolytic decomposition of water in the reactor vessel and the suppression pool (oxygen also evolves in this process)

c. Corrosion of metals and paints in the primary containment

d. Release of free hydrogen already in the reactor coolant at the time of the LOCA.

To preclude the possibility of a combustible mixture of hydrogen and oxygen accumulating in the primary containment, the containment atmosphere is inerted with nitrogen gas during power operation of the reactor. The means provided for inerting the containment is described in Section 9.4.5.1. With the concentration of oxygen being controlled to below the lower flammability limit, the level of hydrogen buildup in the primary containment following a postulated LOCA is of no particular concern for combustible gas control.

To ensure that the oxygen concentration in the primary containment is maintained below the lower flammability limit, the following features are provided:

a. A containment hydrogen recombiner subsystem

b. A combustible gas analyzer subsystem

c. The capability to mix the primary containment atmosphere to prevent the local accumulation of hydrogen and oxygen (accomplished by the drywell air cooling system, which is discussed in Section 9.4.5.2)

d. The capability for a controlled purge of the primary containment following a LOCA (accomplished by the CAC system, which is discussed in Section 9.4.5.1)

Both the containment hydrogen recombiner subsystem and the combustible gas analyzer subsystem are part of the CAC system, which is shown in drawing M-57.

6.2.5.1 Design Bases

a. The containment hydrogen recombiner subsystem is designed to maintain the oxygen concentration in the primary containment below the lower flammability limit of 5% by volume.

b. The combustible gas analyzer is designed to operate either in standby or continuous mode during normal operation. However, the combustible gas analyzer is required to continuously monitor hydrogen and oxygen concentrations in the primary containment following a LOCA.

c. Those lines that penetrate the primary containment and are associated with the containment hydrogen recombiner subsystem and the combustible gas analyzer subsystem are provided with automatic isolation valves to ensure the integrity of the containment boundary during accident conditions. Two isolation valves in series are provided on the recombiner lines.

d. The controls for containment isolation valves on lines associated with post-LOCA combustible gas control and monitoring are designed so that the valves may be reopened by utilizing key-locked bypass switches to override the isolation signals.

e. The containment hydrogen recombiner subsystem and the safety-related portions of the drywell air cooling system are designed to remain functional after an SSE.

f. The containment hydrogen recombiner subsystem, the combustible gas analyzer subsystem, and the safety-related features of the drywell air cooling system are designed so that a single failure of an active component, assuming a LOOP, cannot result in the loss of a safety function.

g. The CAC system is designed to permit a controlled purge of the primary containment atmosphere following a LOCA, as a backup means of combustible gas control and as an aid in cleanup.

h. The containment hydrogen recombiner subsystem, the combustible gas analyzer subsystem, and the portions of the CAC system that are related to post-LOCA purging are designed to facilitate periodic inspection and testing of safety-related features.

i. The containment hydrogen recombiner subsystem, the combustible gas analyzer subsystem, and the safety-related portions of the drywell air cooling system are designed to remain operable in the environments existing in their respective areas following a LOCA.

6.2.5.2 System Description

6.2.5.2.1 Containment Hydrogen Recombiner Subsystem

The containment hydrogen recombiner subsystem is part of the CAC system, which is discussed in Section 9.4.5.1 and shown schematically in drawing M-57. The recombiner subsystem consists of two redundant hydrogen recombiner packages, each of which has adequate processing capacity to control the quantity of oxygen postulated to be generated in the primary containment after a LOCA. The recombiners are of the thermal recombination type, manufactured by the Atomics International Division of Rockwell International. The recombiners are similar in design and construction to those described in Reference 6.2-9 and are identical to those described in Reference 6.2-10.

A schematic diagram of one recombiner package is shown in drawing M-58. Each hydrogen recombiner package consists of three modules: the recombiner skid assembly, the power cabinet, and the control cabinet. The recombiner skid assembly, which is shown in Figure 6.2-38, consists of the process components. The process components include valves, canned motor/blower assembly, gas heater pipe, reaction chamber, water spray cooler, and water separator. The gas heater pipe and the reaction chamber are located within an insulated enclosure that also contains electric heater elements. The recombiner skid assembly is located outside the primary containment in the reactor enclosure.

The power cabinet houses the power distribution components for the recombiner package. The cabinet is located adjacent to its associated recombiner skid assembly and contains the 480 V power supply, control transformer, blower motor starter, circuit breakers, control relays, and the silicon-controlled rectifiers that control electrical power to the heater elements.

The control cabinet contains all of the instrumentation, annunciators, lights, and switches necessary for operation of the recombiner package. The control cabinet is located in the control room.

Each recombiner package is designed to process 60 scfm of gas (inlet flow) containing 5% oxygen, or up to about 150 scfm of gas (inlet flow) containing 2% oxygen, with the balance consisting of unlimited amounts of hydrogen, nitrogen, and water vapor. Each recombiner package will also process up to about 150 scfm of air containing 4% hydrogen. As containment pressure decreases

following an accident, recombiner flow may decrease below the 150 scfm nominal operating value, as discussed in Section 6.2.5.3. The recombination process is accomplished by increasing the temperature of the process stream to approximately 1300°F, at which temperature the hydrogen and oxygen combine spontaneously to form water vapor by the reaction $2H_2 + O_2 \rightarrow 2H_2O$. Virtually complete recombination occurs, so that the concentration of the limiting gas in the effluent from the recombiner package is negligible.

During recombiner operation, gas from the drywell flows through the high volume purge piping of the CAC system to the gas inlet piping of the recombiner package. The effluent from the recombiner package flows through the gas outlet piping to the high volume purge piping associated with the suppression chamber, and then into the suppression chamber. By taking suction from the drywell and discharging to the suppression chamber, a differential pressure is created between these two volumes. This differential pressure is limited to 1.0 psid by the primary containment vacuum relief valve assemblies (described in Section 9.4.5.1), that open to allow air to flow from the suppression chamber back into the drywell.

The recombiner gas inlet and outlet lines are each provided with two normally closed valves for containment isolation. These valves can be operated by hand switches in the control room, and are automatically closed upon receipt of a containment isolation signal. The isolation signals can be overriden by using key-locked bypass switches. The recombiner outlet lines are each provided with pressure relief valves to protect the outlet piping from overpressurization in the event of recombiner cooling water line isolation valve leakage from the RHR system during recombiner isolation. Containment isolation is discussed further in Section 6.2.4.

Blank flanges will be installed on the outboard side of the isolation valves for pressure boundary maintenance.

The process stream entering the recombiner skid assembly flows first through a valve that is used to regulate the flow rate through the recombiner. Next along the process path is the blower, that provides sufficient head to overcome the system flow losses and also the 1.0 psid differential pressure between the drywell and the suppression chamber. From the blower, the gas flows through the gas heater pipe that spirals around the reaction chamber.

The gas is heated as it flows through the gas heater pipe, due to radiated heat from the electric heater elements and the reaction chamber. Next, the gas flows into the reaction chamber, where the exothermic recombination of hydrogen and oxygen occurs. The flow field in the reaction chamber is highly turbulent, with sufficient mixing to rapidly bring the inlet gas temperatures to a level where virtually complete recombination occurs. Reaction chamber temperature is not critical, and considerable deviation from the nominal operating temperature of 1300°F may be tolerated without seriously affecting recombiner performance. The geometric configuration and volume of the reaction chamber provide gas flow movement and transport times so that recombination is completed over a varied range of hydrogen-oxygen concentrations. Recombined gas flows from the reaction chamber to the water spray cooler where it is cooled to less than 250°F. The hot process gas is mixed with water spray in the throat region of a venturi, and the hot gas is cooled by vaporization of the water and by direct contact with the water droplets. The cooling water is supplied to the recombiners from the RHR system. Cooled gas flowing from the cooler is passed through a water separator that prevents any remaining water droplets from entering the gas recirculation line. The separated water drains down to the suppression pool through the recombiner gas outlet piping. Recirculation (dilution) gas is drawn from the top of the water separator and is routed to the recombiner gas inlet piping.

Operation of the hydrogen recombiner package is initiated manually from the control cabinet. When gas flow has been established and the water inlet valve is fully open, the heater elements are energized. Less than 2 hours are required for the system to reach operating temperature. As the temperature of the heated enclosure increases, the gas being circulated through the recombiner is heated. The recombination reaction begins to occur at the outlet of the gas heater pipe when the temperature at that location reaches approximately 1150°F. When the temperature at the gas heater pipe outlet reaches 1300°F, power to the heater elements is automatically turned off. When the gas heater pipe cools to the point at which it can no longer sustain the reaction, the reaction moves into the reaction chamber. When the temperature at the gas heater pipe outlet falls below 1300°F, an interlock is cleared and power is returned to the heater elements at a lower level than during startup. Temperatures in the gas heater pipe stay below those required for reaction, so the reaction stays in the reaction chamber. A temperature controller located in the control cabinet is used to maintain reaction chamber temperature at about 1300°F.

6.2.5.2.2 Combustible Gas Analyzer Subsystem

The combustible gas analyzer subsystem is part of the CAC system, which is discussed in Section 9.4.5.1 and shown schematically in drawing M-57. The combustible gas analyzer subsystem consists of two analyzer packages, each of which contains a hydrogen sensor and an oxygen sensor. The analyzer packages are provided with sufficient sample points so that both analyzer packages can take samples from either the drywell or the suppression chamber.

Each analyzer package consists of a sample cabinet located in the reactor enclosure and a remote control panel located in the control room. Sample points in the primary containment are located as follows:

a. Drywell

   1. el 291', azimuth 10°; 15' from containment centerline
   2. el 255', azimuth 215°; 25' from containment centerline
   3. el 242', azimuth 214°; 1.5' from inside wall of reactor pedestal.

b. Suppression chamber

   1. el 222', azimuth 70°; at inside of containment wall
   2. el 222', azimuth 250°; at inside of containment wall.

The sample suction and return lines are each provided with two normally open solenoid-operated valves for containment isolation. These valves are operated by hand switches in the control room, and are automatically closed upon receipt of a containment isolation signal. The isolation signals to the valves can be overridden by using key-locked bypass switches. Containment isolation is discussed further in Section 6.2.4.

Sample location is controlled by a touchscreen at remote control panel. Gases from the sample point thus selected are routed through a hydrogen sensor and an oxygen sensor located in the sample cabinet.

The operation of the hydrogen and oxygen sensors is based on the measurement of the partial pressure of the oxygen and/or hydrogen in the gas sample. The partial pressure sensors are galvanic in nature and consist of two electrodes; a catalytic sensing electrode and metal oxide

counter electrode for the hydrogen sensor and gold electrode and metal counter electrode for the oxygen sensor. The electrodes for the sensors are immersed in an electrolyte. The electrodes are externally connected by a resistive load. When the ambient atmosphere contains hydrogen and/or oxygen, the gas is ionized at the sensing electrode. The end result is an exchange of electrons through the resistive load connecting the electrodes that is in proportion to the amount of hydrogen (or oxygen). The voltage developed across the external resistance or load, is a mVDC signal, directly proportional to the partial pressure of hydrogen (or oxygen). Note that each sensor is designed to respond only to hydrogen or only to oxygen and is insensitive to other gasses. The total pressure is measured so the partial pressures can be converted to a concentration of hydrogen or oxygen.

The hydrogen sensor has a range of 0% to 10% (by volume) and the oxygen sensor has a range of 0% to 25% (by volume). The calibrated range of each analyzer is 0% to 7%. The sensors are capable of providing oxygen and hydrogen measurement under ambient pressure and up to 73 PSI for components exposed to containment sample under accident conditions. The hydrogen and oxygen concentrations are indicated at the remote control panel.

Sample gases are drawn through the sensors by a positive displacement pump located in the sample cabinet. Sample gases discharged from the pump are routed back to the primary containment.

6.2.5.2.3 Containment Atmosphere Mixing

The capability is provided to maintain the primary containment atmosphere in a thoroughly mixed condition following a LOCA in order to prevent nonuniform distributions of oxygen from occurring. This function is performed by the drywell air cooling system, which is discussed in Section 9.4.5.2. One fan in each of the unit coolers of the drywell air cooling system runs continuously during normal reactor operation and at least one fan in each of two of the safety-related coolers (1AV-212 or 1BV-212 and 1GV-212 or 1HV-212) continues to run after a LOCA to maintain containment in a thoroughly mixed condition.

The design of the primary containment is such that compartmentalization is minimized. The only regions of the drywell that are segregated to some extent from the remainder of the drywell are the drywell head area above the containment seal plate and the CRD area inside the reactor pedestal. Oxygen is prevented from accumulating in a concentration in excess of 5% (volume) in these areas during normal and post-LOCA operation by the operation of the drywell air cooling system.

Following a LOCA, containment oxygen would be mixed by several mechanisms in addition to the operation of the drywell air cooling system. Sprays and natural convective mixing would contribute significantly to maintaining all gases at nearly uniform concentrations (Reference 6.2-20). The boiling mechanism associated with the radiolysis responsible for the release of oxygen from irradiated water (Reference 6.2-21) would also create a significant amount of turbulent mixing, steam condensation effects, and a temperature gradient. These effects would cause oxygen to be well mixed with steam as it entered the drywell from the line break.

6.2.5.2.4 Post-LOCA Purging

The capability to purge the primary containment in order to control oxygen concentration and aid in cleanup after a LOCA is provided.

The BWROG EPGs make specific recommendations for Post-LOCA purging based on the hydrogen levels in containment. Post-LOCA purging using the low volume purge mode of CAC (discussed in section 9.4.5.1) is recommended when containment hydrogen levels are greater than a specific level in the BWROG EPGs, no deflagration can occur, and the containment can be purged without exceeding the normal release rate limits in the Technical Specifications or ODCM. Post-LOCA low volume purging continues until the containment hydrogen levels fall below the recommended value specified in the BWROG EPGs. Gases exhausted from the containment during post-LOCA purging are processed through the RERS and SGTS in order to remove radioactive particulate and halogen contaminants prior to release to the environment.

If containment hydrogen levels continue to increase a high volume purge of the containment can be performed using nitrogen, depending on the potential for the hydrogen and oxygen concentration to result in a deflagration. Depending on the plant conditions at the time of the high volume purge, RERS and SGTS may or may not be available. Depending on the specific concentrations of hydrogen in containment at the time, offsite release rates are limited to those in the Technical Specifications or ODCM. The high volume purge can be used in accordance with BWROG EPG recommendations to prevent containment failure due to a deflagration and to minimize the consequences of the accident. Post-LOCA high volume purging continues until the containment hydrogen levels fall below the recommended value specified in the BWROG EPGs. The BWROG EPG recommendations regarding purging of the containment are incorporated in the EOPs.

6.2.5.2.5 Venting of Combustible Gases from the Reactor Vessel

Combustible gases generated within the reactor vessel or its connected piping can accumulate in the steam space of the vessel following certain types of accidents. Several means are available to vent these gases from the reactor vessel into the primary containment, where they can be processed by the hydrogen recombiner subsystem.

Operation of either the HPCI or RCIC system provides one such means for combustible gas venting. Both of these systems utilize steam-driven turbines that take steam from the reactor vessel and discharge it to the suppression chamber. Any combustible gases present in the reactor vessel steam space are carried along in the steam driving the HPCI or RCIC turbines.

Combustible gases can also be vented from the reactor vessel through the use of the ADS. The ADS utilizes five of the MSRVs to discharge steam and any other gases present in the reactor vessel to the suppression chamber.

A third means that is available for combustible gas venting involves the RPV head vent line that runs from the top of the reactor vessel head to the drywell equipment drain sump. MOVs in this line can be opened to allow steam and other gases to be discharged to the drywell equipment drain sump. Any gases not condensed in the drain sump are released into the drywell through the drain sump's vent line.

6.2.5.3 Hydrogen and Oxygen Generation Analysis

In establishing the design and assessing the capability of the hydrogen recombiner subsystem and the post-LOCA purge, an analysis was performed to determine the hydrogen and oxygen concentrations in the primary containment (drywell and suppression chamber) as a function of time following a postulated LOCA. The assumptions and design parameters used in this analysis are listed in Tables 6.2-18 and 6.2-19, respectively. These assumptions are in accordance with Regulatory Guide 1.7 (Reference 6.2-12). The computer program used to conduct these primary containment hydrogen and oxygen analyses is the Bechtel in-house computer code, HYDROGEN,

which incorporates the models from Regulatory Guide 1.7, SRP 6.2.5, and the NRC Code COGAP. The analysis considered the generation of hydrogen gas from the following sources:

a. Metal-water reaction involving the Zircaloy fuel cladding and the reactor coolant

b. Radiolytic decomposition of water in the reactor vessel and the suppression pool

c. Corrosion of metals and paints in the primary containment

d. Release of free hydrogen already in the reactor coolant at the time of the LOCA

Radiolytic decomposition of water is considered to be the only source of oxygen gas generation after a LOCA.

Metal-Water Reaction

As a result of a LOCA, fuel cladding temperatures rise beginning after blowdown and continuing until core reflood. Zirconium reacts with steam according to the following reaction (Reference 6.2-11):

$$Zr + 2H_2O \rightarrow ZrO_2 + 2H_2$$

Thus, for each mole of zirconium that reacts, 2 moles of free hydrogen are produced. The extent of the metal-water reaction and associated hydrogen generation depends strongly on the course of events assumed for the accident and on the effectiveness of emergency cooling systems, since the metal-water reaction is highly temperature-dependent. Regulatory Guide 1.7 (Reference 6.2-12) conservatively states that the amount of hydrogen assumed to be generated by metal-water reaction in determining the performance requirements for combustible gas control systems should be five times the maximum amount calculated in accordance with 10CFR50, Appendix K, but no less than the amount that would result from reaction of all the metal in the outside surfaces of the cladding cylinders surrounding the fuel (excluding the cladding surrounding the plenum volume) to a depth of 0.00023 inch.

In accordance with Appendix K, calculations have determined that the maximum core wide metal-water reaction is 0.09% (weight). Five times this calculated value is 0.45% (weight). Based on the fuel design, a reaction that results in a cladding penetration depth of 0.00023 inch is well in excess of the Appendix K value. Therefore, since the metal-water reaction based on 0.00023 inch penetration depth is greater than five times the value calculated in accordance with Appendix K, the value based on 0.00023 inch cladding penetration reaction is used as the basis for determining the amount of hydrogen generated by the metal-water reaction.

The analysis assumes that the hydrogen from the metal-water reaction is generated during the first 2 minutes after the beginning of the accident. The hydrogen thus evolved is assumed to mix homogeneously with the drywell atmosphere.

Radiolysis

Water is decomposed into free hydrogen and oxygen by the absorption of energy emitted by fission products contained in fuel and those mixed with the LOCA water. The quantities of hydrogen and oxygen that are produced by radiolysis are functions of both the energy of ionizing radiation absorbed by the LOCA water and the net hydrogen and oxygen radiolysis yields, $G(H_2)$ and $G(O_2)$, pertaining to the particular physical-chemical state of the irradiated water. As recommended in Regulatory

Guide 1.7 (Reference 6.2-12), the net yields of hydrogen and oxygen from radiolysis of all LOCA water are conservatively assumed to be 0.5 molecule/100 eV for hydrogen and 0.25 molecule/100 eV for oxygen.

The total fission product decay power is taken from Reference 6.2-13, conservatively assuming a 730 day[1] reactor operating time for fission product buildup. The results are comparable to those of proposed Standard ANS 5.1. The fission product distribution after the accident and the fractions of fission product radiation energy assumed to be absorbed by the LOCA water are listed in Table 6.2-18. The rates of energy absorption by the LOCA water are shown in Figure 6.2-39 and the integrated energy absorption is shown in Figure 6.2-40.

Corrosion

The corrosion of zinc and aluminum located either in the drywell or the suppression chamber is evaluated as a potential source of hydrogen after a LOCA. One factor that affects the rate of corrosion of either of these metals is the pH of the water with which the metal is in contact. Since no chemicals are added to the containment spray water, the pH of water in the primary containment after a LOCA should be approximately 7 (neutral).

Zinc in the primary containment is in two forms: zinc-based paint and galvanized steel. The masses and exposed areas of zinc-based paint and galvanized steel are listed in Table 6.2-19.

Corrosion of zinc in contact with water at a nominal pH of 7 is caused by two processes:

1. A one time cycle length of 27 months for Unit 1 cycle 7 and Unit 2 cycle 5 was evaluated to have a negligible impact on total fission product decay power.

   a. $Zn + 2\ H_2O \rightarrow Zn(OH)_2 + H_2$

   b. $2\ Zn + 2\ H_2O + O_2 \rightarrow 2\ Zn(OH)_2$

Both reactions occur in the post-LOCA atmosphere of the containment, and the relative amount of corrosion due to reaction a. as compared to reaction b. depends on the availability of oxygen. Galvanized steel and zinc-based paint surfaces that are not submerged are in contact with atmospheric oxygen along with the spray water; therefore, reaction b. is a major contributor to the corrosion of zinc. For the submerged surfaces, the oxygen present depends on the solubility of oxygen, which decreases with increasing temperature. For this situation, reaction a. dominates zinc corrosion.

A search of the literature available on the subject of zinc corrosion at a pH of 7 gives data for corrosion as a weight loss of zinc (References 6.2-14, 6.2-15, and 6.2-16) and also as hydrogen evolved (References 6.2-17 and 6.2-18). Van Rooyen (Reference 6.2-19) surveyed the available literature and formulated a corrosion rate. The data given as weight loss of zinc should be viewed carefully to determine which corrosion reaction is involved.

Other data are available for corrosion in water at higher pH levels or in water with NaOH additives. However, these data are not applicable to a BWR.

Baylis (Reference 6.2-17) determined the hydrogen generated from a sample of zinc submerged in distilled water for different time periods. This study was performed for temperatures of 100°F and lower. Therefore, the lower temperature corrosion domain can be inferred from this data.

The Franklin Institute Research Laboratories (Reference 6.2-18) performed a study of hydrogen evolution from zinc under simulated LOCA conditions and gave corrosion data for 2 hour and 24 hour periods. These data show that corrosion is faster for the 2 hour period than for the 24 hour period for different temperatures, except at the high temperature end (260°F-300°F) where the corrosion rates are comparable. This effect is due to the buildup of a corrosion-resistant zinc hydroxide protective layer that inhibits corrosion after an extended period of time.

Burchell (Reference 6.2-15) and Cox (References 6.2-14 and 6.2-16) present corrosion as a weight loss of zinc. In both cases, the corrosion rate is higher at the lower temperature domain, peaking at approximately 110°F and then decreasing with increasing temperature. Since the solubility of oxygen decreases with increasing temperature, the decrease in the corrosion rates can be attributed to the depletion of oxygen available. Thus, these corrosion rates show that reaction b. is dominant in the oxygen-rich lower temperature water, and reaction a. becomes dominant with increasing temperature.

Van Rooyen (Reference 6.2-19) determined the corrosion rate of zinc from the available data, but did not differentiate whether the corrosion was due to reaction a. or b. Thus, Van Rooyen's calculated corrosion rate does not accurately present the hydrogen generated from the corrosion of zinc.

The data of References 6.2-17 and 6.2-18 on hydrogen generation from zinc corrosion are bounded by the following corrosion rate:

$$H\,(Zn) = 3.76 \times 10^{-9}\, e^{(0.0218T)} \text{ lb-moles/ft}^2\text{-hr} \qquad \text{(EQ. 6.2-46)}$$

where:

T = temperature in degrees Fahrenheit

This rate equation is used to calculate the hydrogen released due to zinc corrosion and corrosion of zinc paint by conservatively assuming that all corrosion is caused by reaction a.

Since containment spray water does not contain any chemical additives, the pH of the LOCA water is approximately 7. At this pH, the corrosion rate of aluminum is negligible even at high temperatures (References 6.2-14 and 6.2-15). Therefore, aluminum in the containment is not assumed to be the source of any hydrogen generation.

Hydrogen Existing in Reactor Coolant

During normal operation of the reactor, free hydrogen exists in the coolant water in concentrations of 10-50 scc/kg of coolant. Although it is unlikely, it is assumed that all of this hydrogen is stripped from the coolant at the time of the LOCA. The total amount added to the containment atmosphere (corresponding to a concentration of 30 scc/kg of coolant) is listed in Table 6.2-19.

Results

The curves of drywell pressure and temperature as a function of time after a LOCA, which are used in the analysis to adjust for the mass of steam in the drywell atmosphere, are shown in Figures 6.2-3, 6.2-4, 6.2-7, and 6.2-8.

Figure 6.2-41 shows the integrated production of hydrogen from all sources as a function of time after the postulated LOCA. The hydrogen concentrations in a noninerted containment over the short-term and long-term periods after a LOCA are shown in Figures 6.2-42 and 6.2-43, respectively. These figures show hydrogen concentrations for three cases: no hydrogen control, recombiner operation at 150 scfm, and a 150 scfm purge. The analysis shows that hydrogen concentration in the drywell reaches 4% (volume) at about 25 hours after the LOCA, if no control measures are taken. If operation of one recombiner package is started so that recombination begins when the hydrogen concentration reaches 3.5% (volume) (at 19 hours after the LOCA), the concentration peaks at 3.57% (volume) and then decreases as long as the recombiner remains in operation. This analysis assumes a flow rate of 150 scfm. As containment pressure decreases following an accident, recombiner flow may decrease below this value. Field tests show that the system resistance can limit flow to less than 150 scfm when the containment is at atmospheric pressure and normal temperature. Sensitivity calculations have been performed which demonstrate that the hydrogen concentration will not exceed 4 volume percent with a single recombiner operating at a flow rate as low as 95 scfm. Actual recombiner flow rates exceed this requirement by a significant margin. For a 150 scfm purge beginning at 19 hours, the hydrogen concentration continues to increase to a maximum of about 3.8% (volume), occurring at about 45 hours after the LOCA. The purge mode used as a basis for this calculation involves supply and exhaust evenly divided between the drywell and suppression chamber, without repressurization of the primary containment.

The oxygen concentrations in an inerted containment over the short-term and long-term periods after a LOCA are shown in Figures 6.2-44, 6.2-45, and 6.2-46. These figures show oxygen concentration for three cases: no oxygen control, recombiner operation at 60 scfm, and a 60 scfm purge. The oxygen concentration (volume percent) initially drops in both the drywell and suppression chamber because, following a LOCA, the blowdown and subsequent increases in containment temperature and pressure result in significant fractions of other gases, primarily steam. To account for the additional constituents, the volume percent of oxygen decreases. The analysis shows that oxygen concentration in the drywell reaches 5% (volume) at about 54 hours after the LOCA, if no control measures are taken. If operation of one recombiner package is started so that recombination begins when the oxygen concentration reaches 4.5% (volume) (at about 39 hours after the LOCA), the concentration will peak at 4.92% (volume) and will then decrease as long as the recombiner remains in operation. For a 60 scfm purge beginning at 39 hours, the oxygen concentration increases to a maximum of 4.61% (volume), occurring at about 54 hours after the LOCA. The purge mode used as a basis for this calculation involves supply and exhaust evenly divided between the drywell and suppression chamber, without repressurization of the primary containment.

6.2.5.4 Safety Evaluation

The containment hydrogen recombiner subsystem (including supporting structures) is designed to seismic Category I requirements as defined in Section 3.7. Except for tubing internal to the sample cabinets of the combustible gas analyzer subsystem, piping and tubing associated with both subsystems, except for some piping and the hydrogen cylinders of the gas analyzer subsystem, are designed, fabricated, inspected, and tested in accordance with the requirements of the ASME Section III, Class 2. All portions of the two subsystems are located within the reactor enclosure and control structure, which are designed to seismic Category I requirements as discussed in Section 3.8.4. H_2 span gas cylinders are seismically supported in a location outside the reactor enclosure (and other safety-related areas) as required by BTP CMEB 9.5-1. Evaluation with respect to the following areas is discussed in sections as indicated:

a.	Protection from wind and tornado effects	Section 3.3
b.	Flood design	Section 3.4
c.	Missile protection	Section 3.5
d.	Protection against dynamic effects associated with the postulated rupture of piping	Section 3.6
e.	Environmental design	Section 3.11

The containment hydrogen recombiner subsystem and the combustible gas analyzer subsystem both consist of two separate packages that are fully redundant and independent. The redundant packages are powered from different divisions of Class 1E power. A single failure in either subsystem would only render the affected package unavailable, with the redundant package fully capable of performing the required function at full capacity. Failure modes and effects analyses for the containment hydrogen recombiner subsystem and the combustible gas analyzer subsystem are provided in Tables 6.2-20 and 6.2-21, respectively.

Each combustible gas analyzer sample line penetrating the primary containment is provided with redundant isolation valves powered from different divisions of Class 1E power. Since the isolation valves are of a type that fail closed upon loss of power, loss of power to any individual valve or to all valves powered from the same division does not disable the containment isolation function. In the event of a failure of any single valve to close when required, the redundant valve on the same line provides the isolation function. The bypass of an isolation signal to any valve is annunciated in the control room.

Containment isolation provisions for piping used in conjunction with hydrogen recombination and post-LOCA purging are discussed in Section 9.4.5.1.

The design pressures and temperatures for process components of the hydrogen recombiner packages are as follows:

a.	Nonoperating conditions: entire system	55 psig/340°F
b.	Operating conditions:	
	Stainless steel components (gas heater pipe, reaction chamber, and water spray cooler)	30 psig/1400°F
	Carbon steel components (inlet piping, water separator, and outlet piping)	55 psig/340°F

Since the post-LOCA primary containment pressure-temperature transient stays well below these design parameters for the time period greater than 6 hours after the LOCA (Section 6.2.1), no restrictions exist on recombiner operation after this 6 hour period.

As shown in Figures 6.2-44, 6.2-45, and 6.2-46, the operation of one hydrogen recombiner package is sufficient to maintain post-LOCA oxygen concentrations in the containment below 5% (volume). The analysis to determine post-LOCA oxygen concentrations assumes that hydrogen-oxygen recombination begins at 39 hours after the LOCA. Since the recombiner requires a maximum 2 hour heatup period (verified by surveillance testing) before complete recombination of oxygen in the process stream occurs, one recombiner package is activated at or prior to 37 hours after a LOCA.

In the extremely unlikely event that a LOCA occurs and both recombiner packages fail to function properly, purging may be utilized to control the oxygen concentration inside the containment. The oxygen generation analysis shows that the oxygen concentration reaches 4.5% (volume) at 39 hours after the LOCA, and that a 60 scfm purge initiated at that time ensures that the oxygen concentration remains below the 5% level. The effect of the purge on oxygen concentration is shown in Figures 6.2-44, 6.2-45, and 6.2-46.

The BWROG EPGs make specific recommendations for Post-LOCA purging based on the hydrogen levels in containment. Post-LOCA purging using the low volume purge mode of CAC (discussed in section 9.4.5.1) is recommended when containment hydrogen levels are greater than a specific level in the BWROG EPGs, no deflagration can occur, and the containment can be purged without exceeding the normal release rate limits in the Technical Specifications or ODCM. Post-LOCA low volume purging continues until the containment hydrogen levels fall below the recommended value specified in the BWROG EPGs. Gases exhausted from the containment during post-LOCA purging are processed through the RERS and SGTS in order to remove radioactive particulate and halogen contaminants prior to release to the environment.

If containment hydrogen levels continue to increase a high volume purge of the containment can be performed using nitrogen, or air depending on the potential for the hydrogen and oxygen concentration to result in a deflagration. Depending on the plant conditions at the time of the high volume purge, RERS and SGTS may or may not be available. Depending on the specific concentrations of hydrogen in containment at the time, offsite release rates are limited to those in the Technical Specifications or ODCM. The high volume purge can be used in accordance with BWROG EPG recommendations to prevent containment failure due to a deflagration and to minimize the consequences of the accident. Post-LOCA high volume purging continues until the containment hydrogen levels fall below the recommended value specified in the BWROG EPGs. The BWROG EPG recommendations regarding purging of the containment are incorporated in the EOPs.

6.2.5.5 Tests and Inspections

The containment hydrogen recombiner subsystem and the combustible gas analyzer subsystem are preoperationally tested in accordance with the requirements of Chapter 14 and periodically tested in accordance with the requirements of the maintenance program and the Technical Requirements Manual (TRM), respectively. Inservice inspection of the subsystems will be in accordance with the ASME Section XI, for ASME Section III, Class 2 components.

6.2.5.6 Instrumentation Applications

6.2.5.6.1 Containment Hydrogen Recombiner Subsystem

The control cabinet for each hydrogen recombiner package contains the following devices (on the front side of the cabinet) that control and monitor the operation of the recombiner:

a. Operate switch (HS-3)

b. Inlet valve flow control switch (HS-1)

c. Recirculation valve flow control switch (HS-2)

d. Reaction chamber temperature controller (TIC-7)

e. Flow/pressure recorder (XR-1)

f. Temperature recorders (TRS-2 and TRS-4)

g. Annunciator assembly

Also located on the control cabinet, but on the rear of the cabinet, are eight hand switches (HS-6 through HS-10 and HS-14 through HS-16).

The hydrogen recombiner packages have three basic modes of operation: standby, ready, and operate. The recombiner is kept in the "ready" mode when not being tested or otherwise operated. Initially, when the recombiner subsystem is first energized or during maintenance, the system is placed in the "standby" mode. The trickle heaters are energized in order to keep the insulated enclosure warm in the "standby" and "ready" modes. The temperature controller is set at the value that will be used during initial operation of the recombiner. The recombiner is placed in the "ready" mode by actuating the service disconnect switches (HS-6 through HS-9) to the "on" position. The recombiner is left in the "ready" mode for approximately one hour, to allow circuits to stabilize before proceeding to the "operate" mode. Since the recombiner is normally in the "ready" mode, the one hour stabilization time is not a concern prior to going to the "operate" mode. The recombiner is placed in the "operate" mode by actuating switch HS-3, at which time the blower starts and the water inlet valve opens. Interlocks are provided to prevent the heater elements from being energized until the water inlet valve is fully open and the blower inlet gas flow rate exceeds the low flow setpoint. Recombiner inlet flow control and recirculation flow control is achieved using hand switches HS-1 and HS-2 in conjunction with flow/pressure recorder XR-1.

While the recombiner is in the "operate" mode, the "startup" light is on while the reaction chamber gas temperature remains below 1150°F, and the "operate" light is on when this temperature has been exceeded.

The following process alarms are displayed on the annunciator:

a. Blower inlet gas pressure (high)

b. Blower inlet gas flow (low)

c. Blower inlet gas temperature (high)

d. Heater wall temperature (high)

e. Reaction chamber gas temperature (high and low)

f. Reaction chamber shell temperature (high)

g. Return gas temperature (high)

Automatic shutdown of the recombiners (interruption of power to the blower and the heater elements) results if setpoints are exceeded for variables a, c, d, f, and g as listed above. If the setpoint is exceeded for variable b or heater temperature two-thirds through heater (high), heater outlet temperature (high), or the water inlet control valve is not fully open, power to the heater elements is interrupted but the blower continues to run.

The recombiner process alarms listed above are annunciated by a general trouble alarm external to the recombiner control cabinet, as well as by the annunciator on each recombiner control cabinet. Failure of the recombiner trickle heat is also annunciated by this general trouble alarm.

The gas outlet piping from each recombiner package is provided with a level switch to detect (and annunciate in the control room) the accumulation of water in the outlet piping. Such an occurrence could result from leakage of the recombiner cooling water inlet valve while the recombiner is not in operation.

The following process variables are recorded on XR-1:

a. Blower inlet pressure

b. Recombiner inlet flow

c. Blower inlet flow

Separate modules provide alarm and trip outputs for variables a and c. These modules are mounted on an instrument rack located on the front side of the control cabinet.

The following process temperatures are recorded on TRS-2:

a. Blower inlet temperature

b. Reaction chamber shell temperature

c. Return gas temperature

The following process temperatures are recorded on TRS-4:

a. Heater temperature two-thirds through heater

b. Heater outlet temperature

c. Heater wall temperature

Process temperature alarm and trip outputs are provided by the temperature recorders.

The annunciator assembly is a backlighted legend plate, flasher, sequential type annunciator with a common horn. The annunciator, along with the TEST, ACKNOWLEDGE, and RESET push buttons are mounted on the front side of the control cabinet.

During normal conditions, the legend plate is dark and the horn is off. During abnormal conditions, the annunciator indicates an alarm by a fast flashing legend plate and by a horn. The operator can acknowledge the alarm by pressing the ACKNOWLEDGE push button. This causes the horn to stop

sounding and the legend to stop flashing but remain lighted. When conditions return-to-normal, the legend changes from steady to slow flashing and the horn sounds. The operator can clear the alarm by pressing the RESET push button. This causes the window to become dark again.

The alarm sequence is different if the abnormal condition returns to normal before acknowledgement by the operator. In that case, pushing the ACKNOWLEDGE push button causes the legend to change from fast flashing to slow flashing. The horn remains on until the RESET push button is pressed.

The operator can functionally test the entire annunciator system by pressing the TEST push button. After testing, the operator returns the annunciator to the ready condition by pressing the ACKNOWLEDGE and RESET push buttons in sequence.

6.2.5.6.2 Combustible Gas Analyzer Subsystem

The combustible gas analyzer packages are designed to be operable from the remote control panel and includes hydrogen and oxygen concentration indicators. Also provided in the control room are annunciation of high oxygen concentration and high hydrogen concentration, and analyzer package malfunction. Those malfunctions that are annunciated include out of range signal from the partial or total pressure sensors, calibration errors, system configuration errors, low flow, over pressurization, and module hardware faults.

Instrumentation and controls for the containment hydrogen recombiner subsystem and the combustible gas analyzer subsystem are discussed further in Section 7.3.1.1.6.

6.2.6 PRIMARY REACTOR CONTAINMENT LEAKAGE RATE TESTING

This section presents the testing program for the primary reactor containment ILRTs (Type A tests), primary containment penetration leakage rate tests (Type B tests), and primary containment isolation valve leakage rate tests (Type C tests). This program complies with 10CFR50, Appendix A, General Design Criteria, and Performance Based Option B of 10CFR50, Appendix J, "Primary Reactor Containment Leakage Testing for Water-Cooled Power Reactors", to the greatest extent practicable. The details of the program are defined in the Primary Containment Leak Rate Testing Program (PCLRTP) as identified in Chapter 16.

6.2.6.1 Primary Reactor Containment Integrated Leakage Rate Tests

Upon completion of construction of the primary reactor containment, including installation of all portions of the mechanical, fluid, electrical, and instrumentation systems penetrating the containment associated with containment integrity; and upon satisfactory completion of the structural integrity tests as described in Section 3.8, the preoperational containment ILRT was performed in accordance with the requirements of Chapter 14 to verify that the actual containment leakage rate did not exceed the design limit.

Type A tests are conducted at intervals as described in PCLRTP. A general inspection of the accessible interior and exterior surfaces of the primary containment structure and components is performed in accordance with the PCLRTP, to uncover any evidence of structural deterioration that could affect either the containment structural integrity or leak-tightness. If there is evidence of structural deterioration, corrective action is taken. The structural deterioration and corrective action are reported in accordance with 10CFR50, Appendix J. Repairs or adjustments made to the

containment boundary prior to the conduct of the Type A test shall be accounted for in the determination of the As-Found Type A test.

The ILRT (Type A) is performed to determine that the total leakage from the containment does not exceed the maximum allowable leakage rate (La) at the design basis LOCA maximum peak containment pressure (Pa), as defined in Chapter 16. Typical piping and instrumentation are shown in drawing M-60. Acceptance criteria and frequency are defined in the PCLRTP.

The Type A test is conducted in accordance with 10 CFR 50, Appendix J, Option B and the PCLRTP.

A typical data acquisition system is shown in drawing M-60. Prior to commencement of any Type A test the pretest requirements of ANSI/ANS N56.8-2002 are met with specifics as follows:

a. Those portions of fluid systems that are part of the RCPB, and are open directly to the primary containment atmosphere under postaccident conditions and become an extension of the boundary of the primary containment, are opened or vented to the containment atmosphere prior to and during the Type A test, except as noted in Table 6.2-24. Portions of closed systems inside the containment that penetrate primary containment and can rupture as a result of a LOCA are vented to the containment atmosphere, except as noted in Table 6.2-24.

b. All systems not designed to remain water-filled post-LOCA are drained of water to the extent necessary to ensure exposure of the system primary containment isolation valves to containment air test pressure.

c. Those portions of fluid systems that penetrate the primary containment, that are external to the containment and are not designed to provide a containment isolation barrier, are vented to the outside atmosphere, as applicable, to ensure that full postaccident differential pressure is maintained across the containment isolation barrier.

d. Systems that are required to maintain the plant in a safe condition during the Type A test are operable in their normal mode and are not vented, as noted in Table 6.2-24.

e. Systems that are normally filled with water and operating under postaccident conditions are not vented. However, the measured leakage rates (Type C) for containment isolation valves in these systems identified in Table 6.2-24 are reported in the Type A test final report.

f. For planning and scheduling purposes, or ALARA considerations, pathways that are Type B or C tested within the previous 24 calendar months need not be vented or drained during the Type A test.

6.2.6.2 Primary Containment Penetration Leakage Rate Tests

Containment penetrations with designs incorporating resilient seals, gaskets or sealant compounds, air locks and lock door seals, equipment and access hatch seals, and electrical canisters receive preoperational and periodic Type B leakage rate tests in accordance with 10CFR50, Appendix J, Option B and the PCLRTP. A list of all containment penetrations subject to Type B tests is provided in Table 6.2-25.

All Type B tests are conducted at pressure (Pa) as defined in Chapter 16. The acceptance criteria are given in the PCLRTP. Test methods are described in Section 6.2.6.3 below.

Penetrations with threaded caps are provided in the air lock to permit pressure testing of the door seals and the entire lock.

Penetrations for equalizing valves as described in Section 3.8.2.1.2 are provided in the air lock. Figure 6.2-48 shows the locations of all mechanical and electrical penetrations in the air lock. Figure 6.2-49 shows details of the door seals and the pressure test connection.

The personnel air lock volume is pressurized to primary containment peak accident pressure and tested periodically as described in Chapter 16 and the PCLRTP. During the air lock test, tie-downs are installed from inside the lock on the inner door, since normal locking mechanisms are not designed to withstand a differential pressure across the door in the reverse direction in excess of 5 psig. See Figure 6.2-50 for details of the tie-downs for the inner door. The tie-downs are installed from within the air lock. The force exerted by the tie-downs on the inner door is not monitored. Pressurizing the lock barrel also tests the lock mechanical and electrical penetrations, and the door seals.

The door seals are periodically tested at Pa as indicated in Chapter 16. Additionally, the door seals are tested after each opening at 10 psig without installing tie-downs as indicated in Chapter 16 and the PCLRTP.

6.2.6.3 Primary Containment Isolation Valve Leakage Rate Tests

The containment isolation valves that are Type C tested are listed in Table 6.2-25.

Type B and C tests are performed by local pressurization, using either the pressure-decay or flowmeter method. For the majority of isolation valves, the test pressure is applied in the same direction that the valve would see when required to perform its safety function. There are a few exceptions where the test pressure is applied in the reverse direction. Further explanation is provided in Table 6.2-25. For the pressure decay method, the test volume is pressurized with air or nitrogen to at least Pa. The rate of decay of pressure of the known free air test volume is monitored to calculate leakage rate. For the flowmeter method, pressure is maintained in the test volume by making up air, nitrogen, or water (if applicable) through a calibrated flowmeter. The flowmeter fluid flow rate is the isolation valve leakage rate.

All isolation valve seats that are exposed to containment atmosphere subsequent to a LOCA are tested with air or nitrogen at pressure (Pa) as defined in Chapter 16.

Those valves which are in lines designed to be, or remain, filled with a liquid for at least 30 days subsequent to a LOCA are leakage rate tested with that liquid. The liquid leakage measured is neither converted to equivalent air leakage nor added to the Type B and C test totals. Isolation valves tested with liquid are identified in Table 6.2-25 and designated under note (15).

The acceptance criteria for all penetrations and isolation valves subject to Type B and C tests are given in Chapter 16 and the PCLRTP.

6.2.6.4 Scheduling and Reporting of Periodic Tests

The periodic leakage rate test schedules for Types A, B and C tests are given in the PCLRTP.

Type B and C tests can be conducted at any time during normal plant operations or during shutdown periods, so long as the time interval between tests for any individual Type B or C test does not exceed the maximum allowable interval specified in the PCLRTP. Each time a Type B or C test is completed, the overall total leakage rate for all required Type B and C tests is corrected for any differences noted.

Provisions for reporting test results are given in the PCLRTP.

6.2.6.5 Special Testing Requirements

6.2.6.5.1 Drywell Steam Bypass Test

Following the drywell structural integrity test, described in Section 3.8.1.7, a preoperational drywell-to-wetwell leakage rate test is performed at the peak drywell-to-wetwell differential pressure. Table 14.2-4 gives the test descriptions. Also, drywell to wetwell leakage rate tests at a reduced differential pressure corresponding approximately to the submergence of the vents, defined in Chapter 16, are performed following the preoperational Type A test and periodically thereafter. These drywell leakage rate tests verify, over the design life of the plant, that no paths for gross leakage from the drywell to the suppression chamber air space bypassing the pressure-suppression feature exist. The combination of the design pressure and reduced pressure leakage rate tests also verifies that the drywell performs adequately for the full range of postulated primary system break sizes. The drywell leakage rate limits specified in Chapter 16 for the above tests are based on a value of 10% of the allowable bypass $A/(K)^{1/2}$ for small breaks that are described in Section 6.2.1.1.5.4.

Drywell leakage rate tests are performed with the drywell isolated from the suppression chamber. Valves and system lineups are the same as for the Type A test except any paths for equalizing drywell and suppression chamber pressure open during the Type A test are isolated. The drywell atmosphere is allowed to stabilize for a period of 1 hour after attaining test pressure. Leakage rate test calculations, using the wetwell pressure rise method on Unit 1 and the wetwell pressure rise method on Unit 2, commence after the stabilization period.

The pressure rise method (Unit 1) is based on containment atmosphere pressure and temperature observations and the known wetwell free air volume specified in Table 6.2-1. Leakage rate is calculated from the pressure and temperature data, wetwell free air volume, and elapsed time.

The pressure rise method (Unit 2) is based on containment atmosphere pressure and temperature observations and the known wetwell volume specified in Table 6.2-1. Leakage rate is calculated from the pressure and temperature data, wetwell free air volume, and elapsed time.

When the drywell leakage rate test described above is not performed, an alternate test is performed to verify that each set of downcomer vacuum breaker valves does not provide a path for gross leakage from the drywell to the suppression chamber.

The periodic drywell leakage rate test and downcomer vacuum breaker valve leakage rate test pressures, test duration, and acceptance criteria are specified in Chapter 16. Periodic drywell leakage rate tests and downcomer vacuum breaker valve leakage tests are performed at the intervals specified in Chapter 16. This surveillance testing will be in accordance with the Technical Specifications.

6.2.6.5.2 Risk Informed Alternative Treatment Due to 10 CFR 50.69

There is a Risk Informed Categorization and Treatment Program at Limerick which is based on 10 CFR 50.69. This regulation provides an alternative approach for establishing requirements for treatment of SSCs using a risk-informed method of categorizing SSCs according to their safety significance. Specifically, for SSCs categorized as low safety significant, alternate treatment requirements may be implemented rather than treatments chosen by the Appendix J program. Refer to Section 13.5.5 for further information.

6.2.7 POSTACCIDENT SYSTEM ISOLATION

Following an accident in which significant fuel damage is postulated to occur, a number of plant systems whose piping penetrates the primary containment may contain highly radioactive fluids. Adequate system isolation features exist to ensure that the integrity of these systems will be maintained.

6.2.7.1 System Isolation Provisions

The boundaries of potentially contaminated systems are adequately isolated by one of the following:

a. Two normally closed manual valves

b. One normally closed manual valve (low pressure piping)

c. One or two normally closed manual valves and a cap

d. One SRV or one rupture disc

e. Two check valves

f. One remotely actuated valve and one check valve

g. Two remotely actuated valves

In cases where a remotely actuated valve is required to change position to provide system isolation, the valve receives an auto isolation signal. In some cases a system isolation valve does not receive a direct isolation signal but is interlocked to close when a containment isolation valve or other valve opens to permit fluid flow from the containment.

Table 6.2-26 lists remotely actuated system isolation valves, their normal and required accident positions and their actuation signals. Containment isolation valves that also provide postaccident system isolation are not included in this table but are listed in Table 6.2-17.

6.2.7.2 Potentially Contaminated Systems

The following systems whose piping penetrates primary containment may contain highly radioactive fluids after an accident. Other systems have been excluded from this list for the reasons discussed in Section 6.2.8.2.

a. RHR System (drawing M-51)

b. Core Spray System (drawing M-52)

c. HPCI System (drawing M-55)

d. RCIC System (drawing M-49)

e. CRD Hydraulic System (SDV, drawings M-46 and M-47).

f. Safeguard Piping Fill System (drawing M-52)

g. PASS (drawing M-30)

h. CAC System (drawing M-57)

6.2.8 LEAKAGE REDUCTION PROGRAM

To ensure that leakage from systems that may be expected to handle highly radioactive fluids during or after an accident is maintained as-low-as-practical, a leakage reduction program will be established. System isolation provisions have been reviewed in conjunction with this effort and are discussed in Section 6.2.7.

6.2.8.1 Systems to be Leak Tested

The following systems will be leak tested at 24-month intervals. The test conditions will simulate the expected operating conditions during an accident or transient:

a. RHR System

b. Core Spray System

c. HPCI System

d. RCIC System

e. CRD Scram Discharge System

f. Safeguard Piping Fill System

g. PASS (including portions of the Process Sampling System)

h. CAC System (recombiner and sample loops only)

6.2.8.2 Systems Excluded from the Program

The following systems are excluded from the leakage reduction program for the reasons given below:

a. Reactor Recirculation System - The interfaces between the recirculation system and the systems outside containment (other than RHR) are isolated by containment isolation valves.

b. RWCU - The RWCU system is isolated from the recirculation system by containment isolation valves.

c. Main Steam System - The main steam system is isolated by containment isolation valves.

d. Feedwater System - The feedwater system is isolated by containment isolation valves.

e. Process Sampling System - Sample lines from potentially contaminated sources inside the containment are isolated by containment isolation valves. Potentially

contaminated sample lines from the RHR system, associated with postaccident sampling, will be leak tested with the postaccident sample system.

f. Suppression Pool Cleanup System - The suppression pool cleanup system is isolated by containment isolation valves.

g. RERS and SGTS - The reactor enclosure HVAC supply and exhaust valves will isolate the reactor enclosure upon receipt of high radiation isolation signal. The RERS and SGTS will then filter and exhaust air from the reactor enclosure and maintain a subatmospheric pressure. Because the source of radioactivity in these systems is airborne contamination resulting from previous leakage from the containment or contaminated systems, a leakage reduction program for the low pressure RERS/SGTS ducting would not significantly reduce the airborne radioactivity concentrations in the secondary containment. The recirculation and SGTS filters will be tested as described in Sections 6.5.1.3.4 and 6.5.1.1.4.

h. Containment Radiation Sampling System - The containment radiation sampling system, used to provide an indication of primary leakage during normal operation, is isolated by containment isolation valves.

6.2.8.3 Leak Testing Method

System leak test conditions will simulate the expected operating conditions during an accident. Each component in the system will be inspected for leakage. Water leakage will be collected and measured. Steam leakage will be estimated and converted to an equivalent water leak rate. Gas systems will be bubble leak tested with a zero leakage acceptance criteria or leakage will be quantified by means of a pressure decay or helium leak test.

Leakage rate goals will be established for each system based on baseline data from the first tests. Components whose leakage contributes significantly to the total leak rate or increases substantially between tests will be repaired to maintain total leakage as-low-as-practical.

CONTAINMENT DESIGN PARAMETERS*

DRYWELL AND SUPPRESSION CHAMBER	DRYWELL	SUPPRESSION CHAMBER
Internal design pressure, psig	55	55
External to internal design differential pressure, psid	5	5
Drywell deck design differential pressure, psid	30 downward	20 upward
Design temperature, °F	340	220
Drywell net free air volume, ft^3		
Low level(4)		243,580(1)(2)
High level(4)		242,860(1)(2)
Design leak rate, % by weight/day	0.5	0.5
Maximum allowable leak rate, % by weight/day	0.5	0.5
Suppression chamber free air volume, ft^3		
Low level(4)		159,540(2)(3)
High level(4)		147,670(2)(3)
Suppression pool water volume, ft^3		
Low level(4)		122,120(2)(3)
High level(4)		134,600(2)(3)
Suppression pool surface area, ft^2		
Outside pedestal		4974(2)
Inside pedestal		293
Suppression pool depth, ft		
Low level		22'
High level		24'-3"

Table 6.2-1 (Cont'd)

	DRYWELL	SUPPRESSION CHAMBER
VENT SYSTEM		
Number of downcomers		83(5)
Nominal downcomer diameter, ft		2
Total vent area, ft^2		244.7(5)
Downcomer submergence, ft		
Low water level		10'
High water level		12'-3"
Downcomer loss coefficient		2.23(2)

(1) Drywell volume includes downcomer air volume.
(2) These values vary slightly from those actually used in the analysis. The difference in analysis results is negligible.
(3) Including pedestal volume.
(4) Low level and high level refer to suppression pool water level.
(5) The original containment analysis included a total vent area of 256.5 square feet, equivalent to all 87 downcomers. Four of the downcomers have been capped. The impact of capping four downcomers on analysis results is negligable.

*NOTE: The information presented in this table was used for the original containment analysis and such should be considered historical. Refer to Table 6.2-4a for the parameters used in the current containment response analysis.

Table 6.2-2

ENGINEERED SAFETY FEATURE SYSTEMS INFORMATION
FOR CONTAINMENT RESPONSE ANALYSES*

	FULL CAPACITY	CONTAINMENT ANALYSIS VALUE CASE A	CASE B	CASE C
DRYWELL SPRAY				
Number of RHR pumps	2	2	1	0
Number of lines	2	2	1	0
Number of headers	2	2	1	0
Spray flow rate, gpm/pump	9,500	9,500	9,500	0
Spray thermal efficiency, %	See Section 6.2.1.1.3.4.3			
SUPPRESSION CHAMBER SPRAY				
Number of RHR pumps	2	2	1	0
Number of lines	2	2	1	0
Number of headers	1	1	1	0
Spray flow rate, gpm/pump	500	500	500	0
Spray thermal efficiency, %	See Section 6.2.1.1.3.4.3			
SUPPRESSION POOL COOLING SYSTEM				
Number of RHR pumps	2	2	1	1
Pump capacity, gpm/pump	10,000	10,000	10,000	10,000
RHR heat exchangers				
Type - Inverted U-tube, single pass shell, multipass tubes, vertical mounting	-	-	-	-
Number	2	2	1	1

Table 6.2-2 (Cont'd)

	FULL CAPACITY	CONTAINMENT ANALYSIS VALUE CASE A	CASE B	CASE C
Heat transfer area, ft^2/unit	6,281*	-	-	-
Overall heat transfer coefficient, Btu/hr-ft^2-°F/unit	228 *	-	-	-
RHRSW flow rate, gpm/unit	8000	5570	5570	5570
RHRSW temperature, °F	-	95	95	95
Minimum design	40	-	-	-
Maximum design	95	-	-	-
Containment heat removal capability per unit, using 95°F RHRSW and 212°F pool temperature, Btu/hr	128.5 $x10^6$	-	-	-
Peak Containment Heat removal rate Btu/hr at peak suppression pool temperature of 203.4°F	119.9 $x10^6$	-	-	-

* Actual heat transfer surface area and heat transfer coefficient vary with the condition of the heat exchanger (e.g. plugged or fouled tubes). Acceptance criteria are administratively controlled by plant surveillance procedures to assure that the RHR heat exchangers can provide the required Peak Containment Heat Removal Rate at the peak suppression pool water temperature.

** For two-unit operation with one RHRSW loop in service, the RHRSW design minimum required flow rate under accident conditions is 8000 gpm to the LOCA unit and between 5570 and 8000 gpm to the unit under normal shutdown conditions. An evaluation has been performed, however, to confirm that a RHRSW flow rate as low as 5570 gpm is sufficient to meet the design heat removal requirements of the unit with the LOCA under certain conditions.

Table 6.2-3

ACCIDENT ASSUMPTIONS AND INITIAL CONDITIONS
FOR CONTAINMENT RESPONSE ANALYSES*

Components of effective break area (recirculation line break), ft^2	
Recirculation line	3.538
Jet pumps	0.537
Primary steam energy distribution(1), 10^6 Btu	
Steam energy	26.7
Liquid energy	365.0
Sensible energy	
Reactor vessel	93.97
Reactor internals (less core)	59.08
Primary system piping	23.2
Fuel(2)	6.299
Other assumptions used in analysis	
Feedwater valve closure time, sec	Instantaneous
MSIV closure time, sec	
Recirculation line break (includes 0.5 second delay)	3.0
Main steam line break (includes 0.5 second delay)	5.0
Scram time, sec	<1

(1) All energy values except fuel are based on a 32°F datum.
(2) Fuel energy is based on a datum of 285°F.

*NOTE: The information presented in this table was used for the original containment analysis and such should be considered historical. Refer to Table 6.2-4a for the parameters used in the current containment response analysis.

Table 6.2-4

INITIAL CONDITIONS FOR CONTAINMENT RESPONSE ANALYSES*

REACTOR COOLANT SYSTEM[1]	
Reactor power level, MWt	3,435
Average coolant pressure, psia	1,055
Average coolant temperature, °F	551.1
Mass of RCS liquid, lb	669,900
Mass of RCS steam, lb	24,100
Volume of liquid in vessel, ft^3	11,922.3
Volume of steam in vessel, ft^3	10,122
Volume of liquid in recirculation loops, ft^3	1,320.4
Volume of steam in steam lines, ft^3	1,218.0
Volume of liquid in feedwater line, ft^3	1,232.5

Pump Heat per pump	Hp	1250

F. Containment Spray

Variable	Units	Value Used for Analysis
Drywell Spray		
Flow Rate Per Pump	gpm	9500
Pump Heat per Pump	Hp	1187.5
HX K-Factor	Btu/sec-°F	289.8
Wetwell Spray		
Flow Rate Per Pump	gpm	500
Pump Heat per Pump	Hp	62.5
HX K-Factor	Btu/sec-°F	15.2

Table 6.2-5

SUMMARY OF SHORT-TERM CONTAINMENT RESPONSES TO RECIRCULATION LINE AND MAIN STEAM LINE BREAKS

	RECIRCULATION LINE BREAK	MAIN STEAM LINE BREAK
Peak drywell pressure, psig	44.0	36.20
Peak drywell deck downward differential pressure, psid	25.995	19.5
Time of peak pressures, sec	13.66	20.12
Peak drywell temperature, °F	290.9	330
Peak suppression chamber pressure, psig	30.57	30.55
Time of peak suppression chamber pressure, sec	34.75	50
Peak suppression pool temperature during blowdown, °F	135.7	136
Calculated drywell pressure margin, %	20	34
Calculated suppression chamber pressure margin, %	44	44
Calculated deck differential pressure margin, %	13	35
Energy released to containment at time of peak pressure, 10^6 Btu	262.23	-
Energy absorbed by passive heat sinks at time of peak pressure, 10^6Btu	0	0

NOTE: The information presented in this table for the recirculation line break results is based on the original design basis conditions. Refer to Table 6.2-5A for the recirculation line break results for current plant conditions.

The information presented in this table for the main steam line break results is based on the original design basis conditions. As described in Section 6.2.1.1.3, the main steam line break was not reanalyzed for the current conditions; however, the results presented here reasonably represent the general characteristics of the main steam line break analysis results. See explanation at the beginning of Section 6.2.1.1.3.

Table 6.2-5A

CONTAINMENT LOCA RESPONSE AT RERATE POWER

Parameter	Analysis	Design Limit
Peak Drywell Pressure (psig)	42.1 (1)	55
Peak Wetwell Pressure (psig)	39.0 (2)	55
Peak Drywell-to-Wetwell Pressure Difference (psid)	28.5 (3)	30
Peak Bulk Pool Temperature (°F) (LOCA)	203.4 (4)	220* 212**

* Structural
** Low pressure ECCS pump NPSH @ 0 psig in the suppression chamber

---

(1) Short Term Analysis performed for: Power=3694 MWt; Core Flow=110%; FWTR=105°F

(2) Short Term Analysis performed for: Power=3527 MWt; Core Flow=81%; FWTR=105°F

(3) Short Term Analysis performed for: Power=3694 MWt; Core Flow=100%; FWTR=0°F

(4) Long Term Analysis performed for: Power = 3528 MWt; Core Flow = 100%; FWTR = 0°F

(Initial Reactor pressure assumed to be 1053 psig)

Table 6.2-6

SUMMARY OF LONG-TERM CONTAINMENT RESPONSES TO RECIRCULATION LINE AND MAIN STEAM LINE BREAKS

	CASE A	CASE B	CASE C
Secondary peak suppression chamber pressure, psig	6.56	14.19	16.7
Peak suppression pool temperature, ^{o}F	173.6	211.3	212.5
HPCI flow rate, gpm		Not Used	
CS flow rate, gpm	12,500	6,250	6,250
RHR flow rate, gpm/pump	10,000	10,000	10,000

NOTE: The information presented in this table is based on the original design basis conditions. Refer to Table 6.2-5A for the Case C results for current plant conditions and methodology. The results for Cases A, B, and C shown is this table reasonably represent the general characteristics and relative differences between the three cases.

Table 6.2-7

ENERGY BALANCE FOR RECIRCULATION LINE BREAK ACCIDENT

	Energy, 10^6 Btu			
	INITIAL	DRYWELL PEAK PRESSURE	END OF BLOWDOWN	LONG-TERM PEAK PRESSURE
Reactor coolant	392.3	139.5	12.325	58.1
Fuel and cladding[1]	6.299	6.296	6.116	-
Core internals and primary primary system piping	82.29	82.99	82.26	28.097
Reactor vessel metal	93.97	93.97	93.97	32.56
Pump heat added	0	0	0.38045	185.3
Blowdown enthalpy[2]	0	262.23	409.6	409.6
Decay heat[3]	0	23.28	35.82	1,563.0
Metal-water reaction heat	0	0.02838	0.085	0.25
Drywell structures	0	0	0	0
Drywell air	[4]	[4]	[4]	1.98
Drywell steam	2.236	56.33	42.06	9.79
Suppression chamber air	1.005	2.622	2.7233	1.097
Suppression chamber steam	0.3849	0.7054	1.0749	5.6238
Suppression pool water	64.3	666.4	823.8	1,382.7
Energy transferred by heat exchangers	0	0	0	1,304.0
Passive heat sinks	0	0	0	0

(1) Does not include sensible energy in the fuel above initial reactor vessel saturation temperature (this energy is accounted for in decay heat as fuel relaxation energy)
(2) Blowdown is accounted for in drywell condition, and should not be used to sum the total energy
(3) Includes fuel relaxation energy
(4) Included in drywell steam

NOTE: The information presented in this table is based on the original design basis conditions. The current recirculations line break results are discussed in Section 6.2.1.8. The results presented here reasonably represent the general characteristics of the current recirculation line break analysis results.

Table 6.2-8

ACCIDENT CHRONOLOGY FOR
RECIRCULATION LINE BREAK ACCIDENT [1]

	TIME (SEC) ALL ECCS IN OPERATION	MINIMUM ECCS AVAILABLE
Vents cleared	0.733	0.733
Drywell reaches peak pressure	12.66	13.66
Maximum positive differential pressure occurs	0.85	0.85
Suppression chamber reaches pressure peak	33.72	34.75
Initiation of the ECCS	30	30
End of blowdown	36.35	37.69
Vessel reflooded	72.03	91.03
Initiation of RHR heat exchanger	600[2]	600[2]
Suppression chamber reaches secondary pressure peak	7,047	42,854

NOTE: (1) The information presented in this table is based on the original design basis conditions. The current recirculation line break results are discussed in Section 6.2.1.8. The results presented here reasonably represent the general characteristics of the current recirculation line break analysis results.

(2) Initiating time for analysis only. Containment heat removal will be initiated in accordance with emergency operating procedures based on plant conditions.

Wetwell-to-Drywell Vacuum Breakers		
Number of valve assemblies operable (two required to operate and one redundant)	3 of 4	
Flow area per assembly, ft^2	2.05	
Flow coefficient[4]	0.495	
Vacuum breaker full open pressure[4] (psid)	4.48	
RHR System - Drywell Spray Mode		
Service water flow rate, gpm	9,000	
Service water temperature, °F	40	
Heat exchanger effectiveness	0.249	
Spray Temperature: (Initially)	47.6°F	
(at 300 seconds)	49.7°F	

(1) Initial conditions prior to small break as discussed in Section 6.2.1.1.4.4
(2) Conditions after small break, preceding drywell spray actuation (see Section 6.2.1.1.4.5).
(3) High water level

Table 6.2-9

INITIAL AND BOUNDARY CONDITIONS FOR
DRYWELL SPRAY ACTUATION ANALYSIS
(Used in Reference 6.2 - 24 Analysis)

(4) Value given is for total flow path. Actual test results indicate that full open pressure differential across the vacuum breaker assembly only is 2.89 psid. For the ISA computer analysis, the following different pressures were used for opening the valves:

dp (across two valves) at which VB assembly starts to open equals 2.81 psid

dp (from wetwell to drywell) at which VB assembly is fully open equals 4.48 psid

(5) The initial conditions and parameters differ slightly from those indicated in UFSAR Table 6.2-1; however, the use of the conditions and assumptions such as the loss of noncondensables through the purge lines, which were used in the ISA Analysis (reference 6.2-24) produces a more severe transient for purposes of comparing the performance of two vs three operating vacuum breaker valve assemblies. Table A provides the initial conditions used in the original analysis which assumes that the purge valves are closed. The assumptions that are shown in Table B were used to created a worst case analysis to justify reducing the number of operable vacuum breakers from 4 to 3. This scenario assumes that the purge valves are open at the time of a small break LOCA.

Table 6.2-10

REACTOR BLOWDOWN DATA FOR RECIRCULATION LINE BREAK[1][2][3][4]

REACTOR VESSEL TEMPERATURE (°F)	TIME (sec)	REACTOR VESSEL PRESSURE (psia)	LIQUID FLOW (lb_m/sec)	LIQUID ENTHALPY (Btu/lb_m)	STEAM FLOW (lb_m/sec)	STEAM ENTHALPY (Btu/lb_m)
551.1	-	1055	47620	550.1	-	1190.3
550.4	0.733	1048	47620	549.4	-	1190.5
549.9	1.03	1045	47620	549.1	-	1190.6
549.3	1.53	1040	47620	549.0	-	1190.65
548.5	3.16	1032	32290	547.5	-	1191.0
549.3	4.16	1040	32380	549.0	-	1190.65
550.2	5.16	1047	32470	549.3	-	1190.5
550.1	6.16	1055	32560	550.1	-	1190.3
552.5	8.16	1067	32700	552.1	-	1189.9
553.3	10.16	1074	32790	553.5	-	1189.5
552.8	13.66	1069	32720	552.2	-	1189.9
542.0	15.16	979.2	14160	538.5	4895	1192.8
518.7	18.16	803.2	10480	509.2	4438	1199.4
500.7	20.16	685.5	8518	487.7	4054	1202.5
454.3	25.00	441.6	4788	435.8	2919	1205.6
403.4	30.00	257.0	2387	387.53	1851	1202.4
328	35.00	100.7	2673	298.76	609.2	1187.9
294.6	37.5	61.78	2505	263.8	265.8	1178.2
292.8	37.69	60.06	-	262.5	277.7	1178.1
282.6	38.6	51.26	-	252.2	121	1175.1
281.0	38.75	49.98	-	250.2	-	1174.4

(1) The volume of the primary system below the elevation of the recirculation line break is 4641 ft^3.

(2) The maximum diameter for the 251 sized vessel is 254 in corresponding to an inside cross-sectional vessel area of 352 ft^2. (The actual flow area is a function of elevation due to the varying amount of space occupied by the vessel internals).

(3) The surface area and maximum depth of the liquid pool formed on the drywell floor following a DBA LOCA and/or containment spray actuation are approximately 4800 ft^2 and 18 inches, respectively.

(4) The blowdown data provided includes the effect of ECCS additions prior to the end of blowdown. The amount of water in the vessel at the end of blowdown for the DBA is 1559 ft^3.

NOTE: The information presented in this table is histroical and is based on the original design basis conditions. The current recirculation line break results are discussed in Section 6.2.1.8.

Table 6.2-11

REACTOR BLOWDOWN DATA FOR MAIN STEAM LINE BREAK[1][2][3]

REACTOR VESSEL TEMPERATURE (°F)	TIME (sec)	REACTOR VESSEL PRESSURE (psia)	LIQUID FLOW (lb_m/sec)	LIQUID ENTHALPY (Btu/lb_m)	STEAM FLOW (lb_m/sec)	STEAM ENTHALPY (Btu/lb_m)

(1) The termination regions are: IRE - Inside reactor enclosure
ORE - Outside reactor enclosure

(2) The bypass leakage barriers are defined as follows (Section 6.2.3.3.3):

1. Redundant primary containment isolation valves.
2. Closed piping system inside containment.
3. A water seal maintained for 30 days following a LOCA.
4. The line beyond the outboard primary containment isolation valve is vented to the reactor enclosure by use of a vent line.
5. A MSIV alternate drain pathway (Section 6.7) is provided.
6. The line contains a temporary spool piece that is removed during normal operation and replaced by blind flanges so that any leakage through the flange is into the reactor enclosure.
7. Closed seismic Category I piping system outside containment.
8. The line contains a spectacle flange with the blind side installed during normal operation. Any leakage through the flange will be into the reactor enclosure.
9. The line contains two spring loaded check valves and two manual stop valves.
10. Blind flange permanently installed in line in the reactor enclosure.
11. Rupture disc installed downstream of primary containment isolation valves with burst pressure greater than maximum LOCA pressure.

(3) The feedwater fill system will provide a water seal in the feedwater lines for all line breaks other than a feedwater line break inside containment. For a feedwater line break inside containment, a water seal is maintained by the CST water supply as discussed in Section 6.2.3.2.3.1.a.

(4) No significant amounts of radioactivity will be released to the environment as discussed in Section 6.2.3.2.3.

Table 6.2-16

ACCIDENT CHRONOLOGY FOR MAIN STEAM LINE BREAK ACCIDENT

Time	Event
0	Break occurs
0	Scram assumed to occur
0	Isolation signal
0.5	MSIV start to close
1.0	Vessel water level reaches main steam line elevation
5.5	MSIV fully closed
30	ECCS flows start
59	End of blowdown
430	Vessel refloods

NOTE: The information presented in this table is historical and is based on the original design basis conditions. As described in Section 6.2.1.1.3, the main steam line break was not reanalyzed for the current conditions; however, the results reasonably represent the general characteristics of the main steam line break analysis results.

Table 6.2-17 (Cont'd)

(1) Valve Type:

Ball	BL
Butterfly	BF
Check	Ck
Gate	GT
Globe	GB
Pressure relief	PSV
Stop-check	SCK
Testable check	TCK
Spring load piston-actuated check	SLPACK
Explosive (shear)	XP
Excessive flow check	XFC
Ball check	BLCK
Hydraulic control unit	HCU

(2) See Figure 6.2-36. Numbers in this column refer to details in the figure.

(3) Ac MOVs required for isolation functions are powered from the ac standby power buses. Dc operated isolation valves are powered from the station batteries.

(4) Normal valve position (open or closed) is the position during normal power operation of the reactor.

(5) Isolation Signal Codes

Signal	Description
A*	Reactor vessel level 3 trip (a scram occurs at this level also)
B*	Reactor vessel level 2 trip
C*	Reactor vessel level 1 trip (main steam line isolation occurs at this level)
D*	High radiation in main steam lines and vicinity
E*	Main steam line high flow
	Deleted
F*	High temperature in Outboard MSIV room

Table 6.2-17 (Cont'd)

Signal	Description
G*	High drywell pressure and low reactor vessel pressure
H*	High drywell pressure
J*	Line break in RWCU system (high differential flow, high temperature in RWCU compartments)
K*	Break in RCIC steam line (high temperature in pipe routing area, high temperature or high differential temperature in RCIC compartment, high steam flow), or high RCIC turbine exhaust diaphragm pressure
KA	Low RCIC steam supply pressure
L*	Break in HPCI steam line (high temperature in pipe routing area, high temperature or high differential temperature in HPCI compartment, or high steam flow), or high HPCI turbine exhaust diaphragm pressure
LA	Low HPCI steam supply pressure
LFHP	With HPCI pumps running, opens on low flow in associated pipe, closes when flow is above setpoint
LFRC	With RCIC pump running, opens on low flow in associated pipe, closes when flow is above setpoint
LFCH	With CS pump running, opens on low flow in associated pipe, closes when flow is above setpoint.
LFCC	Steam supply valve fully closed or RCIC turbine stop valve fully closed
M*	Low differential pressure between the instrument gas line and the primary containment
P*	Low main steam line pressure at inlet to turbine (RUN mode only)
Q*	Low condenser vacuum and turbine stop valve in bypass mode or more than 90% open

Table 6.2-17 (Cont'd)

Signal	Description
R*	High radioactivity in refueling floor ventilation exhaust ducts
S*	High radiation in the reactor enclosure
T	Low differential pressure between the outside atmosphere and the refueling area
U	Low differential pressure between the outside atmosphere and the reactor enclosure
V*	High reactor pressure (shutdown cooling mode only)
W*	North stack effluent high radiation
Y	SLCS actuated or RRCS actuated
RM*	Remote manual switch from control room (all power-operated isolation valves are capable of being operated remote manually from the control room)

* These are the isolation functions of the primary containment and reactor vessel isolation control system; other functions are given for information only.

(6) The standard closing rate for automatic isolation gate valves is based on a nominal line size of 12 inches. Using the standard closing rate, a 12 inch line is isolated in 60 seconds. Conversion to closing time can be made on this basis using the actual size of the line in which the gate valve is installed.

The closure times for isolation valves in lines in which HELBs could occur are identified with a single asterisk. The closure times for isolation valves in lines which provide an open path from the containment to the environs are identified with a double asterisk. Closure times for the valves identified by a single or double asterisk are considered maximum closure times. Closure times for all other valves are nominal times.

The closure time for F105 is a maximum closure time.

Table 6.2-17 (Cont'd)

(7) Power Source

Electrical Separation Source:

A - Class 1E electrical channel
B - Class 1E electrical channel
C - Class 1E electrical channel
D - Class 1E electrical channel
W - RPS electrical separation channel
X - RPS electrical separation channel
Y - RPS electrical separation channel
Z - RPS electrical separation channel
N - non-Class 1E

For explanation of electrical separation channels, refer to Section 8.1.

(8) Deleted

(9) The spring-loaded piston, which is actuated by an isolation signal or a loss of power, will not close this valve against normal flow on loss of power from the normal direction.

(10) The TIP drive guide tubes provide a path for the flexible drive cable of the TIP probes. The drive cable is automatically retracted on an isolation signal. When the drive cable is fully retracted, the ball valve closes. The shear valves is provided to isolate the guide tubes by cutting the cable if the drive cable cannot be withdrawn.

(11) The CRD insert and withdraw lines can be isolated outside containment. Upstream of the HCUs, two redundant simple check valves are provided on each main water header (i.e. charging, cooling, drive and exhaust). Air operated scram inlet and outlet valves are also provided. Leakage may occur through the scram outlet valves. A low leakage flowrate will be treated by the clean radwaste system. Excessive leakage will result in either automatic scram or operator initiated scram. When scram is complete, the SDV system is automatically isolated by the redundant vent and drain valves.

(12) Only nonessential systems require diverse signals for automatic isolation. Therefore, this column is not applicable, (NA), for essential systems.

Table 6.2-17 (Cont'd)

(13) These valves are sealed closed whenever the reactor is critical and reactor pressure is greater then 600 psig. The valves are expected to be opened only in the following instances:

a. Flushing of the condensate and feedwater systems during plant startup.

b. RPV hydrostatic testing, which is conducted following each refueling outage prior to commencing plant startup.

(14) Diverse isolation signals are not sensed as discussed in Section 6.2.4.3.1.

(15) These valves are normally closed, will be open only during reactor shutdown, are interlocked to open only on low reactor pressure, and connect to a closed system outside containment. Therefore, closure times less then 60 seconds are not required.

(16) Deleted

(17) Both isolation signals required for valve closure.

(18) Valve HV-61-102 is locked closed, the motor operator is normally de-energized and the valve position is controlled procedurally. The valve remains closed during 10 CFR50, Appendix J, Type A testing, and type C testing is not required. Valve HV-61-202 has been deleted from the Unit 2 design.

(19) All outside containment isolation valves have been located as close to containment as practical. Examples of containment isolation valve locations greater than 10 feet from containment are identified and justified below.

a. Deleted

b. Valves HV-F032A-B, HV-109A-B, HV-F039, HV-F013, HV-130A-B, HV-F105, HV-133A-B (Penetrations X-9A-B) provide a third isolation barrier for the feedwater lines. These valves are located at distances from the penetration dictated by equipment accessibility considerations.

c. Valve 1016 (penetrations X-9A-B, X-44) also provides a third isolation barrier for the feedwater lines and an outboard isolation barrier for the alternate RWCU return penetration (X-44). The valve is located in closer proximity to the latter penetration.

Table 6.2-17 (Cont'd)

d. Valves HV-121 & 131 (penetrations X-25, X-201A) are isolation valves for both drywell and wetwell penetrations. They have been located nearer to one penetration and therefore at some distance from the other.

e. Relief valves F030A-D (penetrations X-203A-D) are located as close to the RHR pumps as possible in order to perform their intended function of providing overpressure protection for the pumps. These valves are part of a closed system outside containment.

f. Relief valve 106B and globe valve F104B, (penetration X-238) have been located as close as practical to the RHR heat. Their location is dictated by functionality and pipe stress considerations. Valves 106A and F103A, (penetration X-239) are located similarly.

g. DELETED

h. Valves HV-114, HV-115 (penetration X-26) are restricted to their location because of necessary piping interties and for valve accessibility.

i. Valve 109 (penetration X-25, X-201A) provides the outboard barrier for both the drywell penetration and the wetwell penetration. Physical separation of the penetrations and the resulting piping arrangement prohibits a closer placement to either penetration.

j. Valves HV-57V-180 and HV-57V-181 (Unit 1 penetration X-201B) are associated with the hardened containment vent and located at distances from the penetration dictated by equipment located in the compartment. Valves HV-57V-280 and HV-57V-281 (Unit 2 penetration X-201A) are associated with the hardened containment vent and located at distances from the penetration dictated by equipment located in the compartment.

(20) Closure times of 6 seconds or less are provided for all isolation valves on the purge lines, with the exception of valves HV-57-105 and HV-57-111. Valves HV-57-105 and HV-57-111 are 2 inch MOVs in the low volume purge lines with closure times of 15 seconds or less. This closure time has been justified by an analysis of the radiological consequences of a LOCA that occurs during purging, as discussed in Section 9.4.5.1.2.

(21) 124A, 124B, 125A, and 125B (penetrations X-53, X-54, X-55 and X-56) do not receive an automatic isolation signal. Valves HV-57V-180 and HV-57V-181 associated with Unit 1 penetration X-201B also do not receive automatic isolation signals and are not normally powered. Valves HV-57V-280 and HV-57V-281 associated with penetration X-201A (Unit 2) also do not receive automatic isolation signals and are not normally powered.These valves are administratively controlled such that these valves are treated as locked closed valves. Therefore, these valves do not have a required closure time.

(22) These lines are below the minimum water level in the suppression pool, the system is a closed system outside primary containment, and will maintain a water seal following an accident. Therefore, 10CFR50 Appendix J, Type C testing is not required.

Table 6.2-17 (Cont'd)

(23) There are electrical interlocks between HV-057-121 and HV-057-131 and in between HV-057-221 and HV-057-231, which prevent both interlocked valves from being open at the same time. This interlock is consistent with requirements of UFSAR Section 9.4.5.1.2.2 to limit the number of high volume purge lines in use during the operational modes of startup, power operation and hot shutdown to one supply line and one exhaust line.

(24) Valves HV-57-262, HV-57-263, HV-57-1(2)64, HV-57-269 (penetrations X-25, X-201A, and X-202) are administratively controlled such that these valves are treated as seal closed barriers. Therefore, these valves do not have a required closure time.

Table 6.2-18

ASSUMPTIONS USED IN EVALUATING THE PRODUCTION
OF COMBUSTIBLE GASES FOLLOWING A LOCA

PARAMETER	VALUE
Fraction of fission product radiation energy absorbed by the coolant:	
Betas from fission products in fuel rods	0.0
Betas from fission products mixed with coolant	1.0
Gammas from fission products in fuel rods	0.1
Gammas from fission products mixed with coolant	1.0
Hydrogen yield rate $G(H_2)$	0.5 molecule/100 eV
Oxygen yield rate $G(0_2)$	0.25 molecule/100 eV
Extent of initial core metal-water reaction involving cladding surrounding the fuel	0.00023 inch depth into original cladding
Evolution time of hydrogen produced from metal-water reaction	2 minutes
Corrosion rate for zinc and zinc paint	3.76×10^{-9} exp(0.0218T) lb-moles/ft^2-hr (where T = temperature in degrees Fahrenheit)
Fission product distribution model:	
Coolant water	1% of solids + 50% of halogens
Containment atmosphere	100% of noble gases
Fuel rods	All other fission products

Table 6.2-19

PARAMETERS USED IN EVALUATING THE PRODUCTION OF HYDROGEN FOLLOWING A LOCA

PARAMETER	VALUE
Reactor thermal power:	3,527 MWt (1)
Drywell free volume:	248,700 ft^3
Suppression chamber free volume:	149,000 ft^3
Zircaloy cladding surrounding active fuel:	
Mass	67,700 lb (1)
Surface area	89,210 ft^2 (1)
Zinc (as galvanized steel) in drywell:	
Mass	1,850 lb
Surface area	32,055 ft^2
Zinc paint in drywell:	
Volume of paint	1.92 ft^3
Surface area	7,692 ft^2
Zinc content of zinc paint	87%
Zinc paint in suppression chamber:	
Volume of paint	39.67 ft^3
Surface area	68,000 ft^2
Zinc content of zinc paint	87%
Volume of free hydrogen normally in reactor coolant (at 60°F and atmospheric pressure):	195 ft^3

(1) Reference 6.2-42 accounts for GNF3 fuel at 3527 MWt.

Table 6.2-20

CONTAINMENT HYDROGEN RECOMBINER SUBSYSTEM FAILURE MODES AND EFFECTS ANALYSIS

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Emergency (LOCA)	Power supply	LOOP	Loss of both recombiner packages	Alarm in the control room	None. The recombiner packages are powered from the Class 1E buses. When standby power becomes available, the recombiner packages resume operation.
Emergency (LOCA or LOCA + LOOP)	Power supply	Loss of one Class 1E bus or the associated diesel generator	Loss of one recombiner package	Alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.
Emergency (LOCA or LOCA + LOOP)	Containment isolation valve in one gas inlet or gas outlet line	Failure of valve to reopen after containment isolation signal is bypassed	No flow through recombiner package	Flow indication and low flow alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.
Emergency (LOCA or LOCA + LOOP)	Blower in one recombiner package	Abnormally low blower speed or complete failure to operate	Insufficient flow through recombiner package	Flow indication and low flow alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.
Emergency (LOCA or LOCA + LOOP)	Heater elements or SCRs in one recombiner package	Abnormally low heater output	Reaction chamber temperature too low for complete recombination	Alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.

Table 6.2-20 (Cont'd)

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Emergency (LOCA or LOCA + LOOP)	Water inlet valve in one recombiner package	Failure to open fully	Abnormally high return gas temperature	Alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.
Emergency (LOCA or LOCA + LOOP)	Gas inlet valve in one recombiner package	Case 1: Excessive valve opening	High flow through the recombiner package, with the possibility of excessive temperatures in the reaction chamber	Flow indication and high temperature alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.
		Case 2: Insufficient valve opening	Insufficient flow through the recombiner package	Flow indication and low flow alarm in the control room	None. The redundant recombiner package is unaffected and is activated manually by the operator.

Table 6.2-21

COMBUSTIBLE GAS ANALYZER SUBSYSTEM FAILURE MODES AND EFFECTS ANALYSIS

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Normal or Emergency	Power supply	LOOP	Closure of containment isolation valves on all sample lines. Loss of both analyzer packages.	Alarm in the control room	None. The analyzer packages are powered from the Class 1E buses. When standby power becomes available, the containment isolation valves reopen and the analyzer packages resume operation.
Normal or Emergency	480V Fuses	Loss of one fuse.	A/B phase fuse failure would cause loss of one analyzer package. C phase fuse failure would cause pump not to start and analyzer package would not be able to perform function.	A/B phase fuse failure would cause alarm in the control room. C phase fuse failure would be detected upon use or during testing every month.	None. The redundant analyzer package is unaffected and continues to operate.
Emergency (LOCA or LOCA + LOOP)	Power supply	Loss of one Class 1E bus or the associated diesel Generator.	Loss of one analyzer package. Closure of containment isolation valves on associated sample lines.	Alarm in the control room	None. The redundant analyzer package is unaffected and continues to operate.
Emergency (LOCA or LOCA + LOOP)	Sample pump in one analyzer package.	Failure of the operating pump.	Loss of sample flow through the affected analyzer package.	Alarm in the control room	None. The redundant analyzer package is unaffected and continues to operate.
Emergency (LOCA or LOCA + LOOP)	Hydrogen analyzer cell in one analyzer package,	Analyzer cell failure.	Incorrect hydrogen concentration for the affected analyzer package.	Alarm in the control room	None. The redundant analyzer package is unaffected and continues to operate.
Emergency (LOCA or LOCA + LOOP)	Oxygen analyzer cell in one analyzer package.	Analyzer cell. failure.	Incorrect oxygen concentration for the affected analyzer package.	Alarm in the control room	None. The redundant analyzer package is unaffected and continues to operate.

Table 6.2-21 (Cont'd)

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Emergency (LOCA or LOCA + LOOP)	Sample line containment isolation valves.	Failure of one valve to reopen when containment isolation signal is bypassed.	Case A, a sample suction line: inability to draw sample through affected line only.	Case A: alarm in the control room due to low flow when the affected line is selected.	None. The redundant analyzer package is unaffected and continues to operate.
			Case B, a sample return line: blockage of all flow through affected analyzer package.	Case **B**: alarm in the control room due to low flow Immediately.	
Emergency (LOCA or LOCA + LOOP)	Sample line containment isolation valves.	Failure of one valve to close when containment isolation signal is received.	Reduction in containment isolation barriers from two valves to one valve in the affected line.	Indicating lights in the control room.	None. The redundant valve provides isolation.
Normal or Emergency	Other electrical components and cables.	Open circuits and shorted circuits or loss of input / output due to various failure mechanisms or errors.	Loss of functions associated with failure of specific component (indication, alarms, controls, etc.	Depending on failed component alarm indication in control room or failure will be self-revealing.	None. The redundant analyzer package is unaffected and continues to operate.
Normal or Emergency	MCR Signal Conditioner and PLC Assembly	Failure to provide indication or control function.	Unable to obtain Combustible gas concentration readings.	Depending on failed component alarm indication in control room or failure will be self-revealing.	None. The redundant analyzer package is unaffected and continues to operate.

Table 6.2-24

SYSTEM VENTING AND DRAINING EXCEPTIONS FOR PRIMARY CONTAINMENT INTEGRATED LEAKAGE RATE TEST

I. The drywell chilled water system, located inside the primary containment, is required to maintain the plant in a stabilized condition during the Type A test and is not vented and operates in its normal mode.

II. Portions of systems that are normally filled with water and operating under post-LOCA conditions are not specifically vented to the containment atmosphere or to the outside atmosphere. They remain water-filled during the Type A test. These systems are listed below. (Note: Venting to the primary containment atmosphere does occur for these systems, since the reactor vessel is vented to the primary containment atmosphere and/or system penetrations are open to the suppression pool or containment atmospheres.)

III. For planning and scheduling purposes, or ALARA considerations, pathways that are Type B or C tested within the previous 24 calendar months need not be vented or drained during the Type A test.

NOTES

1. Seismic Category I, Quality Group A instrument line with an orifice and excess flow check valve or remote manual isolation valve. The excess flow check valve is subjected to operability testing except as discussed in Note 28, but no Type C test is performed or required. The line does not isolate during a LOCA and can leak only if the line or instrument should rupture. Leak-tightness of the line is verified during the integrated leak rate test (Type A test) by conducting the test with these valves open.

2. Penetration is sealed by a blind flange or door with double O-ring seals. These seals are leakage rate tested by pressurizing between the O-rings. For more detail, see Section 6.2.6.2.

3. Inboard butterfly valve installed such that testing in the reverse direction is equivalent to testing in the forward direction.

4. Inboard gate valve tested in the reverse direction. Valve seating forces are greater than unseating forces due to post-LOCA containment pressure by at least a factor of 3.

5. Inboard globe valve installed such that testing in the reverse direction is conservative.

6. The primary steam penetrations are tested by pressurizing between the valves. Testing of the inboard MSIV in the reverse direction tends to unseat the valve and is therefore conservative. The valves are Type C tested at a test pressure of 22 psig.

7. Gate valve tested in the reverse direction. Valve seating forces are greater than unseating forces due to post-LOCA containment pressure by at least a factor of 3.

8. Electrical penetrations are tested by pressurizing between the seals

Table 6.2-25 (Cont'd)

9. The isolation provisions for this penetration consist of two isolation valves and a closed system outside containment. Because a water seal is maintained in these lines by the safeguard piping fill system, the inboard valve may be tested with water. The outboard valve will be pneumatically tested.

10. The isolation provisions for this line consist of one isolation valve outside containment and a closed system outside containment. A single active failure can be accommodated. The closed system is missile-protected, seismic Category I, quality group B and designed to the temperature and pressure conditions that the system will encounter post-LOCA.

    System leakage will be minimized in accordance with NUREG-0737, Item III.D.1.1. Any leakage out of the closed system will be into the reactor enclosure, thus facilitating collection and treatment.

11. The valve does not receive an isolation signal but remains open to measure containment conditions post-LOCA. Leak-tightness of the penetration is verified during the Type A test by conducting the test with these valves open.

12. All isolation barriers are located outside containment.

13. Isolation provisions for the CRD insert and withdrawal lines are described in Section 6.2.4.3.1.2.3. The SDV vent and drain valves are Type C tested. Redundant check valves are provided on each main water header (i.e. charging, cooling, drive and exhaust). These valves are Type C tested with water.

14. The isolation provisions for this line consist of a suppression pool water seal, at least one isolation valve outside containment, and a closed system outside containment. The isolation valve is not exposed to the primary containment atmosphere because the line terminates below the minimum water level of the suppression pool. The closed system is missile-protected, seismic Category I, quality group B, and designed to the temperature and pressure conditions that the system will encounter post-LOCA. Because these valves will remain water covered following a LOCA, 10CFR50 Appendix J, Type C testing is not required. System leakage is minimized in accordance with NUREG-0737, Item III.D.1.1. Any leakage out of the closed system will be into the reactor enclosure, thus facilitating collection and treatment.

15. The isolation barrier remains water-filled post-LOCA and may be tested with water.

16. These lines penetrate the diaphragm slab and are not subject to Appendix J leakage rate testing.

17. Table 1.8-2 contains a cross-reference to figure numbers.

18. Feedwater penetrations will remain water-filled post-LOCA as described in Section 6.2.3.2.3.

19. Check valve used instead of flow orifice.

20. The ball valves (XV-141A-E) are Type C tested. It is not practical to leak test the shear valves (XV-140A-E) because squib detonation is required for closure; however, the following tests will be conducted to ensure that these valves will perform their intended function:

    a. The continuity of the explosive charge will be verified at least once per 31 days.

    b. One of the squib charges will be initiated at least once per 24 months. The replacement charge for the shear valve will be from the same manufacturing batch as the one fired, or from another batch that has been certified by having one sample from that batch successfully fired.

       In addition, all charges will be replaced at the manufacturer's recommended intervals. These requirements will be incorporated into the plant administrative procedures and surveillance test procedures.

21. Seismic Category I, Quality Group B instrument line with an excess flow check valve. Because the instrument line is connected to a closed cooling water system inside containment, no flow orifice is provided. The excess flow check valve is subject to operability testing, but no Type C test is performed or required. The line does not isolate during a LOCA and can leak only if the line or instrument should rupture. Leak-tightness of the line is verified during the integrated leak rate test (Type A test) by conducting the test with these valves open.

22. Deleted

Table 6.2-25 (Cont'd)

23. The RHR system safety pressure relief valves will be exempted from the initial LLRT. The relief valves in these lines will be exposed to containment pressure during the initial ILRT and all subsequent ILRTs. In addition, modifications will be performed at the first refueling to facilitate local testing or removal and bench testing of the relief valves during subsequent LLRTs. Justification for exclusion from separate testing of these valves as part of the initial LLRT program is based on the substantial containment isolation barriers provided by the design of the relief valves and the RHR system:

    a. The relief valves are maintained normally closed by their springs.

    b. The relief valves are oriented such that containment pressure would tend to seat the valve disc and enhance sealing.

    c. The relief valves are not exposed to the primary containment atmosphere because the lines terminate below the minimum water level of the suppression pool.

    d. The lines outside containment are part of a closed system which is missile-protected, Seismic Category I, quality group B, and designed to the temperature and pressure conditions that the system will encounter.

    e. System leakage will be minimized in accordance with NUREG-0737 Item III.D.1.1.

    f. Any leakage out of the system will be into the reactor enclosure, thus facilitating collection and treatment.

    g. Those relief valves that are flanged to facilitate removal will be equipped with double O-ring seal assemblies on the flange closest to primary containment.

24. Valve 41-1016 is an outboard isolation barrier for penetrations X-9A, B and X-44. Leakage through valve 41-1016 is included in the total for penetration X-44 only.

25. Butterfly valves are flanged. Those that serve as inboard isolation valves are equipped with double O-ring seal assemblies on the flange closest to primary containment. These seals are leak rate tested by pressurizing between the O-rings.

26. Relief valves PSV-51-1F030A, B, and C are flanged to facilitate removal and ISI testing. PSV-51-1F030D will be flanged prior to the end of the first refueling outage. In all cases, the flanges closest to primary containment will be equipped with double O-ring seal assemblies prior to the end of the first refueling outage. The seals will be leak rate tested by pressurizing between the O-rings. In the interim, the flanged valves are equipped with gasketed connections. The connections are exposed to suppression pool water and are tested during the integrated leak rate test. In addition, they are inspected as part of the system leakage reduction program (Section 6.2.8).

27. Penetration is sealed by a flange with double O-ring seals. Both the TIP purge supply (Penetration X-35B) and the TIP drive tubes (Penetration X-35C through G) are welded to their respective flanges. The seals are leak rate tested by pressurizing between the O-rings.

28. The reactor vessel head seal leak detection line (Penetration X-29A) excess flow check valve is not subject to operability testing. This valve will not be exposed to primary system pressure except under the unlikely conditions of a seal failure where it could be partially pressurized by reactor pressure. Any leakage path is restricted at the source; therefore, this valve need not be operability tested.

29. Valve HV-61-102 is locked closed, the motor operator is normally de-energized and the valve position is controlled procedurally. The valve remains closed during 10 CFR 50, Appendix J Type A testing, and Type C testing is not required. Valve HV-61-202 has been deleted from the Unit 2 design.

30. Inboard valve will be tested from the containment side using a temporary test connection at the open pipe end inside the drywell.

31. Valve HV-55-126 has been used for Unit 1 only.

32. The isolation provisions for this line consist of a suppression pool water seal, blind flange, and a closed system outside containment. The flange is not exposed to the primary containment atmosphere because the line terminates below the minimum water level in the suppression pool. The line is not used to support the system's functions. Because the line will maintain a water seal following a LOCA, 10 CFR 50 Appendix J, Type B testing is not required.

33. The isolation provisions for this line consist of one isolation valve outside containment and a closed system outside containment. A single active failure can be accommodated. The closed system does not communicate with the outside atmosphere, meets Seismic Category I and Safety Class 2 design requirements, designed to temperature and pressure conditions that the system will encounter post-LOCA, is protected from a HELB, is missile-protected, and is capable of being leak tested.

34. Type C testing of these valves is not required. A water seal for these lines will be maintained for 30 days.

Table 6.2-26 (Cont'd)

(1) Closure of these valves establishes a redundant boundary for potentially contaminated systems. Containment isolation valves that also provide system isolation are not included in this table (see Table 6.2-17). Where Unit 1 valves are listed, the design is typical for Unit 2.

(2) Normal valve position (open or closed) is the position during normal power operation of the reactor.

(3) Postaccident position is the required position of the valve during DBA conditions.

(4) Actuation signal codes

Signal	Description
A	Reactor vessel level 3 trip (a scram occurs at this level also)
B	Reactor vessel level 2 trip
C	Reactor vessel level 1 trip (main steam line isolation occurs at this level)
G	High drywell pressure and low reactor vessel pressure
H	High drywell pressure
IA	Interlocked to close when any of the HPCI (F041) or RCIC suppression pool suction valves (HV49-F029 or HV49-F031) open
IB	Interlocked to close when the HPCI turbine steam supply isolation valve (F001) opens
IC	Interlocked to close when the RCIC turbine steam supply isolation valve (F045) opens
ID	Interlocked to close when the RCIC suppression pool suction valves (F029 or F031) open
R	High radioactivity in reactor enclosure or refueling floor ventilation exhaust ducts, as applicable
T	Low differential pressure between the outside atmosphere and either the secondary containment or refueling area, as applicable
RPS	Reactor Protection System Scram Signal

(5) DELETED

(6) With the Reactor Enclosure Secondary Containment Zones I or II interlocked with Refuel Area Secondary Containment Zone III, The Reactor Enclosure HVAC valve isolation signals are combined for all associated valves as follows: B, H, R, T. In addition, the same valves isolate on RE Vent. Exh. High Rad (S) and Outside Atmos. to RE - Low DP (U).

Table 6.2-27

ESSENTIAL/NONESSENTIAL SYSTEMS

	ESSENTIAL	COMMENTS
SLCS	Yes	Should be available as backup to CRD system.
LPCI	Yes	Safety System
HPCI	Yes	Safety System
Core Spray	Yes	Safety System
Service Water	No	Not required for shutdown.
CAC	Yes	Combustible gas control function necessary to monitor and control containment hydrogen/oxygen levels.
ADS	Yes	Safety System/control RPV pressure
SGTS	Yes	Necessary to control emissions to environment.
RECW	No	Not required for DBA, but necessary for the recirculation cleanup system operation and fuel pool heat exchangers.
RCIC	Yes	Necessary for core cooldown following isolation from the turbine condenser and feedwater makeup.
ESW	Yes	Necessary to remove heat following accident. Includes the UHS.
RHRSW	Yes	Necessary to remove heat following accident. Includes the UHS.
PCIG	No	Not required for shutdown.
Compressed Air	No	Not required for shutdown.
Main Steam	No	Not required for shutdown.
Feedwater Line	No	Not required for shutdown, except for the portion to which the RCIC and HPCI systems connects.
Sampling Systems	No	Not required for shutdown. Some sampling capability will be provided for postaccident assessment in accordance with NUREG-0737 Item II.B.3.

Table 6.2-27 (Cont'd)

	ESSENTIAL	COMMENTS
CRD System	Yes	Parts of system are necessary for reactor shutdown.
RWCU	No	Not required for shutdown.
Radwaste Collection	No	Not required for shutdown.
Recirculation System	No	Not required for shutdown.
RHR Heat Exchangers	Yes	Main heat sink during isolation.
RHR Shutdown Cooling	Yes	Not essential, but desirable to use if available. Not redundant, but safety-grade.
RHR Containment/Suppression Spray	Yes	Necessary to control pressure.
RHR - Suppression Pool Cooling	Yes	Main heat sink during isolation.
Drywell Chilled Water	No	Not required for shutdown, but desirable to keep running.
Clarified Water	No	Not required for shutdown.
Condensate	No	Not required for shutdown.
Fuel Pool Cooling	No	Not required for shutdown but continuous pool cooling is desired. Seismic Category I makeup line is provided.
Control Drywell Purge	Yes	Backup to hydrogen control.
MSIV Alternative Drain Pathway	Yes	Ensures that highly radioactive fluids are confined to the reactor building.
TIP System	No	Not required for shutdown.
Fire Protection System	Yes	Availability is essential for shutdown following a fire.
Makeup Demineralizer	No	Not required for shutdown.
ECCS Fill System	Yes	Required to ensure ECCS operability.
Feedwater Fill System	Yes	Required to mitigate radiological consequences.

Table 6.2-27 (Cont'd)

	ESSENTIAL	COMMENTS
Primary Containment Leak Test System	No	Not required for shutdown.
Suppression Pool Cleanup System	No	Not required for shutdown.
Long-Term ADS Gas Supply	Yes	Long-term backup to ADS accumulators inside containment.

6.3 EMERGENCY CORE COOLING SYSTEMS

6.3.1 DESIGN BASES AND SUMMARY DESCRIPTION

Section 6.3.1 provides the design basis for the Emergency Core Cooling System (ECCS) systems and a brief summary design description. Detailed system descriptions are provided in Section 6.3.2. Section 6.3.3 contains the results of the performance analysis.

The current ECCS-LOCA analysis was performed using the SAFER/GESTR-LOCA methodology described in References 6.3-5 and 6.3-7 and supplemented by the implementation of the PRIME methodology described in Reference 6.3-15 with updates as discussed in Reference 6.3-16 and Reference 4.1-1. The SAFER/GESTR analysis was performed assuming the thermal power listed in Table 6.3-1 (which bounds the current plant conditions). The results of the original SAFER/GESTR-LOCA are provided in Reference 6.3-6.

This analysis addressed the fuel types that were in operation at the time. However, those 8x8 (e.g., GE9) and 9x9 (e.g., GE11/GE13) fuel designs are no longer in operation and therefore are not considered when evaluating the limiting peak cladding temperature.

For the implementation of GNF3 fuel (10x10 fuel design) an updated SAFER/PRIME analysis has been performed and documented in Reference 6.3-16. Reference 6.3-18 provides updates to Figures 1-d, 2-d, 3-d, and 4-d of Reference 6.3-16. The input parameters used for the current ECCS-LOCA analysis are listed in Table 6.3-1. Table 6.3-2 summarizes the revised operational sequence of ECCS for the design basis LOCA. The licensing basis peak cladding temperature values for GNF3 fuel are provided in Table 6.3-5.

There exist changes or errors that affect the analysis of record PCT calculation. These changes or errors are documented via 10 CFR 50.46 reporting. After accounting for all changes or errors, the licensing basis PCT remains below the 2,200°F limit. Refer to the docketed annual or thirty-day 10 CFR 50.46(a)(3) report for details.

The original ECCS-LOCA analysis was performed using the methodology described in reference 6.3-1. The input parameters used for the original ECCS-LOCA are listed in Table 6.3-1A. Table 6.3-2A contains the operational sequence of ECCS assumed in the original ECCS-LOCA analysis. Tables 6.3-1A and 6.3-2A are retained for historical purposes, because they provide the basis for most of the ECCS performance parameters specified in the current plant Technical Specifications.

6.3.1.1 Design Bases

6.3.1.1.1 Performance and Functional Requirements

The ECCS is designed to provide protection against postulated LOCA's caused by ruptures in primary system piping. The functional requirements (e.g., coolant delivery rates), specified in Table 6.3-1 for the current ECCS-LOCA analysis and in Table 6.3-1A for the original LOCA analysis, are such that the system performance under all LOCA conditions postulated in the design satisfies the requirements of 10CFR50.46, "Acceptance Criteria for Emergency Core Cooling System for Light-Water-Cooled Nuclear Power Reactors." These requirements are summarized in Section 6.3.3.2. In addition, the ECCS is designed to meet the following requirements:

a. Protection is provided for any primary system line break up to and including the double-ended break of the largest line.

b. Two independent phenomenological cooling methods (flooding and spraying) are provided to cool the core.

c. One high pressure cooling system is provided, which is capable of maintaining the water level above the top of the core and preventing Automatic Depressurization System (ADS) actuation for breaks of lines less than 1-inch nominal diameter.

d. No operator action is required until 10 minutes after an accident, to allow for operator assessment and decision.

e. The ECCS is designed to satisfy all criteria specified in this section for any normal mode of reactor operation.

f. A sufficient water source and the necessary piping, pumps, and other hardware are provided so that the containment and reactor core can be flooded for possible core heat removal following a LOCA.

6.3.1.1.2 Reliability Requirements

The following reliability requirements apply:

a. The ECCS conforms to all licensing requirements and to good design practices of isolation, separation, and common mode failure considerations.

b. In order to meet the above requirements, the ECCS network has built-in redundancy so that adequate cooling can be provided, even in the event of specified failures. As a minimum, the following equipment makes up the ECCS:

1. One HPCI system
2. Two Core Spray (CS) loops
3. Four Low Pressure Coolant Injection (LPCI) loops
4. One ADS

c. The ECCS is designed so that a single active or passive component failure, including power buses, electrical and mechanical parts, cabinets, and wiring, cannot disable the ADS.

d. If there is a break in a pipe that is not a part of the ECCS, no single active component failure in the ECCS, including all common and support components, prevents automatic initiation and successful operation of less than one of the following combinations of ECCS equipment:

1. Three LPCI loops, one CS loop and the ADS and HPCI (i.e., single diesel generator failure). If the single failure occurs in a diesel generator that supplies power to an ESW pump, the diesel generator in the other unit is needed to support the other ESW pump that supplies that loop.

2. Four LPCI loops, two CS loops and the ADS (i.e., HPCI failure)

e. If there is a break in a pipe that is a part of the ECCS, no single active component failure in the ECCS, including all common and support components, prevents automatic initiation and successful operation of less than one of the following combinations of ECCS equipment:

1. Three LPCI loops and the ADS
2. Two LPCI loops, one CS loop, and the ADS and HPCI

These are the minimum ECCS combinations which result after assuming any failure (from d. above), and assuming that the ECCS line break disables the affected loop/system.

f. Long-term (later than 10 minutes after initiation signal) cooling requirements call for the removal of decay heat via the RHRSW system. In addition to the break which initiated the loss-of-coolant event, the system can sustain one failure, either active or passive, and have at least one low pressure ECCS pump (LPCI or CS) operating for makeup, one RHR pump with a heat exchanger, and 100% RHRSW flow to the heat exchanger operating for heat removal.

g. Offsite ac power is the preferred source of ac power for the ECCS network, and every reasonable precaution is made to assure its high availability. However, onsite safeguard ac power has sufficient diversity and capacity to meet all the above requirements, even if offsite ac power is not available.

h. The onsite diesel fuel reserve is in accordance with IEEE 308 (1974) criteria.

i. The diesel load configuration is one LPCI pump and one CS pump, connected to a single diesel generator (4 sets per unit).

j. Electrical systems which interface with, but are not part of, the ECCS are designed and operated so that failure(s) in the interfacing systems do not propagate to, and/or affect the performance of, the ECCS.

k. 1. Nonsafety-related electrical systems in the accident unit interfacing with the Class 1E buses are automatically shed from the Class 1E buses when a LOCA signal exists.

2. Nonsafety-related electrical systems in the nonaccident unit will remain connected to the Class 1E buses when a LOCA signal exists in the other unit.

l. No more than one storage battery is connectable to a dc power bus.

m. Each fluid loop/system of the ECCS network, including flow rate and sensing networks, is capable of being tested during shutdown. All active components are capable of being tested during plant operation, including logic required to automatically initiate component action.

n. Provisions for testing the ECCS network components (electronic, mechanical, hydraulic and pneumatic, as applicable) are installed in such a manner that they are an integral and nonseparable part of the design.

o. While a break in a non-ECCS or ECCS pipe concurrent with a single active component failure in an ECCS or support component will result in remaining combinations of ECCS as described in items d. and e. above, certain technical specification limiting conditions for operation (LCOs) are based on ECCS requirements as given in NEDO-24708A. This document, prepared in response to NRC questions arising from licensee responses to I. E. Bulletin 79-08 (Events relevant to boiling water power reactors identified during Three Mile Island incident), specifies the minimum ECCS system requirements to successfully terminate a transient or LOCA initiating event (with scram) assuming multiple failures with realistic conditions. For the postulated suction line breaks (including DBA), one low pressure ECCS (one LPCI pump or one CS loop) and ADS to depressurize thereby allowing the low-pressure ECCS to inject is adequate to reflood the vessel and maintain core cooling sufficient to preclude fuel damage. NEDC-30936P-A, specifically applicable to LGS and supplemented by 006N4699, references NEDO-24708A and reaffirms that one low pressure ECCS will reflood the vessel and maintain core cooling. It adds the advisory that for a large break LOCA, following 2 hours of LPCI injection, an alternate cooling path may be necessary for long term core cooling. This is because LPCI injecting directly into the core shroud could possible keep the body of water around the core substantially subcooled, quenching any steam cooling effects.

6.3.1.1.3 ECCS Requirements for Protection from Physical Damage

The ECCS piping and components are protected against damage from the effects of movement, thermal-stresses, the effects of the LOCA, and the SSE.

The ECCS is protected against the effects of pipe whip, which might result from piping failures up to, and including, the design basis event LOCA. This protection is provided by separation, pipe whip restraints, or energy-absorbing materials if required. One of these three methods is applied to provide protection against damage to piping and components of the ECCS, which otherwise could reduce ECCS effectiveness to an unacceptable level.

For the purpose of mechanical separation ECCS components are divided into two divisions. The Division 1 ECCS components include the following:

a. Core spray loop A

b. RHR loop A and RHR-LPCI loop C

c. ADS

The Division 2 ECCS components include the following:

a. Core spray loop B

b. RHR loop B and RHR-LPCI loop D

c. HPCI

With the exception of the RHR pumps, each of the ECCS pumps and its associated components are located in individual compartments within the reactor enclosure. The two RHR pumps in each division are located in a common compartment. This compartmentalization ensures that

environmental disturbances such as fire, pipe rupture, flooding, etc., affecting one system do not affect the remaining systems. For ECCS mechanical components located outside the pump compartments, such as the outboard containment isolation valves, separation between the different divisions is provided by distance or by locating the components in different compartments.

Electrical separation is described in Sections 7.1 and 8.3.

6.3.1.1.4 ECCS Environmental Design Basis

Each loop/system of the ECCS injection network, except the HPCI system, has a safety-related injection/isolation testable check valve located in piping within the drywell. The HPCI system injects through one of the core spray spargers and through the feedwater sparger, and the (non-ECCS) RCIC system injects through the feedwater system. However, both systems have isolation valves in the drywell portion of their steam supply piping. No portion of the ECCS and RCIC piping is subject to drywell flooding, since water drains into the suppression chamber through the downcomers. The valves are qualified for the following environmental conditions:

a. Normal and upset plant operating ambient temperatures, relative humidities, and pressures as discussed for each area of the drywell in Section 3.11.

b. Envelope-of-accident conditions for temperature, relative humidity, and pressure within the drywell for various time periods following the accident as discussed in Section 3.11.

c. Normal and envelope-of-accident radiation environment (gamma and neutron) as discussed in Section 3.11.

The portions of ECCS and RCIC piping and equipment located outside the drywell and within the secondary containment are qualified for the following environmental conditions:

a. Normal and upset plant operating ambient temperatures, relative humidities, and pressures as discussed in Section 3.11.

b. Envelope-of-accident conditions for temperature, relative humidity, and pressure for various time periods following the accident as discussed in Section 3.11.

c. Normal and envelope-of-accident radiation environment (gamma and neutron) as discussed in Section 3.11.

6.3.1.2 Summary Descriptions of ECCS

The ECCS injection network is comprised of a HPCI system, a low pressure CS system, and the LPCI mode of the RHR system. These systems are briefly described here as an introduction to the more detailed system design descriptions provided in Section 6.3.2. The ADS, which assists the injection network under certain conditions, is also briefly described. BWRs with the same ECCS design are listed in Table 1.3-2.

6.3.1.2.1 High Pressure Coolant Injection System

The HPCI system pumps water into the reactor vessel through one of the CS spargers and through one of the feedwater sparger. The primary purpose of HPCI is to provide sufficient coolant to the reactor vessel following a small break LOCA until reactor pressure is below the pressure at which

CS operation or LPCI mode of RHR system operation maintains core cooling. The HPCI system is also required to provide sufficient coolant to the reactor vessel to prevent the actuation of the ADS and maintain reactor level above the top of the reactor core in the event of a small pipe break with a break size of one-inch diameter or less.

6.3.1.2.2 Core Spray System

The two CS system loops pump water into peripheral ring spray spargers, mounted above the reactor core. The primary purposes of the CS loops are to provide inventory makeup and spray cooling during large breaks in which the core is calculated to uncover. Following ADS initiation, CS provides inventory makeup following a small break.

6.3.1.2.3 Low Pressure Coolant Injection Subsystem

LPCI is an operating mode of the RHR system. Four pumps deliver water from the suppression pool to separate vessel nozzles, which lead to direct discharge inside the core shroud region (four loops). The primary purpose of LPCI is to provide vessel inventory makeup following large pipe breaks. Following ADS initiation, LPCI provides inventory makeup following a small break.

6.3.1.2.4 Automatic Depressurization System

The ADS utilizes five of the reactor SRVs to reduce reactor pressure during small breaks or after containment isolation, in the event of HPCI failure. When the vessel pressure is reduced to within the design of the low pressure systems (CS and LPCI), these systems provide inventory makeup so that acceptable postaccident temperatures are maintained.

6.3.1.2.5 Management of Gas Accumulation in Fluid Systems

On January 11, 2008, the NRC issued Generic Letter 2008-01, “Managing Gas Accumulation in Emergency Core Cooling, Decay Heat Removal, and Containment Spray (Reference 6.3-12). Generic Letter 2008-01 requested licensees to evaluate the licensing basis, design, testing, and corrective action programs for the Emergency Core Cooling, Decay Heat Removal, and Containment Spray systems to ensure that gas accumulation is maintained less than the amount that challenges operability of these systems, and that appropriate action is taken when conditions adverse to quality are identified. As a consequence, Limerick performed in-depth system reviews for the RHR, HPCI, Cores Spray, and RCIC systems in accordance with the criteria of GL 2008-01, investigating whether the existing Licensing Basis, Design Basis, actual field configuration, system restoration processes, and operational procedures would introduce or allow the accumulation of a gas (air) void in system piping. Piping locations in each system that are susceptible to air accumulation are periodically monitored to ensure that the piping systems are maintained sufficiently filled with water. The piping systems addressed in the response to Generic Letter 2008-01 have the potential to develop voids and pockets of entrained gases. Maintaining the pump suction and discharge piping sufficiently full of water is necessary to ensure that the system will perform and will inject the flow assumed in the safety analyses into the Reactor Coolant System or containment upon demand. This will also prevent damage from pump cavitation or water hammer, and pumping of unacceptable quantities on non-condensable gas (e.g., air, nitrogen, hydrogen) into the reactor vessel following an ECCS start signal or during shutdown cooling.

6.3.2 SYSTEM DESIGN

More detailed descriptions of the individual systems, including individual design characteristics of the systems, are covered in detail in Sections 6.3.2.2.1 through 6.3.2.2.4. The following discussion provides details of the combined systems, and in particular, those design features and characteristics which are common to all systems.

6.3.2.1 Piping and Instrumentation and Process Diagrams

The P&IDs for the ECCS and the process diagrams which identify the various operating modes of each system are identified in Section 6.3.2.2.

6.3.2.2 Equipment and Component Descriptions

The starting signal for the ECCS comes from at least two independent and redundant sensors of high drywell pressure and low reactor water level. The ECCS is actuated automatically, and is designed to require no operator action during the first 10 minutes following the accident. A time sequence for starting of the systems is provided in Table 6.3-2 for the current ECCS-LOCA analysis, and in Table 6.3-2A for the original ECCS-LOCA analysis.

Electric power for operating the ECCS (except the dc powered HPCI and ADS systems) is from the preferred offsite ac power supply.

Upon loss of the preferred source, operation is from the onsite standby diesel generators. Four diesel generators supplying individual ac buses in a unit have sufficient diversity and capacity so that any three units satisfy minimum ECCS requirements, which are stated in Section 6.3.1.1.2.b. One CS pump (2 loop) and one LPCI loop are powered by each ac bus. Section 8.3 contains a more detailed description of the power supplies for the ECCS.

Regulatory Guide 1.1

Regulatory Guide 1.1 prohibits design reliance on pressure and/or temperature transients expected during a LOCA for assuring adequate NPSH. The requirements of this guide are applicable to the HPCI, CS, and LPCI pumps.

The BWR design conservatively assumes 0 psig containment pressure and maximum expected temperatures of the pumped fluids. Thus, no reliance is placed on pressure and/or temperature transients to ensure adequate NPSH.

Requirements for NPSH at the centerline of the pump suction nozzles for each pump are given in drawings E41-1020-G-002 (HPCI), E21-1020-G-001 (CS), and E11-1020-G-002 (LPCI).

6.3.2.2.1 High Pressure Coolant Injection System

The HPCI system consists of a steam turbine-driven, constant flow pump assembly and associated system piping, valves, controls, and instrumentation. The P&IDs for the HPCI, drawings M-55 and M-56, show the system components and their arrangement. The HPCI process diagram, drawing E41-1020-G-002, shows the design operating modes of the system.

The principal HPCI equipment is installed in the reactor enclosure. Suction piping comes from both the CST and the suppression pool. Injection water is piped to the reactor via the CS Loop B sparger pipe and through the Loop A feedwater sparger. The steam supply for the turbine is piped from a main steam

line in the primary containment. This piping is provided with an isolation valve on each side of the primary containment. Remote controls for valve and turbine operation are provided in the main control room. The controls and instrumentation of the HPCI system are described, illustrated, and evaluated in detail in Section 7.3.

The HPCI system provides coolant to the reactor vessel following a small break LOCA until reactor vessel pressure is below the pressure at which CS operation or LPCI operation maintains core cooling. The HPCI system is also capable of providing sufficient coolant to the reactor vessel to prevent the actuation of the ADS and ensure that the reactor core remains covered in the event of a small pipe break with a break size of one-inch diameter or less. This permits the plant to be shut down, while maintaining sufficient reactor vessel inventory until the reactor is depressurized. For design basis events HPCI needs to operate for a maximum of six hours in order to fulfill its safety functions.

The HPCI system is designed to pump water into the reactor vessel for a wide range of pressures in the reactor vessel. The normal alignment of the HPCI system initially injects water from the CST instead of water from the suppression pool. An alternate alignment to the suppression pool is also available during periods whan the CST is not available. This provides reactor grade water to the reactor vessel. Water is pumped into the reactor vessel through a core spray sparger and a feedwater sparger; this flow split is provided by orificing.

The pump assembly is located below the water levels of the CST and the suppression pool, to ensure positive suction head to the pumps. Pump NPSH requirements are met by providing adequate suction head and adequate suction line size.

The HPCI turbine-pump assembly and piping are protected from the detrimental physical effects of pipe whip, flooding, and high temperature.

The HPCI turbine is driven by steam from the reactor vessel, generated by decay and residual heat. The steam is extracted from a main steam line upstream of the MSIVs. Inboard and outboard HPCI isolation valves in the steam line to the HPCI turbine are normally open. This keeps the piping to the turbine at an elevated temperature to permit rapid startup of the HPCI system. Signals from the HPCI control system open or close the turbine control valve adjacent to the turbine. The outboard isolation valve has a bypass line containing a normally closed valve. This bypass line permits pressure equalization and drainage around the isolation valve, and downstream line warmup prior to opening of the isolation valve.

A condensate drain pot is provided upstream of the turbine stop valve to prevent the HPCI steam supply line from filling with water. The drain pot normally routes the condensate to the main condenser, but upon receipt of a HPCI initiation signal and subsequent opening of the steam supply valve, or a loss of control air pressure signal, isolation valves on the condensate line automatically close.

The turbine power is controlled by a flow controller that senses pump discharge flow and provides a variable signal to the turbine governor to maintain constant pump discharge flow over the pressure range of operation. The turbine control system is capable of limiting speed overshoot to 15% of maximum operating speed on a quick start, while driving only the pump inertia load.

Limit switches are provided on the turbine control (governor) valves(s) to indicate fully open and closed positions. Both lights are "on" in midposition.

As reactor steam pressure decreases, the HPCI turbine throttle valves open further to pass the steam flow required to provide the necessary pump flow. The capacity of the system is selected to provide sufficient core cooling to prevent clad temperatures in excess of the limits (10CFR50.46) while the pressure in the reactor vessel is above the pressure at which CS and LPCI become effective.

Exhaust steam from the HPCI turbine is discharged to the suppression pool. A drain pot at the low point in the exhaust line collects moisture present in the steam. Collected moisture is discharged through an orifice to the barometric condenser.

The HPCI turbine gland seals are vented to the barometric condenser for cooling. Noncondensable gases from the barometric condenser are pumped to the reactor enclosure equipment compartment exhaust filter during normal plant operation and to the RERS during reactor enclosure isolation.

A redundant system of check valves and isolation valves is installed as a vacuum breaker line, which connects the air space in the suppression chamber with the HPCI turbine exhaust line. This eliminates any possibility of water from the suppression pool being drawn into the HPCI turbine exhaust line. The isolation valves in this vacuum breaker line automatically close via a combination of low HPCI steam supply pressure and high drywell pressure. Test connections are provided on either side of the two check valves.

Potential damage from water hammer in the HPCI turbine supply and exhaust lines is prevented by the use of design features such as exhaust line vacuum breakers, drain pots upstream and downstream of the turbine, and a sparger in the turbine exhaust line in the suppression pool. Further discussion of water hammer is provided in Section 1.12.3.

Startup of the HPCI system is completely independent of ac power. Only dc power from the station battery and steam extracted from the nuclear system are necessary.

The various operations of the HPCI components are summarized below.

The HPCI controls automatically start the system and bring it to design flow rate within 60 seconds from receipt of a RPV low water level signal, or a primary containment (drywell) high pressure signal. Refer to Chapter 15 for more analysis details.

The HPCI turbine is directly shut down by any of the following signals:

a. Turbine overspeed: this prevents damage to the turbine.

b. RPV high water level: this indicates that core cooling requirements are satisfied.

c. HPCI pump low suction pressure: this prevents damage to the pump due to loss of flow.

d. HPCI turbine exhaust high pressure: this indicates a turbine or turbine control malfunction.

e. Isolation of either inboard or outboard HPCI isolation valves.

f. Low steam supply pressure.

If an initiation signal is received after the turbine is shut down, the system restarts automatically, if no shutdown signal exists.

Because the steam supply line to the HPCI turbine is part of the RCPB, certain signals automatically isolate this line, causing shutdown of the HPCI turbine. Automatic shutoff of the steam supply is described in Section 7.3. However, automatic depressurization and the low pressure systems of the ECCS act as backup; and automatic shutoff of the steam supply does not negate the ability of the ECCS to satisfy the safety objective.

In addition to the automatic operational features of the system, provisions are included for remote manual startup, operation, and shutdown (provided automatic initiation or shutdown signals do not exist).

HPCI operation automatically actuates the following valves:

a. HPCI pump discharge shutoff valve, if closed (F007)

b. HPCI steam supply shutoff valve (F001)

c. HPCI turbine stop valve

d. HPCI turbine control valves

e. HPCI steam line drain isolation valve (F028, F029)

f. HPCI test valves, if open (F008, F011, F071)

g. Minimum flow bypass valve (F012)

h. HPCI pump discharge injection valves (F006, F105)

i. HPCI lube oil cooling water valve (F059)

j Condensate pump discharge isolation valves, if open (F025, F026)

Startup of the auxiliary oil pump and proper functioning of the hydraulic control system are required to open the turbine stop and control valves. Operation of the barometric condenser components is required to prevent out-leakage from the turbine shaft seals. Startup of the condenser equipment is automatic, but its failure does not prevent the HPCI system from fulfilling its core cooling objective. Prior to startup of the HPCI turbine, the turbine control system is set to maintain the turbine at the low speed design condition. Upon receipt of an initiation signal, a speed ramp generator module automatically runs the control system toward its high speed design point, thereby controlling the transient acceleration of the turbine. The flow controller then automatically overrides the speed ramp generator, and when rated flow is established, the flow controller signal adjusts the setting of the turbine control so that rated flow is maintained as nuclear system pressure decreases.

A minimum flow bypass is provided for pump protection. The bypass valve automatically opens on low flow, provided pump discharge pressure is above a pressure permissive setpoint (indicates pump is running) and automatically closes on high flow, stop valve closure or steam supply valve closure. When the bypass is open, flow is directed to the suppression pool. A line used for system testing

leads from the HPCI pump discharge line to the CST. The shutoff valves in this line are sequenced to close by the signal that actuates system operation, and valve F011 is interlocked closed when the F041 valve, suppression pool to pump suction valve, is open. All automatically operated valves are capable of remote manual operation.

The normal alignment of the HPCI system is to initially inject water from the CST. An alternate alignment to the suppression pool is also available when the CST is not available. When the water level in the tank falls below a predetermined level or the suppression pool level is high, the pump suction is automatically transferred to the suppression pool. A vortex breaker is located at the suction nozzle of the CST to prevent vortex formation. A calculation has been performed to demonstrate that air core vortex formation will not occur with the CST level at the transfer level, and with the HPCI pumps operating at 5600 gpm. This transfer may also be made from the main control room using remote controls. When the pump suction has been transferred to the suppression pool, a closed-loop is established for recirculation of water escaping from a break.

To ensure continuous core cooling, general containment isolation signals do not operate any HPCI valves. The HPCI system incorporates a relief valve in the pump suction line to protect the components and piping from inadvertent overpressure conditions.

Level instrumentation for the CST and the HPCI suction line are protected from the effects of cold weather. The HPCI suction line and the CST instrument sensing lines that are exposed to the outdoor environment are provided with heat tracing. Indication is provided in the control room if this heat tracing should become inoperative. The CST level instrumentation for control room monitoring is located in the reactor enclosure. The level instrumentation used to automatically transfer the HPCI pump suction from the CST to the suppression pool is located on the portion of the HPCI line in the reactor enclosure and is not subject to the effects of cold weather.

The HPCI pump and piping are designed and located to avoid damage from the physical effects of DBAs, such as pipe whip, missiles, temperature, pressure, and humidity.

The HPCI equipment and support structures are designed in accordance with seismic Category I criteria (Section 3.9). The system is assumed to be filled with water for seismic analysis.

Provisions are included in the HPCI system which permit the HPCI system to be tested. These provisions are:

a. A full flow test line is provided to route water from and to the CST, without entering the RPV.

b. A bypass flow test line is provided to route water from and to the suppression pool, without entering the RPV.

c. Instrumentation is provided to indicate system performance during normal test operations.

d. All MOVs are capable of manual operation for test purposes. During all modes of manual MOV operation using the handswitch from the main control room, a "dead zone" is present for a portion of the valve travel. The "dead zone" is present when the valve is not fully closed and green light only indication exists. If the valve is stopped in the "dead zone", operator action is required to restart the valve.

e. Drains are provided to leak test the major system valves.

Interlocks for the HPCI system are described in Chapter 7. The operating requirement parameters for the components of the HPCI system, listed below, are shown on the process diagram (drawing E41-1020-G-002).

a. One 100% capacity booster and main pump assembly with accessories

b. Piping, valves, and instrumentation for:

1. Steam supply to the turbine

2. Turbine exhaust to the suppression pool

3. Makeup supply from the CST to the pump suction

4. Makeup supply from the suppression pool to the pump suction including pump suction strainers described in Section 6.2.2.2.

5. Pump discharge to the core spray sparger and feedwater line, including a test line to the CST, a minimum flow bypass line to the suppression pool, and a coolant water supply to accessory equipment

The basis for the design conditions is the ASME Section III, "Nuclear Power Plant Components."

A design flow functional test of the HPCI is performed during plant operation by taking suction from the CST, and discharging through the full flow test return line back to the CST. The discharge valve to the core spray and feedwater lines remain closed during the test, and reactor operation is undisturbed. All components of the HPCI system are capable of individual functional testing during normal plant operation. Control system design provides automatic alignment from test to operating mode if system initiation is required. The three exceptions are as follows:

a. The auto/manual station is in "manual" on the flow controller. This feature is required for operator flexibility during system operation.

b. Steam inboard/outboard isolation valves: closure of either or both of these valves requires operator action to properly sequence their opening. An alarm sounds when either of these valves leaves the fully open position.

c. Parts of the system which are bypassed or deliberately rendered inoperable. This is automatically indicated in the control room.

Periodic inspection and maintenance of the turbine-pump unit are conducted in accordance with plant programs and procedures. Other than surveillances required by technical specifications, the types of inspection and maintenance are based on manufacturer’s recommendations and industry guidelines and the frequency is based on industry and site specific experience. Valve position indications and instrumentation alarms are displayed in the control room.

6.3.2.2.1.1 NPSH Available with Suction from the CST

The available NPSH is calculated in accordance with Regulatory Guide 1.1. The following data were used in the calculation:

a. Condensate water level is at el 191'- 7.25" at the bottom of the 34 inch section of pipe HCB-105. This level is approximately 27 ft below the static transfer level (i.e. 0 gpm HPCI flow), which is within the CST nozzle.

b. CST water is at 120°F.

c. Atmospheric pressure is assumed above the condensate water level.

d. $NPSH = h_s - h_{vp} - h_f + h_a$

where:

h_s	=	static head above pump suction nozzle centerline	
	=	191.6 ft to 182.25 ft	= 9.3 ft
h_f	=	friction head loss	= 4.0 ft
h_{vp}	=	vapor pressure (head loss)	= 3.9 ft
h_a	=	atmospheric head	= 34.3 ft
NPSH	=	35.7 ft	

6.3.2.2.1.2 NPSH Available with Suction from the Suppression Pool

The available NPSH is calculated in accordance with Regulatory Guide 1.1. The following data were used in the calculation:

a. Suppression pool is at the minimum postaccident level reached while the pump is running of el 201'-5.64".

b. Suppression pool water is at its maximum temperature for the given operating mode, 170°F.

c. Atmospheric pressure is assumed over the suppression pool.

d. $NPSH = h_s - h_{vp} - h_f + h_a$

where:

h_s	=	static head above pump suction nozzle centerline	
	=	201.47 ft to 182.25 ft	= 19.2 ft
h_f	=	friction head loss (including 2 psi loss across suction strainers)	= 11.7 ft

h_{vp}	=	vapor pressure (head loss)	= 14.2 ft
h_a	=	atmospheric head	= 34.8 ft
NPSH	=	28.1 ft	

6.3.2.2.2 Automatic Depressurization System

If the RCIC system or the HPCI system cannot maintain the reactor water level, the ADS reduces the reactor pressure so that flow from LPCI and/or CS systems enters the reactor vessel in time to cool the core and limit fuel cladding temperature.

The ADS employs five of the nuclear system SRVs to relieve high pressure steam to the suppression pool. The design, number, location, description, operational characteristics, and evaluation of the SRVs and their pneumatic accumulators are discussed in detail in Section 5.2.2. The instrumentation and controls for the ADS are discussed in Section 7.3. Gas supplies for long term operation of ADS are described in Sections 9.3.1.3 and 7.6.

6.3.2.2.3 Core Spray System

Each of the two redundant CS system loops consists of: two 50% capacity centrifugal pumps powered from Class 1E buses; a spray sparger in the reactor vessel above the core (a separate sparger for each CS loop); piping and valves to convey water from the suppression pool to the sparger; and associated controls and instrumentation. A connection to the HPCI system is provided to allow HPCI injection through the CS Loop B vessel connection. The CS P&ID (drawing M-52) presents the system components and their arrangement. The CS process diagram (drawing E41-1020-G-001) shows the design operating modes of the system. A simplified system flow diagram showing system injection into the reactor vessel is included in drawing E41-1020-G-001.

When low water level in the reactor vessel and/or high pressure in the drywell is sensed, and if reactor vessel pressure is low enough, the CS system automatically starts and sprays water into the top of the fuel assemblies to cool the core. The time sequence assumed in the current ECCS-LOCA analysis for CS system operation is given in Table 6.3-2. The time sequence assumed in the original ECCS-LOCA analysis for CS system operation is given in Table 6.3-2A. The CS injection piping enters the vessel, divides, and enters the core shroud at two points near the top of the shroud. A semicircular sparger is attached to each outlet. Nozzles are spaced around the sparger to spray the water radially over the core and into the fuel assemblies.

The CS system is designed to provide cooling to the reactor core only when the reactor vessel pressure is low, as is the case for large LOCA break sizes. However, when CS operates in conjunction with the ADS, the effective core cooling capability of CS is extended to all break sizes because the ADS rapidly reduces the reactor vessel pressure to the CS operating range.

The CS pumps and all MOVs can be operated individually by manual switches located in the control room. Operating indication is provided in the control room by a flowmeter, and valve and pump indicator lights.

To assure continuity of core cooling, signals to isolate the containment do not operate any CS system valves. Suppression pool test return valves isolate on an automatic CS initiation signal.

Loop A and B injection lines are each provided with two isolation valves. One of these valves is a pneumatically-testable check valve located inside the drywell, as close as practical to the reactor vessel. CS injection flow causes this valve to open during LOCA conditions (i.e., no power is required for valve actuation during the LOCA). If the CS line should break outside the containment, the check valve in the line inside the drywell prevents loss of reactor water.

The outer isolation valve on Loop A is a motor-operated gate valve, and the outer isolation valve on Loop B is a pneumatically-testable check valve. These valves are located as close as practicable to the CS discharge line containment penetration. The pneumatically-testable check valve is designed so that air failure will not close the valve against normal flow. Upstream of the HPCI injection connection on Loop B is a motor-operated gate valve which isolates CS Loop B upstream of the valve from HPCI injection pressure. This valve, and the Loop A outer isolation valve are also referred to as the CS injection valves. These valves are capable of opening with the maximum differential pressure across the valve expected for any system operating mode. These valves are normally closed. The containment isolation design of the CS system is discussed in detail in Section 6.2.4.

The CS system piping and components are designed and arranged to avoid unacceptable damage from the physical effect of pipe whip, missiles, high temperature, pressure or humidity. All principal active CS equipment is located outside the primary containment.

A check valve (one per CS pump), flow element, and restricting orifice are provided in the CS discharge line from the pump to the injection valve. The check valve is located below the minimum suppression pool water level, and is provided so that the piping downstream of the valve can be continuously filled with water by the condensate transfer or safeguard piping fill systems (Section 6.3.2.2.6). The flow element is provided to measure system flow rate during LOCA and test conditions, and for automatic control of

the minimum low flow bypass valve. The flow rate is indicated in the main control room. The restricting orifice is sized during preoperational testing of the system to limit system flow to acceptable values, as described on the CS system process diagram.

A low flow bypass line with a motor-operated globe valve connects to the CS discharge line upstream of the check valve on the pump discharge line. The line bypasses water to the suppression pool preventing pump damage when other discharge line valves are closed, or when reactor pressure is greater than the CS system discharge pressure following system initiation. The valve automatically closes when flow in the main discharge line is sufficient.

A normally open motor-operated pump suction valve is provided that can be remote-manually closed to isolate the CS system from the suppression pool should a leak develop in the system. This valve is located as close to the suppression pool penetration as practical. Because the CS system conveys water from the suppression pool, a closed-loop is established for the spray water escaping from the break.

The design pressure and temperature of the system components are based on ASME Section III. The design pressures and temperatures at various points in the system can be obtained from the miscellaneous information blocks on the CS process diagram (drawing E41-1020-G-001).

The CS pumps are located in the reactor enclosure below the water level in the suppression pool, assuring positive pump suction. Pump NPSH requirements are met with the containment at atmospheric pressure. Each CS Pump has a local pressure gauge to indicate the suction head. The pump suction strainers are described in Section 6.2.2.2.

The CS system incorporates relief valves to prevent the components and piping from inadvertent overpressure conditions.

For the CS “A” loop:

- One relief valve located on the pump discharge is set at 500 psig at a capacity of 16 gpm – 10% accumulation to 1340 psig at a capacity of 24 gpm – 10% accumulation.
- One relief valve is located on the suction side of each pump in the “A” loop and is set for 100 psig at a capacity of 10 gpm – 10% accumulation.

For the CS “B” loop:

- One relief valve located on the pump discharge is set at 500 psig at a capacity of 16 gpm – 10% accumulation to 1340 psig at a capacity of 24 gpm – 10% accumulation.
- One relief valve is located on the suction side of each pump in the “B” loop and is set for 100 psig at a capacity of 10 gpm – 10% accumulation.

The CS system piping and support structures are designed in accordance with seismic Category I criteria (Section 3.9). The system is assumed to be filled with water for seismic analysis. The CS system has the capability to be lined up to the CST, with the plant shutdown, to provide a clean water source for pipe flushes, cavity flood-up and as an alternate ECCS make-up volume.

Provisions are included in the design which permit the CS system to be tested. These provisions are:

a. All active CS components are testable during normal plant operation.

b. A full flow test line is provided in each loop of CS to route water to and from the suppression pool without entering the RPV.

c. A suction test line supplying water from the CST is provided to allow the capability to test pump discharge into the RPV during normal plant shutdown.

d. Instrumentation is provided to indicate system performance during normal and test operations.

e. All motor-operated and check valves are capable of operation for test purposes. During all modes of manual MOV operation using the handswitch from the main control room, a "dead zone" is present for a portion of the valve travel. The "dead zone" is present when the valve is not fully closed and green light only indication exists. If the valve is stopped in the "dead zone", operator action is required to restart the valve.

6.3.2.2.4 Low Pressure Coolant Injection Subsystem

The LPCI subsystem is an operating mode of the RHR system. The LPCI subsystem is automatically actuated by low water level in the reactor and/or high pressure in the drywell coincident with low reactor pressure. It uses four motor-driven RHR pumps to draw suction from the suppression pool and inject cooling water flow into the reactor core via separate vessel nozzles and core shroud penetrations.

The LPCI subsystem, like the CS system, is designed to provide cooling to the reactor core only when the reactor vessel pressure is low, as is the case for large LOCA break sizes. However, when LPCI operates in conjunction with the ADS, the effective core cooling capability of LPCI is extended to all break sizes because the ADS rapidly reduces the reactor vessel pressure to the LPCI operating range.

Drawing E41-1020-G-002 shows a process diagram and process data for the RHR system, including the LPCI mode. The RHR system P&ID is shown in drawing M-51.

LPCI operation includes using associated valves, control, instrumentation, and pump accessories. LPCI is normally powered from the preferred ac power source, and from the standby ac power source upon a loss of preferred ac power.

If there is a LOCA, the four loops of the LPCI subsystem inject water into the reactor vessel. Separate power sources are provided for the LPCI injection valves, so that the failure of a single electrical division does not prevent the valves in other divisions from opening.

To ensure continuity of core cooling, signals to isolate the primary containment do not operate any RHR system valves which interfere with the LPCI mode of operation.

The process diagram (E11-1020-G-002) and the P&ID (drawing M-51) indicate that a great many flow paths are available other than the LPCI injection line. However, the low water level and/or high drywell pressure coincident with low reactor pressure signals which automatically initiate the LPCI mode are also used to isolate all other modes of operation and revert other system valves to the LPCI lineup. Inlet and outlet valves from the heat exchangers receive no automatic signals, as the system is designed to provide rated flow to the vessel whether they are open or not. Further discussion of valve logic is provided in Section 7.3.1.1.

A check valve in the pump discharge line is used, together with a discharge line fill system (Section 6.3.2.2.6), to prevent water hammer resulting from starting the pump with a partially drained discharge line.

Further discussion of water hammer is provided in Section 1.12.3.

A flow element in the pump discharge line originates automatic signals for control of the pump minimum flow valve. The minimum flow valve permits a small flow to the suppression pool if sufficient system flow is not available.

There is sufficient system resistance to preclude RHR pump damage due to pump run-out in the LPCI and containment spray operating modes. A combination of valve throttling and flow orifices prevents pump run-out during suppression pool cooling and test modes.

Using the suppression pool as the source of water for LPCI establishes a closed-loop for recirculation of water escaping from a pipe break inside containment.

The design pressures and temperatures at various points in the system, during each LPCI subsystem mode of operation can be obtained from the miscellaneous information blocks on the RHR process diagram (drawing E11-1020-G-002).

LPCI pumps and equipment are described in detail in Section 5.4.7, which also describes the other functions served by the same pumps in other modes of RHR system operation. The RHR heat exchangers are not associated with the emergency core cooling function. The heat exchangers are discussed in Section 5.4.7.2.2. Portions of the RHR system required for accident protection, including support structures, are designed in accordance with seismic Category I criteria (Section 3.9). The LPCI pump characteristic curves are shown in Figure 5.4-15.

The LPCI subsystem incorporates a relief valve on each of the pump discharge lines, which protects the components and piping from inadvertent overpressure conditions. These valves are set as shown in Table 5.4-3.

Provisions are included in the LPCI subsystem to permit testing of the LPCI loops. These provisions are:

a. All active LPCI components are designed to be testable during normal plant operation.

b. A discharge test line is provided for the four pumps to route suppression pool water back to the suppression pool without entering the RPV.

c. Instrumentation is provided to indicate system performance during normal and test operations.

d. All MOVs, AOVs, and check valves are capable of manual operation for test purposes. During all modes of manual MOV operation using the handswitch from the main control room, a "dead zone" is present for a portion of the valve travel. The "dead zone" is present when the valve is not fully closed and green light only indication exists. If the valve is stopped in the "dead zone", operator action is required to restart the valve.

e. Shutdown cooling lines taking suction from the recirculation system permit testing of the pump discharge into the RPV after normal plant shutdown.

f. All relief valves are or will be removable for bench testing during plant shutdown.

6.3.2.2.4.1 NPSH for LPCI Mode

The available NPSH is calculated in accordance with Regulatory Guide 1.1. The following data are used for a typical NPSH calculation:

a. Suppression pool is at its minimum post accident depth, el 199'-11.5".

b. Centerline of pump suction is at el 174'-10.5".

c. Suppression pool water is at its maximum temperature for the given operating mode.

d. Pressure is atmospheric above the suppression pool.

e. Maximum suction strainer losses are 5.0 psi at 11,000 gpm.

$$NPSH = h_{ATM} + h_S - h_{VAP} - h_F$$

where:

h_{ATM} = atmospheric head

h_S = static head

h_{VAP} = vapor pressure head

h_F = frictional head

Operating modes and conditions are given on the process flow diagram (drawing E11-1020-G-002). NPSH requirements are given on the pump curve (Figure 5.4-15).

Case 1 LPCI Pump Run-out (Mode A-2)

Maximum suppression pool temperature is 180°F.

h_{ATM} = 34.94'

h_S = 25.08'

h_{VAP} = 17.85'

h_F = 4.61’

Strainer head loss = 11.85’

NPSH available = 34.94 + 25.08 - 17.85 - 4.61 - 11.85
= 25.71

Case 2 RHR Accident Mode B

Maximum suppression pool temperature assumed is 212°F

h_{ATM} = 35.4'

h_S = 25.08'

h_{VAP} = 35.4'

h_F = 3.8’

Strainer head loss at 10,000 gpm = 10.67’

NPSH available = 35.4 + 25.08 - 35.4 - 3.8’ - 10.67’
= 10.61’

6.3.2.2.5 ECCS NPSH Margin and Vortex Formation

NPSH calculations for ECCS pumps, such as that in the previous section, have shown adequate margin to ensure capability of proper pump operation under accident conditions. This capability will be verified during preoperational testing by verifying expected pump operating parameters at specific operating conditions. The absence of air entrainment and vortex formation in the flow approaching the suction strainers in the suppression pool during ECCS pump operation will also be verified during preoperational testing. Pump performance and pump noise will be monitored during these tests to determine if pumps are sensitive to suction flow conditions in the suppression pool.

6.3.2.2.6 Safeguard Piping Fill System

A requirement of the core cooling systems is that cooling water flow to the RPV be initiated rapidly when the system is called upon to perform its function. This quick-start system capability is provided by quick-opening valves, quick-start pumps, and standby ac power sources. The lag between the signal to start the pump and the initiation of flow into the RPV can be minimized by keeping the core cooling pump discharge lines full. Additionally, if these lines are empty when the systems are called for, the large momentum forces associated with accelerating fluid into a dry pipe could cause physical damage to the piping. Therefore, the safeguard piping fill system is designed to maintain the pump discharge lines in a filled condition.

Since the ECCS discharge lines are elevated above the suppression pool, check or stop-check valves are provided near the pumps to prevent backflow from emptying the lines into the suppression pool. Past experience shows that these valves may leak slightly, producing a small backflow that eventually empties the discharge piping. To ensure that the leakage from the discharge lines is replaced and the lines are always kept filled, suppression pool water is provided for each system of the ECCS by the safeguard piping fill system. There are two safeguard fill pump trains, as shown in drawing M-52. Each fill train and its associated ECCS lines are powered from separate Class 1E electrical divisions. Each fill train also provides water to both of the feedwater lines after a LOCA to prevent bypass leakage, as described in Section 6.2.3.2.3.

During normal plant operating conditions, the safeguard piping fill system (SPFS) is on standby and water from the condensate transfer system is used through different connections to keep the ECCS lines full.

The fill system is a safety-related system and is designed to seismic Category I criteria, as described in Section 3.7. Quality group classification is discussed in Section 3.2. A single failure of an active component in one fill system train will prevent that train from performing its intended function, but will not affect the operation of the other train. When the SPFS is in use, the fill pumps operate continuously, with recirculation back to the suppression pool via two core spray pump suction lines. The pumps are powered from the diesel generators during a LOOP. The pumps are operated from the control room and alarms in the control room indicate low fill pump discharge pressure.

As discussed in Section 5.4.7.1.1.5, all of the components comprising the steam condensing mode of the RHR system have either been abandoned in place or physically removed from the plant. Therefore, the mode is no longer functional.

6.3.2.3 Applicable Codes and Classification

The applicable codes and classification of the ECCS are specified in Section 3.2. All piping systems and components (pumps, valves, etc.) for the ECCS comply with applicable codes, addenda, code cases, and errata in effect at the time the equipment is procured. The equipment and piping of these systems are designed to the requirements of seismic Category I. This seismic designation applies

to all structures and equipment essential to the core cooling function. IEEE standards applicable to the controls and power supplies are specified in Section 7.1.

6.3.2.4 Materials Specifications and Compatibility

Materials specifications and compatibility for the ECCS are presented in Section 6.1. Nonmetallic materials, such as lubricants, seals, packings, paints and primers, insulation, as well as metallic materials are selected as a result of an engineering review and evaluation for compatibility with other materials in the system and the surroundings, with concern for chemical, radiolytic, mechanical and nuclear effects. Materials used are reviewed and evaluated with regard to radiolytic and pyrolytic decomposition, and attendant effects on safe operation of the ECCS.

6.3.2.5 System Reliability

A single failure analysis shows that no single failure prevents the starting of the ECCS and/or the delivery of coolant to the reactor vessel. The most severe effects of single failures with respect to loss of equipment occur if a LOCA occurs in an ECCS pipe coincident with a LOOP. The consequences of the most severe single failures are shown in Table 6.3-3.

Certain technical specification LCO periods are justified based on NEDO-24708A which states that for postulated LOCAs, one low pressure ECCS (one LPCI pump or one CS loop) and ADS to depressurize is adequate to reflood the vessel and maintain core cooling sufficient to preclude fuel damage. NEDC-30936P-A, specifically applicable to LGS references NEDO-24708A and reaffirms this conclusion, with the advisory regarding the possible necessity of an alternate cooling path following 2 hours of post large-break LOCA LPCI injection into the core shroud.

6.3.2.6 Protection Provisions

Protection provisions are included in the design of the ECCS. Protection is afforded against missiles, pipe whip, and flooding. Also accounted for in the design are thermal-stresses, loadings from a LOCA, and seismic effects.

The ECCS piping and components located outside the primary containment are protected from internally and externally generated missiles by the reinforced concrete structure of the ECCS pump rooms. The layout and protection of the pump rooms are covered in Section 6.2.3.

The ECCS is protected against the effects of pipe whip which might result from piping failures up to, and including, the design basis event LOCA. This protection is provided by separation, pipe whip restraints, and energy-absorbing materials. These three methods are applied to provide protection against damage to piping and components of the ECCS which otherwise could result in a reduction of ECCS effectiveness to an unacceptable level. See Section 3.6 for criteria on pipe whip.

The component supports, which protect against damage from movement and from seismic events, are discussed in Section 5.4.14. The methods used to provide assurance that thermal-stresses do not cause damage to the ECCS are described in Section 3.9.3.

The ECCS relief valves discharge lines that penetrate the primary containment and that have outlets below the surface of the suppression pool are designed to protect against the possibility of water hammer. RHR system valves in this category are: PSV-1(2)06A and PSV-1(2) 06B (Dwg. M-51). Each PSV discharge line connects to a 10 inch line which has been designed and installed with a continuous slope to the suppression pool to preclude water pockets from forming. These design

features prevent the occurrence of excessive dynamic loads resulting from water hammer during relief valve actuation, and thereby preclude line cracking or rupture. The dynamic loadings have been included in the piping stress analysis. Supports are designed to ensure that they are capable of withstanding the normal plus dynamic loading resulting from the relief valve opening. Section 1.12.3 contains further discussion of water hammer.

6.3.2.7 Provisions for Performance Testing

Periodic system and component testing provisions for the ECCS are described in Section 6.3.2.2 as part of the individual system descriptions.

6.3.2.8 Manual Actions

The ECCS is actuated automatically, and is designed to require no operator action during the first 10 minutes following the accident. Only limited operator action is required before 20 minutes following a LOCA.

During the long-term cooling period (after 10 minutes), the operator takes action, as specified in Section 6.2.2.2, to place the containment cooling system into operation. This action will ensure that suppression pool temperature limits are not exceeded. This is the only manual action that the operator needs to accomplish for the ECCS during the course of the LOCA.

The operator has multiple instrumentation available in the control room to assist him in assessing the post-LOCA conditions. This instrumentation provides reactor vessel pressure and water level, and containment pressure, temperature, and radiation levels, as well as indicating the operation of the ECCS. ECCS flow indication is the primary parameter available to assess proper operation of the system. Other indications, such as position of valves, status of circuit breakers, and essential power bus voltage are also available to assist in determining system operating status.

All controls required to perform the above manual actions are located in the control room. If the RHRSW radiation monitors are inoperable either due to loss of power or component malfunction/failure, the RHRSW pump trip bypass can also be accomplished from the Control Room. The EOPs written in accordance with the BWROG EPGs have been incorporated into LGS training and procedures. The EOPs, with main sections on reactor control and containment control, specify operator actions based on the symptoms that are occurring. Implementation of these training and procedural measures will ensure that LGS operators are adequately equipped to deal with plant emergencies consistent with the design bases assumptions.

The instrumentation and controls for the ECCS are discussed in detail in Section 7.3. Monitoring instrumentation available to the operator is discussed in more detail in Chapter 5 and Section 6.2.

6.3.2.9 Correct Positioning of Manual Valves

Consideration has been given to the possibility that manual valves in the ECCS might be left in the wrong position when an accident occurs. Remote indication in the control room is not required for all critical ECCS manual valves unless they are located in primary containment and therefore are not accessible for survey during normal plant operation. (Critical ECCS manual valves are those that provide system isolation, other than vent, drain, or test connection valves, or are located in the main flow paths.) The positions of those critical valves that are not provided with remote position indication in the control room are administratively controlled and have the following additional protection features:

a. Manual valves in the main ECCS flow paths and manual system isolation valves for ECCS pump suction piping are physically locked in their normal position; access to the keys is controlled administratively.

b. All other manual ECCS isolation valves are redundant to provide double isolation.

The only manual valves in the RHR system that were evaluated are those associated with LPCI mode. The boundary of the LPCI mode piping also includes all piping associated with the suppression pool cooling mode.

Vent, drain, and test connection valves are valves which are not critical to the ECCS function, and administrative controls such as prestartup valve lineup checks suffice to reasonably ensure that such valves will not degrade ECCS performance. In addition, many of these valves are redundant or locked in position, and test connections are capped.

The position of each manually operated valve will be identified in a valve checkoff list. When verification of system operability is required, performance of the valve checkoff list in conjunction with the applicable lineup procedure is one method which may be used. When operability is verified in this manner, an independent verification of valve lineup will be accomplished by redundant performance of each valve checkoff list used. Use of a lineup procedure with its associated valve checkoff lists will not be the exclusive method available for verification of operability, but can be used in any circumstance and supersedes the other methods discussed below. If valve positions are to be changed for surveillance or maintenance purposes, the procedure or other administrative control will have steps requiring return-to-normal valve lineup prior to completion. The shift supervisor will not consider the system operable until all valves identified within the boundaries of the surveillance/maintenance activities have been returned to the position specified in the valve checkoff list. If valve positions in the ECCS are changed for operational purposes, these changes will be made in accordance with procedures having similar administrative controls.

6.3.3 ECCS Performance Evaluation

The performance of the ECCS is determined through application of the 10CFR50, Appendix K evaluation models, and by conformance to the acceptance criteria of 10CFR50.46. The analytical models are documented in GESTAR II (Reference 4.1-1).

The ECCS performance is evaluated for the entire spectrum of break sizes for postulated LOCAs. The accidents, as listed in Chapter 15, for which ECCS operation is required are located in the following sections:

a.	Feedwater piping breaks outside primary containment	15.6.6
b.	Spectrum of BWR steam system piping failures outside of containment	15.6.4
c.	LOCAs inside primary containment	15.6.5

6.3.3.1 ECCS Bases for Technical Specifications

The maximum average planar linear heat generation rates calculated in this performance analysis provide the bases for Technical Specifications designed to ensure conformance with the acceptance criteria of 10CFR50.46, "Acceptance Criteria for Emergency Core Cooling Systems for Light-Water-Cooled Nuclear Power Reactors." Minimum ECCS functional requirements are specified in Sections 6.3.3.4 and 6.3.3.5; and testing requirements are discussed in Section 6.3.4. Limits on minimum suppression pool water level are discussed in Section 6.2.

Certain technical specification LCO periods are justified based on the results of NEDO-24708A, NEDC-30936P-A and 006N4699 which state that one low pressure ECCS (one LPCI pump or one CS loop) and ADS is adequate to reflood the vessel and maintain core cooling sufficient to preclude fuel damage following a suction line break (including DBA). NEDC-30936P-A adds an advisory about the possible necessity of an alternate cooling path following 2 hours of post large-break LOCA LPCI injection into the core shroud. The justification provided by these documents is required to provide a basis for the maximum period specified to restore equipment or systems declared inoperable to operable status.

6.3.3.2 Acceptance Criteria for ECCS Performance

The applicable acceptance criteria, extracted from 10CFR50.46, are listed below. For each criterion, applicable parts of Section 6.3.3 (where conformance is demonstrated) are indicated. A description of the methods used to show compliance is contained in GESTAR II (Reference 4.1-1).

Criterion 1, Peak Cladding Temperature:

"The calculated maximum fuel element cladding temperature shall not exceed 2200°F." Conformance to Criterion 1 is demonstrated in Table 6.3-5.

Criterion 2, Maximum Cladding Oxidation:

"The calculated total oxidation of the cladding shall nowhere exceed 0.17 times the total cladding thickness before oxidation." Conformance to Criterion 2 is shown in Table 6.3-5.

Criterion 3, Maximum Hydrogen Generation:

"The calculated total amount of hydrogen generated from the chemical reaction of the cladding with water or steam shall not exceed 0.01 times the hypothetical amount that would be generated if all the metal in the cladding cylinder surrounding the fuel, excluding the cladding surrounding the plenum volume, were to react." Conformance to Criterion 3 is shown in References 6.3-6, 6.3-9, and 6.3-16.

Criterion 4, Coolable Geometry:

"Calculated changes in core geometry shall be such that the core remains amenable to cooling." As described in section III of Reference 6.3-6, conformance to Criterion 4 is demonstrated by conformance to Criteria 1 and 2.

Criterion 5, Long-Term Cooling:

"After any calculated successful initial operation of the ECCS, the calculated core temperature shall be maintained at an acceptably low value and decay heat shall be removed for the extended period of time required by the long-lived radioactivity remaining in the core." Conformance to Criterion 5 is

demonstrated generically for GE BWRs in section III.A of Reference 6.3-1 and confirmed in References 6.3-6, 6.3-9, and 6.3-16. Briefly summarized, the core remains covered to at least the jet pump suction elevation, and the uncovered region is cooled by spray cooling.

The LGS equipment for long-term cooling following a postulated LOCA includes two complete core spray systems and two RHR systems. System components required for long-term coolant recirculation and decay heat removal are designed to remain operable during and following a LOCA. The redundancy provided is such that maintenance is not expected to be required during the long-term core cooling period (180 days) following a LOCA. However, the RHR and core spray systems are designed with provisions for flushing as shown in drawings M-51 and M-52.

6.3.3.3 Single Failure Considerations

The functional consequences of single failures (including operator errors which might cause any manually controlled electrically operated valve in the ECCS to move to a position which could adversely affect the ECCS) are discussed in Section 6.3.2. All potential single failures are no more severe than one of the single failures identified in Table 6.3-3.

It is therefore only necessary to consider each of these single failures in the ECCS performance analyses. For the original Reference 6.3-1 methodology, failure of one of the diesel generators is, in general, the most severe failure for large break; and a loss of the HPCI system is the most severe failure for small break. For the ECCS analysis performed with SAFER/GESTR-LOCA method (References 6.3-5 and 6.3-7) the limiting failure for all breaks is the division 2 dc (battery) failure.

The worst failure of an ECCS pump seal or valve packing during the long-term cooling mode would produce a leak of less than 50 gpm. The ECCS equipment compartments, located on the lowest elevation of the reactor enclosure, are watertight and equipped with flood alarms. Any passive failure including pump seal or valve packing failure occurring in an ECCS long-term cooling loop can be isolated by turning off the pump and shutting the suction isolation valve. If the packing of the suction isolation valve should fail, the leak could still be isolated because all of the suction isolation valves are gate valves.

6.3.3.4 System Performance During the Accident

In general, the system response to an accident can be described as the following:

a. Receiving an initiation signal

b. A small lag time (to open all valves and have the pumps up to rated speed)

c. Finally, the ECCS flow entering the vessel

Key ECCS actuation setpoints and time delays for all the ECCS are provided in Table 6.3-1 for the current ECCS-LOCA analysis and in Table 6.3-1A for the original ECCS-LOCA analysis. The minimization of the delay from the receipt of signal until the ECCS pumps have reached rated speed is limited by the physical constraints on accelerating the diesel generators and pumps. The delay time due to valve motion in the case of the high pressure system provides a suitably conservative allowance for valves available for this application. In the case of the low pressure system, the time delay for valve motion is such that the pumps are at rated speed prior to the time the vessel pressure reaches the pump shutoff pressure.

The operational sequence of ECCS for the DBA is shown in Table 6.3-2 for the current ECCS-LOCA analysis and in Table 6.3-2A for the original ECCS-LOCA analysis.

Operator action is not required, except as a monitoring function, during the short-term cooling period following the LOCA. The HPCI system is designed to inject water into the reactor vessel for small breaks that do not depressurize the vessel.

If a small break occurs and the HPCI system does not function, the ADS will cause vessel blowdown, and the low pressure systems will then act to restore vessel water level. In either case, no operator action is required to restore reactor water level. To establish decay heat removal, the operator will realign the RHR system to the suppression pool cooling mode. The necessary operator actions are described in Section 6.2.2.2.

If a small break occurs and the HPCI system functions properly, reactor vessel water level will be maintained, and no automatic depressurization will occur. The operator must then manually depressurize the vessel, using a minimum number of ADS valves, and establish long-term cooling as above.

All control switches necessary for ADS operation and realignment of the RHR system are located in the control room. The instrumentation available to monitor RHR pressure and flow, reactor vessel pressure, level and temperature, suppression pool temperature, pump status and relevant valve positions are discussed in Chapter 7.

Direction for accomplishing the above actions are available to the operator in the EOPs and appropriate system operating procedures.

The preceding discussion of operator actions in response to a small break LOCA is applicable even when single active failures and LOOP are assumed.

The available NPSH for the pumps in the HPCI system has been calculated based on minimum postaccident suppression pool level, maximum suppression pool temperature, 50% plugged strainers, and no credit for wetwell pressurization. The available NPSH for the RHR and Core Spray pumps has been calculated based on the same assumptions used for the HPCI except for the criteria for the determination of the dirty strainer pressure drop. The dirty strainer pressure drop for these strainers is based on the entire amount of fibrous debris generated in the drywell during a design basis LOCA (within the zone of influence of the worst case pipe break location) transported to the suppression pool and all debris is available to clog the strainer. The results of these calculations show that available NPSH is greater than the required NPSH by a margin of at least 10 feet for RHR, at least 7 feet for Core Spray, and at least 4 feet for HPCI.

6.3.3.5 Use of Dual-Function Components for ECCS

With the exception of the LPCI and ADS systems, the systems of the ECCS are designed to accomplish only one function: to cool the reactor core following a loss of reactor coolant. To this extent, components or portions of these systems (except for pressure relief) are not required for the operation of other systems which have emergency core cooling functions, or vice-versa. Because either the ADS initiating signal or the overpressure signal opens the SRV, no conflict exists.

The LPCI subsystem, however, uses the RHR pumps, and some of the RHR valves and piping. When the reactor water level is low, the LPCI subsystem has priority, through the valve control logic,

over the other RHR modes of operation. Immediately following a LOCA, the RHR system is aligned to the LPCI mode. Further discussion of valve logic is provided in Section 7.3.1.1.

6.3.3.6 Limits on ECCS System Parameters

Refer to GESTAR II (Reference 4.1-1).

6.3.3.7 ECCS Analyses for LOCA

6.3.3.7.1 LOCA Analysis Procedures and Input Variables

Refer to GESTAR II (Reference 4.1-1).

The significant input variables used by the LOCA codes are listed in Table 6.3-1 and Figure 6.3-11, for the current ECCS-LOCA. The significant input variables used for the original ECCS-LOCA analysis are shown in Table 6.3-1A and Figure 6.3-11A.

6.3.3.7.2 Accident Description

The original methodology for analysis of the LOCA is reflected in Reference 6.3-1. Reference 6.3-5 provides a detailed description of the current methodology for analysis of the LOCA. The results of the Reference 6.3-5 and 6.3-7 methods are detailed in References 6.3-6, 6.3-9, and 6.3-16.

6.3.3.7.3 Break Spectrum Calculations

A complete spectrum of postulated break sizes and locations is considered in the evaluation of ECCS performance.

A summary of the results of the break spectrum calculations is shown in tabular form in Table 6.3-5. Conformance to the acceptance criteria (PCT $\leq$2200°F, local oxidation <17%, and core-wide metal-water reaction <1%) is demonstrated in the above paragraphs. Details of calculations for specific breaks are included in subsequent paragraphs.

6.3.3.7.4 Large Recirculation Line Break Calculations

The characteristics that determine which is the most limiting large break are:

a. the calculated hot node reflooding time,

b. the calculated hot node uncovery time, and

c. the time of calculated boiling transition.

The time of calculated boiling transition increases with decreasing break size, since jet pump suction uncovery (which leads to boiling transition) is determined primarily by the break size for a particular plant. The calculated hot node uncovery time also generally increases with decreasing break size, as it is primarily determined by the inventory loss during the blowdown. The hot node reflooding time is determined by a number of interacting phenomena such as depressurization rate, counter current flow limiting, and a combination of available ECCS.

The period between hot node uncovery and reflooding is the period when the hot node has the lowest heat transfer. Hence, the break that results in the longest period during which the hot node remains uncovered results in the highest calculated PCT. If two breaks have similar times during which the hot node remains uncovered, then the larger of the two breaks will be limiting as it would have an earlier boiling transition time (i.e., the larger break would have a more severe LAMB/SCAT blowdown heat transfer analysis).

The DBA was determined to be the break that results in the highest calculated PCT in the 1.0 ft^2 to DBA region.

The component areas that comprise the suction and discharge break areas in the LOCA analysis are as follows:

a. Suction Break

Recirculation Suction Line Nozzle/Safe End	3.541 ft^2	
Jet Pump Discharge Nozzles - One Bank	0.548 ft^2	
	Total	4.089 ft^2

b. Discharge Break

Recirculation Pump Minimum Area	1.736 ft^2	
Jet Pump Discharge Nozzles - One Bank	0.548 ft^2	
	Total	2.284 ft^2

6.3.3.7.5 Steam Flow Induced Process Measurement Error

The impact on the ECCS-LOCA analysis of a Steam Flow Induced Error (SFIE) in the Level 3 scram has been evaluated. SFIE is a process measurement error in Reactor vessel level measurement induced by steam flowing in the annulus region between the dryer and vessel wall across the mouth of the instrument reference leg tap during a loss of coolant inventory event. For Limerick, SFIE can result in a level measurement error up to 4.67 inches at extended (20%) Power Uprate (3952 MWt). This error adversely impacts the timing of the Level 3 (L3) scram Analytical Limit (AL) for events resulting in a decrease in coolant inventory. Reference 6.3-13 provides an evaluation of this process error for ECCS-LOCA analysis.

For Limerick, the limiting LOCA analysis (and Licensing Basis PCT) is limited by large breaks. Therefore, the Limiting PCT is not affected by the reduction in the L3 analytical limit.

6.3.3.8 LOCA Analysis Conclusions

Having shown compliance with the applicable acceptance criteria of Section 6.3.3.2, it is concluded that the ECCS will perform its function in an acceptable manner and meet all of the 10CFR50.46 acceptance criteria.

6.3.4 TESTS AND INSPECTIONS

6.3.4.1 ECCS Performance Tests

All systems of the ECCS are tested for their operational ECCS function during the preoperational and/or startup test program. Each component is tested for power source, range, direction of rotation, setpoint, limit switch setting, torque switch setting, etc., as applicable. Each pump is tested for flow capacity for a comparison with vendor data (this test is also used to verify flow-measuring capability). The flow tests involve the same suction and discharge source; i.e., the suppression pool or CST.

All logic elements are tested individually and as a system to verify complete system response to emergency signals, including the ability of valves to revert to the ECCS alignment from other positions.

Finally, the entire system is tested for response time and flow capacity, taking suction from its normal source and delivering flow into the reactor vessel. This last series of tests is performed with power supplied from both offsite power and onsite emergency power.

See Chapter 14 for a thorough discussion of preoperational testing for these systems.

6.3.4.2 Reliability Tests and Inspections

The average reliability of a standby (nonoperating) safety system is a function of the duration of the interval between periodic functional tests. The factors considered in determining the periodic test interval of the ECCS are: the desired system availability (average reliability), the number of redundant functional system success paths, the failure rates of the individual components in the system, and the schedule of periodic tests (simultaneous versus uniformly staggered versus randomly staggered). For the ECCS, the above factors are used to determine safe test intervals, utilizing the methods described in Reference 6.3-2.

All of the active components of HPCI, CS, and LPCI are designed so that they may be tested during normal plant operation. Full flow test capability of each ECCS injection system is provided by test lines back to their suction sources. The full flow test is used to verify the capacity of each ECCS pump loop while the plant remains undisturbed in the power generation mode. In addition, each individual valve may be tested during normal plant operation. Input jacks are provided, and by racking out the injection valve breaker, each ECCS loop can be tested for response time.

The ADS logic is designed so that it may be tested during normal plant operation. The SRVs and associated solenoid valves are all tested at least once during the plant startup following each refueling outage. Those SRVs and their associated solenoid valves, which are overhauled during a plant outage, are tested during the startup following that outage.

Testing of the initiating instrumentation and controls portion of the ECCS is discussed in Section 7.3. The safeguard power system, which supplies electrical power to the ECCS if offsite power is unavailable, is tested as described in Section 8.3. Testing is specified in the Technical Specifications. Visual inspections of all the ECCS components located outside the primary containment can be made at any time during power operation. Components inside the primary containment can be visually inspected only during periods of access to the primary containment. When the reactor vessel is open, the spargers and other reactor vessel internals can be inspected.

6.3.4.2.1 HPCI Testing

The HPCI system can be tested at full flow with CST water at any time during plant operation, except when the reactor vessel water level is low, when the condensate level in the CST is below the reserve level, or when the HPCI F041 valve from the suppression pool to the pump are open. If an initiation signal occurs while the HPCI system is being tested, the system aligns automatically to the operating mode.

A design flow functional test of the HPCI system over the operating pressure and flow range is performed by pumping water from the CST and back through the full flow test return line to the CST. The HPCI system turbine-pump is driven at its rated output by steam from the reactor. The HPCI F041 valve, suction valve from the suppression pool, and the discharge valves to the core spray line remain closed. The HPCI F042 valve, suppression pool to pump suction PCIV remains open. These valves are tested separately to ensure their operability.

The HPCI test conditions are tabulated on the HPCI process flow diagram (drawing E41-1020-G-002).

6.3.4.2.2 ADS Testing

The ADS valves are tested once per fuel cycle. This testing includes simulated automatic actuation of the system throughout its emergency operating sequence, but excludes actual valve actuation.

During plant operation the ADS system can be checked as discussed in Section 7.3.

6.3.4.2.3 CS Testing

The CS pumps and valves can be tested during reactor operation. The injection valve and injection line check valve for the A-loop and the outboard and inboard injection line check valves for the B-loop are normally tested with the reactor shutdown. The injection lines to the reactor can be tested when the reactor is shutdown and the CS suction is lined up to the CST. With the injection valve closed and the return line open to the suppression pool, full flow pump capability is demonstrated. The system test conditions during reactor shutdown are shown on the CS system process diagram (drawing E41-1020-G-001. The portion of the CS system outside the drywell may be inspected for leaks during tests.

If an initiation signal occurs during the test, the CS System aligns to the operating mode. The test return line valves close automatically to ensure that CS pump discharge is correctly routed to the RPV.

6.3.4.2.4 LPCI Testing

Each LPCI loop can be tested during reactor operation. The test conditions are tabulated in drawing E11-1020-G-002. During plant operation, this test does not inject cold water into the reactor, because the injection line check valve is held closed by vessel pressure, which is higher than the pump pressure. The injection line portion can be tested with reactor water when the reactor is shut down, and when a closed system loop is created. This prevents unnecessary thermal-stresses.

To test a LPCI pump at rated flow, the test line valve to the suppression pool is opened, the pump suction valve from the suppression pool is opened (this valve is normally open), and the pumps are started using the remote manual switches in the control room. Correct operation is determined by observing instruments locally and in the control room.

If an initiation signal occurs during the test, the LPCI subsystem aligns to the operating mode. The valves in the test bypass lines close automatically to ensure that the LPCI pump discharge is correctly routed to the RPV.

6.3.5 Instrumentation Requirements

Design details, including redundancy and logic of the ECCS instrumentation, are discussed in Section 7.3.

All instrumentation required for automatic and manual initiation of HPCI, CS, LPCI, and ADS is discussed in Section 7.3.2, and is designed to meet the requirements of IEEE 279 and other applicable standards.

Long-term ADS gas supply instrumentation is addressed in Section 7.6.

The HPCI system is automatically initiated on low reactor water level and/or high drywell pressure. The CS and LPCI loops are automatically initiated on low reactor water level, and/or high drywell pressure (in combination with low reactor pressure). The ADS is automatically actuated by sensed variables for reactor vessel low water level and drywell high pressure plus the indication that at least one CS loop or LPCI pump is operating. HPCI, CS, and LPCI automatically realign from system flow test modes to the emergency core cooling mode of operation following receipt of an automatic initiation signal. The CS and LPCI injection into the RPV begins when reactor pressure decreases to loop discharge shutoff pressure.

HPCI injection begins as soon as the HPCI turbine-pump is up to speed and the injection valve is open, since the HPCI is capable of injecting water at full flow into the RPV at pressures up to the reactor pressure specified in Mode A of drawing E41-1020-G-002.

Table 6.3-2

OPERATIONAL SEQUENCE OF ECCS FOR DESIGN BASIS LOCA[1]

TIME (sec)	EVENTS
0	Design basis LOCA is assumed to start; normal auxiliary power is assumed to be lost.
<1	Drywell high pressure is reached. Scram initiated; HPCI is signaled to start, and containment isolates, except for the MSIVs.
Approx 1	Reactor Low Water Level (Level 3) is reached [2]. The second scram initiation signal is received.
Approx 4	Reactor low-low water level (level 2) is reached. HPCI receives the second signal to start.
Approx 5	The reactor low-low-low water level (level 1) is reached; MSIVs are signaled to close; the signal to start LPCI and CS is given.
Approx 25	Reactor low pressure is reached. CS and LPCI receive the second signal to start. CS injection valve receives pressure permissive signal to open.
≤54	The CS pumps are at rated flow and the CS injection valves are open, which completes the CS system startup.
≤70	The LPCI pumps are at rated flow and the LPCI injection valves are open, which completes the LPCI system startup.
Approx 130	The core is effectively reflooded, assuming the worst single failure; heatup is terminated.
>10 min	The operator shifts to containment cooling.

[1] For the purpose of all but the next to the last entry on this table, all ECCS equipment is assumed to function as designed. Performance analysis calculations consider the effects of single equipment failures (Sections 6.3.2.5 and 6.3.3.3).

[2] The Level 3 Analytical value in this table may be slightly different for various events due to a steam flow induced process measurement error. However, the impact of the change is not significant and the event descriptions or conclusions need not be modified (Section 6.3.3.7.5).

Table 6.3-2A

OPERATIONAL SEQUENCE OF ECCS FOR DESIGN BASIS LOCA [1]
BASED ON THE ORIGINAL REFERENCE 6.3-1 METHODOLOGY

TIME (sec)	EVENTS
0	Design basis LOCA is assumed to start; normal auxiliary power is assumed to be lost.
<1	Drywell high pressure [2] and reactor low water level (level 3) are reached [3]. All diesel generators are signaled to start; scram initiated; HPCI is signaled to start, and containment isolates, except for the MSIVs.
Approx 2	Reactor low-low water level (level 2) is reached [3]. HPCI receives the second signal to start.
Approx 5	The reactor low-low-low water level (level 1) is reached; MSIVs are signaled to close; the signal to start LPCI and CS is given.
Approx 22	Reactor low pressure is reached. CS and LPCI receive the second signal to start. CS injection valve receives pressure permissive signal to open.
Approx 26	LPCI injection valve receives ΔP permissive signal to open.
Approx 32	The HPCI injection valve opens and the pump is at design flow, which completes the HPCI startup.
≤34	The CS pumps are at rated flow and the CS injection valves are open, which completes the CS system startup.
≤50	The LPCI pumps are at rated flow and the LPCI injection valves are open, which completes the LPCI system startup.
Approx 165	The core is effectively reflooded, assuming the worst single failure; heatup is terminated.
>10 min	The operator shifts to containment cooling.

(1) For the purpose of all but the next to the last entry on this table, all ECCS equipment is assumed to function as designed. Performance analysis calculations consider the effects of single equipment failures (Sections 6.3.2.5 and 6.3.3.3).

(2) No credit taken in the DBA LOCA analysis for ECCS system initiation on the high drywell pressure signal.

(3) The Level 3 Analytical value in this table may be slightly different for various events due to a steam flow induced process measurement error. However, the impact of the change is not significant and the event descriptions or conclusions need not be modified (Section 6.3.3.7.5).

Table 6.3-3

SINGLE FAILURE EVALUATION[1][4]

No potential single failure has been identified as more severe than one of the following single failures:

ASSUMED FAILURE	SUCTION BREAK[2] SYSTEMS REMAINING
Division 2 dc source	1 CS loop + 3 LPCI + All ADS
Diesel generator[3]	1 CS loop + HPCI + 3 LPCI + All ADS
LPCI injection valve	2 CS loop + HPCI + 3 LPCI + All ADS
HPCI	2 CS loop + 4 LPCI + All ADS
One ADS valve	2 CS loop + 4 LPCI + HPCI + All ADS minus one

(1) Other postulated failures are not specifically considered because they all result in at least as much ECCS capacity as one of the above designated failures.

(2) Systems remaining, as identified in this table, are applicable to all non-ECCS line breaks. For a LOCA from an ECCS line break, the systems remaining are those listed, less the ECCS system in which the break is assumed.

(3) If the single failure occurs in a diesel generator that supplies power to an ESW pump, the diesel generator in the other unit is needed to support the other ESW pump that supplies that loop.

(4) This table demonstrates the performance of safety systems under the single failure criteria. For the minimum system requirements to successfully terminate a transient or LOCA initiating event (with scram), assuming multiple failures with realistic conditions, refer to NEDO-24708.

6.4 HABITABILITY SYSTEMS

The control room habitability systems are designed to provide safety and comfort for operating personnel during normal operations and during postulated accident conditions. These habitability systems for the control room include radiation shielding, charcoal filter systems, HVAC, storage for food and water, kitchen and sanitary facilities, and fire protection. The habitability systems are designed to meet GDC 19 of 10CFR50, Appendix A.

6.4.1 DESIGN BASES

The design bases of the habitability systems, upon which the functional design is established, are summarized as follows:

a. The control room environmental envelope is designed for continuous occupation on a year-round basis. The occupancy of the operating personnel is ensured for a minimum of 30 days after a DBA.

b. The habitability systems are designed to support 5 people during normal and abnormal station operating conditions. A 5 day emergency supply of food and water is provided within the control room habitability envelope. Supplies of potassium iodide adequate to protect 30 people are maintained onsite.

c. Kitchen and sanitary facilities and medical supplies for minor injuries are provided within the boundary of the control room habitability systems for the use of control room personnel during normal and accident conditions.

d. The radiological effects on the control room personnel that could exist as a consequence of the postulated DBAs described in Chapter 15 do not exceed the guidelines set by GDC 19 of 10CFR50, Appendix A, or the dose limits of 10CFR50.67.

e. The design includes provisions to preclude the effects of a chlorine release accident onsite or offsite from affecting the habitability of the control room.

f. The design includes provisions to preclude the effects of an offsite toxic chemical release from affecting the habitability of the control room.

g. Respiratory and skin protection and emergency breathing apparatus are provided within the control room envelope for control room operators.

h. The control room ventilation system is capable of automatic transfer from its normal operational mode to its accident or isolation mode upon detection of conditions which could result in the introduction of airborne radioactivity into the control room.

i. The control room ventilation system is designed to remain functional during and after an OBE and an SSE.

j. The habitability systems are designed to remain functional following a failure of any one of the HVAC system components.

k. Radiation monitors and offsite toxic chemical detectors continuously monitor the outside air at the control room envelope outside air intake. The detection of high radiation or offsite toxic chemical release is alarmed in the control room, and related protection functions are simultaneously initiated.

l. The control room HVAC system design bases are discussed in Section 9.4.1.

m. The seismic category, quality group classification, and corresponding codes and standards that apply to the design of the habitability systems are discussed in Section 3.2.

n. The guidelines of Regulatory Guide 1.52, Regulatory Guide 1.78, and Regulatory Guide 1.95 apply to the design of habitability systems. Conformance for the analyses associated with Regulatory Guide 1.78 is discussed in Section 2.2.3. Conformance to design aspects of the guides is as follows:

    1. There is partial conformance with Regulatory Guide 1.52 as discussed in Section 6.5.1

    2. The habitability system design for offsite toxic chemical protection conforms with Regulatory Guide 1.78. Differences from the analytic models are discussed in Section 2.2.3.

    3. Regulatory Guide 1.95 (Rev 1), which discusses protection from accidental chlorine release, does not apply to LGS per its implementation section. Nevertheless, the LGS design is in conformance.

The design of the habitability systems with respect to the following areas is discussed in separate sections as indicated:

a.	Protection from wind and tornado effects	Section 3.3
b.	Flood Design	Section 3.4
c.	Missile Protection	Section 3.5
d.	Protection against dynamic effects associated with postulated rupture of piping	Section 3.6
e.	Environmental design	Section 3.11

6.4.2 SYSTEM DESIGN

6.4.2.1 Definition of Control Room Envelope

The control room envelope maintained under habitable conditions following an accident is shown on Figure 6.4-1. The envelope consists of the control room, peripheral offices at the west and east ends, toilet room, and utility room; all on el 269'-0". Steam and air tight doors are provided for ingress and egress.

The volume of the emergency zone served by the HVAC system in the accident mode or the isolation mode is approximately 126,000 cubic feet.

6.4.2.2 Ventilation System Design

The control room HVAC system is discussed in detail in Section 9.4.1. The system is shown schematically in drawing M-78, and major system components are described in Table 9.4-1.

Figure 6.4-2 shows the plant layout, including the location of plant facilities, with respect to the control room outside air intake. The control room arrangement is shown in Figure 6.4-1. The seismic category and quality group classification of components, instrumentation, and ducts are listed in Section 3.2 and shown in drawing M-78.

The control room is common for Units 1 and 2. The principal equipment in the system includes:

a. Two 100% capacity air handling units which include cooling coils, and fans for use during normal plant operation and following a DBA, a chlorine accident, or an offsite toxic chemical accident. Electric humidifiers, electric heaters, and roll filters are provided for use during normal plant operation, during a chlorine accident, or during an offsite chemical accident.

b. Two 100% capacity return air fans for use during normal plant operation and following a DBA, chlorine or offsite toxic chemical accident.

c. Two banks of high efficiency air filtration units consisting of a prefilter, HEPA filter, an electric heating coil, a carbon adsorber, and a second HEPA filter for treatment of recirculated air or outside supply air following a DBA, chlorine, or offsite toxic chemical accident. Two filtration unit fans are provided; one for each filtration unit.

d. A single outside air intake for use during normal plant operation and following a DBA.

6.4.2.3 Leak-Tightness

Control room envelope construction joints and penetrations for cable, pipe, HVAC duct, HVAC equipment, dampers, and steam-tight doors have been designed specifically for leak-tightness. A list of potential leak paths to the control room is provided in Table 6.4-2, along with the type of material, joint, or penetration.

For the onsite chlorine storage discussed in Section 2.2.3, a control room design with a maximum allowable control room isolated air exchange rate of 0.25 air changes per hour is provided. The analysis discussed in Section 2.2.3.1.3 demonstrates that this air exchange rate allows the operators more than 2 minutes to put on their breathing masks.

6.4.2.4 Interaction with Other Zones and Pressure-Containing Equipment

a. Design of the control room envelope boundaries, duct-work and isolation valves minimizes interchange of exterior radioactive gases or toxic vapors into the control room envelope.

The control room is surrounded by the turbine enclosure, the reactor enclosure, and the cable spreading room and auxiliary equipment room. Each of these areas is separated from the control room by shield walls, floors, and leak-tight doors and is served by the independent HVAC systems described in Section 9.4.

The HVAC equipment room at el 304' is a part of the control structure. The negative pressure control room duct-work system in the HVAC equipment room is of welded construction and tested for leak-tightness. Dampers on the negative pressure duct-work are of gas-tight construction.

b. Steam lines and central carbon dioxide fire prevention system tanks are not located within the control room envelope.

6.4.2.5 Shielding Design

Control room shielding is discussed in Section 12.3. The shielding is designed for continuous occupancy during a DBA and meets GDC 19 and 10CFR50.67.

6.4.3 System Operational Procedures

6.4.3.1 Normal Operation

During normal operation, one of the two air handling units and one of the two return fans recirculate the control room air. Approximately 2100 cfm of fresh outside air is taken in at the control room ventilation system intake located on the north wall of the control enclosure. By balancing the exhaust and makeup flow rates, the control room is normally maintained at a slightly positive pressure with respect to the surrounding areas. The outside makeup air and recirculated air pass through a roll filter at the inlet of the air handling unit fans. The supply air is cooled or heated by the air handling units as required to maintain the desired temperature. Upon loss of supply or return air flow, the respective standby fans automatically start; the associated fan dampers reposition; and an alarm annunciates in the main control room. The start of standby equipment may also be manually initiated.

The control room is fully air conditioned and will be maintained between 65 and 78°F and between 30 and 90% relative humidity. Control room temperature is sensed by a temperature transmitter which transmits a signal to a temperature indicating controller. The temperature controller maintains the proper temperature by controlling an electric heating coil or cooling coil valve as necessary. Control room minimum humidity is maintained by a return air duct moisture sensor and transmitter, which transmits a signal to the humidity controller which in turn controls an electric humidifier. Excessive humidity is precluded by the cooling coil which condenses excessive moisture.

6.4.3.2 Postaccident Operation

The control room HVAC system is designed to ensure habitability after any of the design basis radiological accidents or a chemical release accident. To provide adequate operator protection in the unlikely event of one of these accidents, three distinct accident modes of operation are included. These modes are referred to as the chlorine isolation mode, the toxic chemical isolation mode, and the radiation isolation mode.

The mode of system operation after each of the individual accidents of concern with the control room HVAC system initially in the normal mode of operation is as follows:

Chlorine accident - Chlorine isolation mode

High radiation accident - Radiation isolation mode

Offsite toxic chemical accident - Toxic chemical isolation mode

In the event of a radiation accident, the control room will be automatically isolated. In the event of an offsite toxic chemical accident, the control room will be remote manually isolated when the predetermined toxic chemical concentrations are detected in the control room air intake plenum and alarmed in the control room.

Note: the possibility exists for a chlorine accident to occur while the control room HVAC system is operating in the radiation isolation mode for testing purposes or as required by the Action statement of an associated Technical Specifications Limiting Condition of Operation, and likewise, a high radiation accident could occur while the control room HVAC system is operating in the chlorine isolation mode for the same purposes. The mode of system operation with the control room HVAC system in these initial system configurations is described in Sections 6.4.3.2.1 and 6.4.3.2.2 below.

The high radiation accident is discussed in detail in Chapter 15 and identification of design basis toxic chemicals including chlorine is discussed in Section 2.2.3.

6.4.3.2.1 Chlorine Isolation Mode

Upon detection or notification of an off-site chlorine spill, operators will initiate a manual chlorine isolation of the control room HVAC system. The following events occur (drawing M-78) to isolate the control room from the outside air when the control room HVAC system is initially in the normal mode of operation.

a. Redundant outside air intake isolation valves close in 3-5 seconds to prevent outside air from entering the control room supply air handling units.

b. For a manual chlorine isolation only, outside air intake isolation valves to the charcoal filter inlets close, if open, in 8-12 seconds to provide isolation to the charcoal filter trains.

c. Control room exhaust isolation valves and control room toilet exhaust isolation valves close in 3-5 seconds.

d. The emergency fresh air charcoal filter recirculation inlet isolation valve opens in 8-12 seconds.

e. The emergency fresh air fan for charcoal filter train A or B starts to establish filtered recirculation of the control room environment.

f. Manual chlorine isolation concentration is indicated and alarmed in the control room.

In the chlorine isolation mode approximately 3000 cfm of the control room atmosphere is recirculated through the charcoal filter train for cleanup.

The normal air handling units continue to recirculate approximately 26,200 cfm of the control room atmosphere, including the charcoal filter train discharge.

Once initiated, the system remains in the isolation mode until the trip switch is manually reset.

6.4.3.2.2 Radiation Isolation Mode

The radiation isolation mode of operation is intended to protect the control room operators if there are design basis radiological accidents.

Upon receipt of an initiating signal, the following automatic functions occur (drawing M-78) when the control room HVAC system is initially in the normal mode of operation:

a. The control room outside air exhaust is isolated.

b. The control room outside air intake, charcoal filter trains, and normal air handling units are aligned, so that all outside air must pass through the charcoal filter trains before it enters the control room.

c. The control room is maintained at a positive pressure (approximately 1/8 inch wg) with respect to the surrounding areas.

d. High radiation is alarmed in the control room.

The control room is now positively pressurized with respect to the surrounding areas. The quantity of outside air taken in at the normal ventilation intake on the north wall of the control structure is mixed with recirculated control room air, and a total of 3000 cfm is passed through the charcoal adsorber filter train for removal of airborne radioactivity.

If the control room HVAC system is initially in the chlorine isolation mode as described in Section 6.4.3.2.1 for any purpose, the system will remain in this mode of operation upon receipt of a high radiation signal, i.e., automatic transfer from the chlorine isolation mode to the radiation isolation mode will not occur. This design recognizes that the infiltration of chlorine into the main control room is a more immediate threat to the operations personnel.

If the control room HVAC system is initially in the chlorine isolation mode as result of maintenance or surveillance testing, the HVAC system can be manually switched to the radiation isolation mode once the operators determine that no chlorine is present.

6.4.3.2.3 Toxic Chemical Isolation Mode

The toxic chemical isolation mode is identical to the chlorine isolation mode as described in Section 6.4.3.2.1, with the exception that toxic chemical detection does not automatically initiate control room isolation.

Upon receipt of a high toxic chemical concentration alarm indicated by the toxic chemical detectors located in the control room outside air intake plenum, the operator manually initiates control room isolation utilizing controls available in the control room in accordance with plant procedures.

High toxic chemical concentration is indicated and alarmed in the control room and the system remains in the isolation mode until the high toxic chemical concentration condition is no longer present and the system is manually reset.

6.4.4 Design Evaluations

The control room habitability system is designed with redundancy and separation of active components to provide reliable operation under normal conditions and to ensure operation under accident conditions. A failure analysis of the system components is shown in Table 6.4-1.

6.4.4.1 Radiological Protection

A detailed discussion of the dose calculation model for control room operators following the postulated DBA is discussed in Section 15.10. The analysis considers both conditions in which the control room HVAC system is initially in the normal mode of operation and the chlorine isolation mode prior to the high radiation accident. The resulting calculated doses for control room ingress, egress, and occupancy (on a rotating shift basis) are less than 5 rem total effective dose equivalent (TEDE). These doses are within the dose limits specified in GDC 19 and 10CFR50.67. The analysis also assumes the installation of a MCR door seal, which ensures zero direct inleakage from the Turbine Enclosure through the MCR doors. Following the DBA LOCA, after the MSIV Leakage Alternate Drain Pathway has been aligned and when a Turbine Enclosure Area Radiation Monitor alarms, a temporary MCR door seal will be erected, to prevent the direct inleakage to the MCR. This action is necessary to prevent a relatively high calculated concentration of Iodine from entering the MCR directly from the Turbine Enclosure.

Control room shielding design, based on the most limiting radiological accident (design basis LOCA) is discussed in Section 12.3. The evaluations in Chapter 12 demonstrate that radiation exposures to control room personnel originate from containment shine, external cloud shine, and containment airborne radioactivity sources. Total exposures resulting from the worst radiological accident are below the dose limits specified by GDC 19 and 10CFR50.67; the portion contributed by containment shine and external cloud shine is reduced to a small fraction of the total by means of the walls which surround the control room.

Two radiation detector units are located in the control room fresh air inlet duct, and another two radiation detector units are located in the auxiliary equipment room HVAC system fresh air inlet duct. All four radiation detectors are situated in duct-work that is directly below the floor penetration level at el 332'. A description of the radiation detector units is provided in Section 7.1.2.1.11.

6.4.4.2 Toxic Gas Protection

The control room HVAC system is designed to satisfy the guidelines of Regulatory Guide 1.78 for toxic chemical protection, and Regulatory Guide 1.95 for chlorine protection (except as discussed in Section 6.4.1). Detection systems are provided for both offsite toxic chemical accidental release and onsite chlorine container accidental release.

Detector design criteria and descriptions and respiratory protection are discussed below.

6.4.4.2.1 Chlorine

The chlorine release accident analysis is described in Section 2.2.3. The control room and isolation system are designed to meet the requirements of a control room that has a maximum allowable isolated air exchange rate of 0.25 air changes per hour.

The analysis considers both conditions in which the control room HVAC system is initially in the normal mode of operation and the radiation isolation mode prior to the chlorine accident.

6.4.4.2.2 Offsite Toxic Chemical System

Three toxic chemical detection systems are provided to detect the offsite toxic chemicals identified in Section 2.2.3, to provide annunciation in the control room, and identification of the chemical and concentration to a control room console.

Each toxic chemical detection system consists of a microcomputer built around a microprocessor and integrated with an infrared spectrometer and a multipoint sampling manifold. Each system is designed to measure and record the concentration of toxic chemicals at one sample location. Each system, located in the control enclosure, monitors the control room outside air intake plenum.

The microcomputer controls the spectrometer, signal averages the infrared transmission measurements at each programmed wavelength, calculates absorbance, and uses a stored coefficient matrix to calculate the concentration of components in the air sample.

During factory calibration, each system is programmed to monitor the toxic gases listed in Table 2.2-6. Calibration coefficients for each gas are stored in the system hard drive.

The sampling program begins with a nitrogen zero gas cycle. Ambient air is collected from the air intake plenum and pumped into the sample cell of the analyzer. The analyzer passes an infrared beam through the sample and measures the amount of light absorbed at each of the analytical wavelengths of a programmed sequence. The computer uses the stored calibration coefficients to calculate the concentration of sample components.

If the concentration of any monitored gas should exceed the selected limits, alarms will be automatically triggered at the analyzer. The toxic chemical high concentration alarm in the control room will be energized when two-out-of-three analyzers alarm. In addition to the concentration alarms, the system will indicate any malfunction related to electronics, optical system, loss of flow by local indication, or a single toxic chemical high concentration alarm.

Three “Inop/Operate” selector switches are installed on the Relay Logic Panel 00-C734, one for each analyzer. Each selector switch allows the associated analyzer, when inoperable, to be placed in the tripped condition. The switch when placed in the "Inop" position bypasses the toxic analyzer trouble annunciator for the affected analyzer and interrupts the data sent to the remote computer and PMS. With one analyzer in the tripped condition, only one of the two operable analyzers are required to alarm to satisfy the two-out-of-three alarm criteria.

A computer display console in the control room can provide an indication of the toxic chemical and its concentration at any given time.

The equipment has built-in test features. A part of the self-test program is automatically performed each time the analyzer is zeroed.

This system has self calibrated features that are always running when the analyzers are in service to keep them within specification or to activate the control room “Trouble” annunciator if any critical parameter is outside its specified range.

Test points are provided on the Relay Logic Panel for each analyzer to facilitate testing of the toxic chemical high concentration alarm relays.

No special maintenance is required.

6.4.4.2.3 Respiratory Protection

Full-faced pressure demand self-contained breathing apparatus rated for 1 hour per cylinder and protective clothing are available for control room operators.

A 6 hour onsite bottled air supply is provided by charged cylinders maintained for backup fire protection and health physics use. Offsite replenishment is provided by compressors (fill capacity greater than 30 cylinders per hour) owned by an offsite vendor, fire company, or another offsite entity.

The number of respiratory devices shall, as a minimum, provide a 6 hour air supply for 6 individuals. Consistent with the provisions of Regulatory Guide 1.95, one extra respiratory device will be provided for every 3 devices needed to meet the minimum capacity.

See Section 13.2 for discussion on Respiratory Protection.

A program for periodic inspection of control room operator respiratory equipment will be established. The program will address inspection for defects, storage conditions, and, as found to be necessary, cleaning, disinfecting, and repairing. In addition, the equipment will be cleaned, disinfected, and inspected after each use. Replacements and repairs will be done only by trained personnel using parts designed for that equipment. The equipment will be stored to protect against dust, sunlight, extreme heat or cold, excessive moisture, and damaging chemicals.

6.4.5 TESTING AND INSPECTION

The control room HVAC emergency system filtration components are tested in a program consisting of the following classifications:

a. Predelivery tests and factory component qualification tests to ensure the quality of the manufactured product.

b. Preoperational tests in accordance with the requirements of Chapter 14.

c. Periodic tests in accordance with the requirements of Chapter 16.

The frequency of tests and inspections is selected to ensure the continued integrity of the system. Charcoal testing frequency is in accordance with Regulatory Guide 1.52 for the efficiency claimed and the bed depth specified. Except that in-place testing and laboratory testing is performed at least once per 48 months as discussed in Table 6.5-2.

Written test procedures establish minimum acceptable values for all tests. Test results are recorded as a matter of performance records, thus permitting early detection of faulty performance.

The predelivery and factory component qualification tests are in accordance with the recommendations and guidelines presented in section C-3 of Regulatory Guide 1.52. HEPA filters have a minimum efficiency of 99.97% when measured with a 0.3 micron DOP aerosol. Carbon lot

testing is required and certified by a qualified testing agency to establish gas adsorption efficiency, uniformity of density, ignition temperature, hardness, and impregnate content.

Filter plenums are tested for leakage under positive pressure. Plenums are pressurized to the design pressure with soap bubble tests made at all welds. The maximum permissible leakage rate is 0.05% of the filter plenum rated flow in cubic feet per minute at 125% of the negative design plenum pressure.

Preoperational tests are conducted in accordance with the requirements of Chapter 14. In general, the tests include:

a. Visual inspection

b. Verification of ability to maintain control room pressurization without exceeding outside air makeup design flow rate

c. Airflow capacity verification test

d. Airflow distribution verification test

e. Air/aerosol uniformity test

f. Inplace HEPA test

g. Inplace adsorber test

h. Laboratory test of adsorbent

i. Electric heater test

Periodic tests of the makeup airflow to the control room HVAC system from the emergency fresh air intake are performed in accordance with the requirements of Chapter 16.

Periodic inplace testing of HEPA filters and charcoal adsorbers and laboratory testing of charcoal adsorbers are performed in accordance with the requirements of Chapter 16.

6.4.6 Instrumentation Requirement

Differential pressure indicators are provided locally to measure the pressure drop across each filter element. The overall pressure drop across each filter train is measured and indicated on the local panel and alarmed in the computer on high differential pressure.

Each charcoal adsorber is provided with three temperature switches that actuate alarms in the control room. The alarms provide information to allow the operator to discontinue operation in the event of fire or radioactivity release due to charcoal desorption. The temperature is also indicated in the control room.

The electric heating coils upstream of the filters are controlled by a minimum temperature control and a humidity control to maintain less than 70% relative humidity. In the recirculation mode, the

filters are supplied with recirculated control room air at approximately 78°F dry-bulb, 50% relative humidity. Thus, in this mode, if the charcoal adsorber is subjected to less than 70% relative humidity, the heater does not operate, and no additional heat load is imposed upon the control room HVAC system.

Radiation and offsite toxic chemical monitors are provided in the outside air intake duct. Radiation monitors are also provided in the main control room. The monitors alarm in the control room upon detection of high radiation or high toxic chemical conditions.

Differential pressure transmitters are provided which sense the differential pressure between the control room and the outside air and indicate positive pressure differential in the control room.

The hand switches for HVAC equipment required for control room habitability are located in the control room.

The flow of control room air recirculating through the emergency fresh air filter system is indicated in the control room.

Section 9.4 addresses instrumentation requirements for the control room supply and return air systems.

The instrumentation used to provide the initiating signals for control room pressurization are discussed in Sections 7.3 and 7.6.

Table 6.4-1

CONTROL ROOM EMERGENCY HVAC SYSTEM
FAILURE ANALYSIS

COMPONENT	MALFUNCTION	COMMENTS
Emergency fresh air fan	Failure of fan resulting in reduction of air flow	If the operating fan fails, the resultant reduction of air flow actuates an alarm in the control room, automatically starts the standby fan, and opens the standby filter train isolation valves.
Electric heating coil	Failure of coil control resulting in constant coil operation	Maximum capacity of the electric heating coil is not sufficient to cause damage.
	Failure of coil resulting in no heat	The heating coil is not required during emergency operation because the humidity will not exceed 70% relative humidity.
Filter train	Failure resulting in high differential pressure across the filter train	High differential pressure across the filter train is indicated on the local panel and automatically actuates an alarm in the computer. The defective filter train is manually isolated and the standby train is manually placed in service. If the high differential pressure results in low flow the standby fan and filter train will start.
	Failure resulting in high radiation at the discharge	The defective filter train is manually isolated and the redundant filter train is manually placed into operation upon receiving a high radiation signal.
Charcoal Adsorber	High temperature in charcoal bed	Temperature sensors are provided on the leaving air side of each charcoal bed to alarm in the control room

Table 6.4-1 (Cont'd)

COMPONENT	MALFUNCTION	COMMENTS
		on rising charcoal temperature. The charcoal temperature is also indicated in the control room. The deluge fire protection system is manually initiated if required.
Isolation Valve	Failure to close or failure to close completely	A series redundant isolation valve and a closed and capped test port connection provide the required isolation.
Operational Damper	Failure to open	Low flow switch actuates standby fan and filter train.
Air handling units and return air fans	All postulated failures	See Table 9.4-3.

Table 6.4-2

CONTROL ROOM POTENTIAL LEAK PATHS

	POTENTIAL LEAK PATHS	TYPE OF MATERIAL JOINT, OR PENETRATION
a.	Control room walls	3' thick reinforced concrete
b.	Control room ceiling	1½' thick reinforced concrete poured on 16 gauge galvanized steel metal decking
c.	Control room floor	1½' thick reinforced concrete poured on 16 gauge galvanized steel metal decking
d.	Control room construction joints - floor to wall, wall to wall, wall to ceiling, slab to slab	All are poured concrete cold joints
e.	Doors - personnel access	2 each - 3'x7' steam-tight metal doors with elastomer seals and sealing mechanism
f.	Electrical cable penetrations	Kaowool fiber and silicone expansion foam - 9" deep Dow-Corning 36548 RTV and Sylgard 170
g.	HVAC duct penetrations	Embedded metal sleeves through concrete walls - flanged and welded to ducts
h.	Control room HVAC ducts (negative pressure) exterior to control room	Welded galvanized steel
i.	Dampers (frames, shaft penetrations, flanges) in control room ducts (negative pressure) exterior to control room	Gas-tight construction maximum 0.1 cfm/damper from ambient into duct-work.
j.	HVAC isolation valves	Pneumatic or electrohydraulic butterfly valves - bubble-tight
k.	Piping penetrations	Bellows-type expansion joint

Table 6.4-2 (Cont'd)

	POTENTIAL LEAK PATHS	TYPE OF MATERIAL JOINT, OR PENETRATION
l.	Emergency fresh air supply system (filter assembly and fans)	Welded filter - leak tested; welded fan housing-bolted; and gasketed access doors; inlet and discharge connections
m.	Control room supply air fan cabinets	Welded cabinet construction; vaneaxial fan and coil connections - bolted; and gasketed inlet and discharge connections
n.	Test port connection and isolation valve	Capped test port connection and closed globe valve. Pneumatic or electrohydraulic butterfly valve - bubble-tight.

6.5 FISSION PRODUCT REMOVAL AND CONTROL SYSTEMS

6.5.1 ENGINEERED SAFETY FEATURE FILTER SYSTEMS

The following filtration systems, required to perform postaccident safety-related functions are provided:

a. SGTS: In its safety-related mode of operation, this system is used to reduce halogen and particulate concentrations in gases potentially present in the reactor enclosure following a LOCA, and gases present following a postulated fuel handling accident in the refueling area before the gases are discharged to the environment (Section 6.5.1.1). The system exhausts a controlled filtered flow to the atmosphere during isolation to restore and maintain a negative pressure in the affected secondary containment zone. In addition, this system performs the nonsafety-related function of reducing halogen and particulate concentrations in gases purged from the primary containment.

b. CREFAS filter units: This system is used to clean the outside air of halogens and particulates that are potentially present in the air following a postulated accident before introducing the air into the control room HVAC system (Section 6.5.1.2).

c. RERS filter units: This system is used to reduce halogen and particulate concentrations in gases in the reactor enclosures following a LOCA. The RERS is the initial cleanup system (the SGTS is the final cleanup system) before discharge of the gases from the reactor enclosures (Section 6.5.1.3).

6.5.1.1 Standby Gas Treatment System

6.5.1.1.1 Design Bases

As described in Section 9.4.2.1, the secondary containment consists of three ventilation zones. Zones I and II surround the primary containment of Units 1 and 2, respectively, below the floor at el 352'. Zone III consists of the common refueling area above the floor at el 352'.

The SGTS is designed to accomplish the following objectives:

a. Exhaust sufficient filtered air from the reactor enclosure and/or refueling area to maintain a negative pressure of about 0.25 inch wg. in the affected volumes during secondary containment isolation (see Section 9.4.2 for discussion of the secondary containment isolation signals)

b. Filter the air exhausted to remove radioactive particulates and both radioactive and nonradioactive forms of iodine from the following areas:

   1. Reactor enclosure (Zone I and Zone II)

   2. Refueling area (Zone III)

   3. Deleted

   4. Primary containment during purging and ventilating

5. Discharge from the HPCI barometric condenser, following filtration by the RERS when the reactor enclosure is isolated

c. Ensure that the failure of any component of the filtration train, assuming LOOP, cannot impair the ability of the system to perform its safety function

d. Remain intact and functional in the event of a SSE

e. Automatically start in response to any one of the following signals:

1. LOCA signal as described in Section 9.4.2.

2. High radiation level in refueling area exhaust air

3. High radiation level in reactor enclosure (Zone I or Zone II) exhaust air

4. Low differential pressure in the reactor enclosure (Zone I or Zone II)

5. Low differential pressure in refueling area (Zone III)

(The SGTS fans can also be started manually in the control room by tripping the refueling area isolation system or the reactor enclosure isolation system.)

f. The design bases employed for sizing the filters, fans, and associated duct-work are as follows:

1. Each filter train is sized and specified for treating the incoming air-steam mixture at 11,000 cfm maximum and 135°F ① for drywell purge (drywell purge is discussed in Section 9.4.5). The SGTS fans are sized for 8400 cfm maximum flow at 20 inches wg. static pressure.

2. The system capacity is maintained with all filters fully loaded (dirty).

3. For HEPA filters, maximum free velocity does not exceed 300 fpm with maximum airflow resistance of 1 inch wg. when clean and minimum efficiency of 99.97% by DOP test method.

4. The charcoal adsorber is rated for 99.0% trapping of radioactive iodine as elemental iodine (I_2) and 99.0% trapping of radioactive iodine as methyl iodide (CH_3I) when passing through charcoal (8 inch bed depth) at 70% relative humidity. The air residence time in the 8 inch charcoal bed is 0.68 seconds considering a maximum total after drawdown leakage rate from Zones I, II, and III of 5764 cfm.

① This information is based on original design conditions. Further evaluation has validated this design for a drywell operating temperature of 150°F.

5. Relative humidity at the charcoal adsorber is limited to 70% by the appropriate heating of air.

6. The SGTS maximum fan capacity is based on the calculated inleakage into secondary containment with the secondary containment maintained at a negative pressure of 0.25 inches of water with reference to the outside atmosphere. The maximum capacity includes an allowance for thermal expansion of the secondary containment air volume due to equipment residual heat transfer to the air during SGTS operation.

6.5.1.1.2 System Description

The SGTS is common to both Units 1 and 2. Each of the two redundant SGTS filter trains consists of an electric air heater, two banks of HEPA filters (upstream and downstream of charcoal adsorber), a vertical 8 inch deep charcoal adsorber bed (with temperature detection sensors and a water flooding system for fire protection), and associated dampers, ducts, instruments, valves, and controls.

For its safety-related mode of operation (Section 6.5.1.a), two redundant 100% capacity SGTS fans are provided for use in conjunction with the SGTS filter trains. Each fan has a controllable capacity of 500 cfm to 8400 cfm, which is sufficient to restore and maintain both reactor enclosures and the common refueling area at the required negative pressure in relation to atmospheric pressure during secondary containment isolation. The air flow varies in response to secondary containment differential pressure controls, which modulate the fan inlet vanes and control dampers in the run-around bypass and discharge ducts provided for each fan. Slide gate dampers with position switches are closed to isolate the SGTS from any secondary containment zone which cannot be isolated and drawn down.

The SGTS is actuated automatically in its safety-related mode of operation. Both SGTS filter trains are maintained in the open position. Upon receipt of a secondary containment isolation signal (Section 6.5.1.1.1.e), both of the SGTS fans are started and the associated controls are activated to open or modulate appropriate dampers and valves so that the system function is accomplished. Following the initial fan start, the operators may elect to place one of the SGTS fans in the standby position.

For its nonsafety-related mode of operation (Section 6.5.1.a), two redundant 100% capacity drywell purge fans are provided for use in conjunction with the SGTS filter trains. Each fan has a capacity of 11,000 cfm which is sufficient for the drywell purge operation.

The SGTS is manually actuated for its nonsafety-related mode of operation.

If one of the SGTS filter train isolation valves fails closed during its safety-related mode of operation, the redundant filter train is automatically placed into service. If one of the SGTS fans fails to establish flow, because of either fan or fan damper failure, the standby SGTS fan automatically starts.

The SGTS is shown schematically on drawing M-76. Specific SGTS component design parameters are shown in Table 6.5-1.

The equipment and materials conform to the applicable requirements and recommendations of the guides, codes, and standards listed in Section 3.2. Conformance with Regulatory Guide 1.52 is discussed in Table 6.5-2.

Components for each SGTS train are designed as discussed in the following paragraphs.

A prefilter is not included in the SGTS filter trains because the SGTS intake is downstream of the recirculation filter system fans so that the air is prefiltered before entering the SGTS filters after RERS start during reactor enclosure isolation. A prefilter is provided in the SGTS duct for air drawn from the refueling area during refueling area isolation. The drywell purge air supply is prefiltered by the reactor enclosure supply air system during the drywell purge mode.

The SGTS fan performance and motor selection are based on the maximum system pressure drop resulting from dirty SGTS filters. The SGTS filter banks are sized for 11,000 cfm drywell purge flow, (see Table 6.5-1 for filter pressure drops).

The charcoal adsorber is a gasketless, welded seam type filled with impregnated activated charcoal that meets the requirements in table 5-1 of ANSI N509 (1980) and Regulatory Guide 1.52 except that laboratory analysis of carbon samples is performed in accordance with ASTM D3803-1989. The bank holds a total of approximately 2400 pounds of charcoal having an ignition temperature of not less than 626°F. The charcoal adsorber is capable of removing not less than 99.0% of elemental iodine and 99.0% of methyl iodide at 70% relative humidity. The maximum loading is 2.5 milligrams of iodine per gram of activated charcoal.

A demister is not required for the SGTS filters. The absence of water droplets in the air stream entering the SGTS filters during post-LOCA isolation, refueling area isolation, and primary containment purging is assured based on the following:

a. The SGTS intake is downstream of the RERS filters and normally exhausts air which has been prefiltered by the RERS filters. However, prior to RERS fan operation (up to 3 minutes post-LOCA), the SGTS can draw air directly through a pressure relief vent located between the RERS and SGTS ducts. This vent is located in an access area on el 283' where there are no significant sources of humidity which can form water droplets. After the RERS fan starts, the vent is maintained at a slight positive pressure with air which has been prefiltered by the RERS filters. The absence of water droplets in the RERS air stream during reactor enclosure isolation is discussed in Section 6.5.1.3.2.

b. There are no sources of water droplets in the refueling area that could enter the duct connection to the SGTS. As discussed below, water droplets from condensation will not reach the SGTS filters during refueling area isolation because of the tortuous flow path and low velocities through the ducts, and low point drains in the ducts. The duct from the refueling area to the SGTS filters passes the Unit 1 reactor enclosure for approximately 260 feet and includes at least 20 bends and turns. If condensation does occur, the amount of condensation would be minor, based on the potential amount of water vapor in the air stream. One inch diameter low point drain is provided for the portion of duct-work in the reactor enclosure to ensure that any condensation will be drained from the duct. When refueling area drawdown begins, the flow rate could reach 2400 cfm or more for a short period of time. As water vapor accumulates in the refueling area, the flow rate will be decreasing. During the period when any significant condensation could occur in the ducts, the flow rate in the duct will be no more than 800 cfm. The air velocity during this period varies from approximately 162 fpm to 325 fpm (1.8 mph to 3.7 mph) for the majority of the duct-work.

c. Water droplets will not reach the SGTS filters during drywell containment purging because of the reasons discussed below.

It is highly unlikely that water droplets will enter the purge lines during drywell purging. As discussed in Section 6.5.1.3.3, the licensee's preventive maintenance program will maintain normal plant leaks to low flow dripping type leakages. Any leakage with spraying water droplets (such as those due to failed seals in pumps and valves) will be identified and corrected as part of the maintenance program. It can be shown that any droplets formed will travel less than 20 feet. There are no potential sources of water droplets within 20 feet of the suppression chamber purge exhaust opening. There are no pumps, and only few valves, within 20 feet of the drywell purge exhaust opening. The closest valve is 8 feet away from the opening. Because the purge system is used during only a limited period of power operation (only open for inerting, de-inerting, pressure control, ALARA or air quality considerations for personnel entry, or Surveillances that require the valves to be open), it is highly unlikely that a valve seal would fail and spray water into the drywell purge exhaust opening during purge system operation.

If water droplets are hypothetically assumed to enter the purge exhaust ducts, or if condensation within the duct-work occurs, the water droplets would not reach the SGTS filters because of the tortuous flow path, the insulated duct-work in the control structure, and the SGTS heaters. Purge air exhausted from the drywell flows approximately 215 feet in the reactor enclosure through three valves, two vertical upward turns, and four additional bends and turns with a flow rate of 11,000 cfm at a velocity of 2240 fpm (25.5 mph) in the duct, and 3731 fpm in the pipe. The purge air from the suppression chamber flows more than 160 feet in the reactor enclosure through valves and six bends and turns with a flow rate of 9750 cfm and a velocity of 1986 fpm (22.6 mph) in the duct, and 6008 fpm in the pipe. At these velocities, if condensation occurs within the duct-work, it is possible for some water droplets to be entrained in the air-steam. Condensation within the reactor enclosure duct-work could occur while purging the suppression chamber, but no significant condensation would occur while purging the drywell because the drywell is maintained at a low relative humidity by the drywell coolers. No significant condensation would occur in the control enclosure duct-work for either purge mode because it is insulated.

The environmental conditions within the reactor enclosure duct-work will be such that only surface type condensation could occur. Droplets will coalesce on the inside surface of the duct creating larger droplets, forming condensate flow on the bottom of the duct. Much of this flow will drain to low points in the duct-work and be removed via drains, and therefore never enters the air stream. Much of the condensate that does become entrained in the air stream is subsequently removed from the air stream due to the any bends and turns in the duct. Water droplets greater than 20 microns in size are removed by the bends and turns, including a square elbow with turning vanes, which act as course moisture separators (Reference 6.5-2). Water droplets less than 20 microns in size may reach the SGTS heaters. However, analyses have been performed to demonstrate that the SGTS heaters can evaporate all water droplets less than 25 microns in size. Thus, no water droplets will reach the SGTS filters.

The effects of water droplets on the SGTS HEPA filters were evaluated, even though there is no credible way for water droplets to reach the HEPA filters. (Effects on the charcoal filters were not evaluated because the HEPA filters are upstream of the charcoal filters and would collect any water droplets postulated to be in the air

stream). When HEPA filters are exposed to high concentrations of liquid, plugging could occur that would decrease air flow through them. Decreased efficiency in collecting particulate matter would not occur unless plugging is severe enough to rupture the HEPA filter. Based on Reference 6.5-2, if the maximum water delivery rate is kept below 0.18 gpm per 1000 cfm of air flow, plugging will not occur. Analyses have been performed to demonstrate that, even if all of the condensation that forms in the duct during the worst case condition of suppression pool purging is hypothetically assumed to reach the HEPA filters in the form of water droplets, the condensate loading is only 8.33×10^{-3} gpm/1000 cfm, which is well below 0.18 gpm/1000 cfm. Thus, plugging of the filters would not occur.

Analyses were performed to demonstrate that the SGTS heaters are capable of reducing the relative humidity of the air during suppression pool purging (9750 cfm for this mode) from 100% relative humidity, with entrained droplets, to less than 70% relative humidity, with no entrained droplets. The SGTS heaters are also capable of reducing the relative humidity of the air during drywell purging (11,000 cfm for this mode), from 100% relative humidity to less than 70% relative humidity.

A water flooding system within the charcoal bed is provided. The water system is connected to the station fire protection system. Valves are mounted outside the charcoal adsorber. Two continuous type thermistors are provided on the leaving air side of the charcoal bed. A rise in the charcoal bed area temperature results in the following:

a. The first temperature setpoint (200°F) actuates an alarm in the control room. The filter train is removed from service until the cause of the alarm has been determined. The operator shall investigate to determine if a fire has occurred and introduce the fire protection water to the charcoal plenum, if necessary, as listed in Item c.

b. The second temperature setpoint (250°F) also actuates an alarm in the control room. The operator shall continue to investigate to determine if a fire has occurred and introduce the fire protection water, if necessary, as listed in Item c. The SGTS charcoal temperature sensor system power trouble alarm is allied with this alarm window.

c. The third temperature setpoint (550°F) actuates an alarm in the control room. The operator shall investigate to determine if a fire has occurred and introduce the fire protection water to the charcoal plenum, if necessary, as follows: The operator manually opens the valves, thus introducing the fire protection water to the charcoal plenum. A drain valve is provided to drain the water from the filter plenum.

Four test canisters are provided for each charcoal adsorber. These canisters contain the same depth of the same charcoal that is in the adsorber. The canisters are mounted so that a parallel flow path is created between each canister and the adsorber. Periodically one of the canisters can be removed and laboratory tested to verify the adsorbent efficiency. Alternate means of sampling (slotted-tube method) may also be used for obtaining representative samples of used activated charcoal per the requirements specified in ANSI N509-1980.

Permanently installed injection and sampling ports are provided for all ESF atmosphere cleanup systems to permit accurate testing in accordance with ANSI N510. Providing fewer charcoal test canisters on the ESF atmosphere cleanup systems than specified in ANSI N509 (1980) section 4.11 results in equal or more frequent replacement of activated carbon. Regulatory Guide 1.52 states that testing of representative samples should be performed (1) initially, (2) at least once per 18

months thereafter for systems in a standby status, or after 720 hours of system operation and (3) following painting, fire, or chemical release in any ventilation zone communicating with the system. However, representative samples of the SGTS are tested at least once per 48 months as discussed in Table 6.5-2. More frequent replacement may result because Regulatory Guide 1.52 further states that when no representative samples are available for testing, the activated carbon should be replaced with new activated carbon.

Access doors, with 30x68 inch openings, to each HEPA filter compartment are provided. An 18 inch access hatch is provided for the charcoal filter compartment.

The HEPA filter and charcoal filter housings are of all-welded construction.

Interior lights with external light switches are provided in the HEPA filter plenums to facilitate inspection, testing, and replacement of components.

The SGTS has been designed to continuously purge the filter plenums with dry instrument air when the filters are not in use. Any amount of dry air continuously purged through the adsorbers and HEPA filters will entrain moisture and maintain moisture levels at a minimum because the duct-work is gas-tight and there is no internal humidity source. (The periodic operation of the ESF atmosphere cleanup (SGTS) train could introduce additional moisture into the system and increase moisture levels above those normally maintained.)

The electric heater maintains the relative humidity below 70% for charcoal adsorber operation by maintaining a constant temperature rise of 15°F across the heater. An analysis of heater capabilities for various entering saturated air conditions up to 150°F (which exceeds any inlet conditions the SGTS system will experience) yields a peak heating requirement of 135,000 Btu/hr, at maximum 11,000 cfm airflow. A 55 kW heater is provided.

The automatic reset cutout (setpoint 260°F) is located inside the heater where the sensed temperature is higher than the actual air temperature downstream of the heater. This heater protection device that was selected and installed by the heater manufacturer. The automatic reset cutout (setpoint 180°F), which is located downstream of the heater, senses the actual temperature of air leaving the heater and causes an alarm signal in the control room when the air temperature exceeds 180°F. Because the SGTS electric heaters operate with a fixed temperature differential of 15°F between the inlet and outlet air temperatures and the maximum inlet temperature is 150°F, the maximum air temperature downstream of the heater should not exceed 165°F. In the event of a heater malfunction, the discharge air automatic reset cutout will shut off the heater when the downstream air temperature exceeds 180°F. The conservatively selected 180°F heater cutout temperature, and an alarm annunciation in the control room to notify the operator if this condition should occur are considered to be equivalent to the 225°F manual heater cutout required by section 5.5 of ANSI N509-76.

6.5.1.1.3 Design Evaluation

The SGTS is designed to preclude direct exfiltration of contaminated air from the secondary containment following a postulated accident or an abnormal occurrence which could result in abnormally high airborne radiation in the secondary containment. Equipment is powered from Class 1E buses, and all power circuits meet IEEE 279 and IEEE 308 requirements to ensure power availability from the standby diesel generator sets in the event of loss of normal offsite ac power. Redundant components are provided where necessary to ensure that a single failure does not impair or preclude system operation. The SGTS is designed to seismic Category I requirements as discussed in Section 3.7 to ensure that the system remains intact and functional in the event of an SSE. Components and materials of the SGTS system have been selected to assure availability of the system under postulated accident conditions. An SGTS failure mode and effect analysis is presented in Table 6.5-3.

6.5.1.1.4 Tests and Inspections

Except for Items D.2 and D.3 of Table 9.4-4, all tests and inspections described in the table apply to the SGTS. Conformance with Regulatory Guide 1.52 is discussed in Table 6.5-2.

ESF atmosphere cleanup systems are accessible during normal operation and during anticipated transients. ESF atmosphere cleanup systems are designed to operate after an accident or during drywell purge. Periodic tests are performed during normal operation on all ESF atmosphere cleanup systems, to ensure that prefilters and HEPA filters are either changed on high pressure readings or checked on abnormal readings.

The system will be preoperationally tested in accordance with the requirements of Chapter 14 and periodically tested in accordance with the requirements of Chapter 16.

6.5.1.1.5 Instrumentation

The SGTS can be actuated manually from the control room. Each SGTS train is designed to function automatically upon receipt of a secondary containment isolation signal. The status of system equipment, which is an indication of pertinent system temperatures and flow rates, is displayed in the control room during both normal and accident operation.

All instrumentation required during and after accident conditions is qualified to meet seismic Category I requirements. Instrumentation conformance with Regulatory Guide 1.52 is discussed in Tables 6.5-2 and 6.5-8.

The following alarms are annunciated in the control room:

a. Fan trouble

b. Heater failure (low temperature rise across the heater)

c. Charcoal filter high temperature alarms

d. Filter system trouble (including valve circuit trouble, charcoal temperature detection system trouble and electric heater trouble)

e. Low pressure differential, referenced to the outside ambient pressure, in the secondary containment ventilation zones being isolated

6.5.1.1.6 Materials

The materials of construction used in or on the SGTS are given in Table 6.5-4.

Materials used in or on the SGTS are selected to ensure that system operability is not affected by radiation, temperature, or other environmental effects. Environmental qualification of the SGTS is discussed in Section 3.11.

By being located in the control structure, the SGTS is protected from extremes of radiation and temperature that could potentially produce radiolytic or pyrolytic decomposition of filter materials. Thus, filter system decomposition products would not be generated.

6.5.1.2 Control Room Emergency Fresh Air Filter Units

6.5.1.2.1 Design Bases

The design bases for the control room emergency fresh air filter units are described in Sections 6.4 and 9.4.1 and as given below.

The design bases employed for sizing the filters, fans, and associated duct-work are as follows:

a. Each filter train is sized and specified for treating incoming air at 3000 cfm at design outdoor temperature.

b. The system capacity is maintained with all filters fully loaded (dirty).

c. For HEPA filters, maximum free velocity does not exceed 300 fpm with maximum airflow resistance of 1 inch wg. when clean and minimum efficiency of 99.97% by the DOP test method.

d. The charcoal adsorber is rated 95.0% for trapping of radioactive iodine as elemental iodine (I_2) and 95.0% trapping of radioactive iodine as methyl iodide (CH_3I) when passing through charcoal (2 inch bed depth) at 70% relative humidity. The air residence time in the 2 inch charcoal bed is not less than 0.25 seconds.

6.5.1.2.2 System Description

The control room emergency fresh air filter system is described in Sections 6.4 and 9.4.1. Conformance with Regulatory Guide 1.52 is discussed in Table 6.5-2.

6.5.1.2.3 Design Evaluation

The control room emergency fresh air filter units work in conjunction with the control room HVAC system to maintain habitability in the control room. The design evaluation is given in Sections 6.4 and 9.4.1. Control room emergency fresh air filter system failure analysis is given in Section 6.4.

6.5.1.2.4 Tests and Inspections

Tests and inspections are described in Sections 6.4 and 9.4.1.

6.5.1.2.5 Instrumentation

Instrumentation requirements are discussed in Section 6.4. Conformance with Regulatory Guide 1.52 is discussed in Tables 6.5-2 and 6.5-8.

6.5.1.2.6 Materials

The materials of construction used in or on the control room emergency fresh air filter systems are given in Table 6.5-5.

Materials used in or on the emergency fresh air filter systems are selected to ensure that system operability is not affected by radiation, temperature, or other environmental effects. Environmental qualification of the system is discussed in Section 3.11.

By being located in the control structure, the emergency fresh air filter systems are protected from extremes of radiation and temperature that could potentially produce radiolytic or pyrolytic decomposition of filter materials. Thus, filter system decomposition products would not be generated.

6.5.1.3 Reactor Enclosure Recirculation System Filter Units

6.5.1.3.1 Design Bases

The RERS is designed to accomplish the following objectives:

a. Filter the air in the reactor enclosures following a LOCA to reduce the concentration of radioactive halogens and particulates potentially present in the reactor enclosures

b. Ensure that failure of any component of the filtration train, assuming loss of offsite power, cannot impair the ability of the system to perform its safety function

c. Remain intact and functional in the event of an SSE

d. Automatically start in response to any one of the following signals (the RERS fans can also be started manually in the control room by tripping the reactor enclosure isolation system):

    1. LOCA signal as described in Section 9.4.2

    2. High radiation level in the reactor enclosure (Zone I or Zone II) exhaust air of the respective unit

    3. Low differential pressure in the reactor enclosure (Zone I or Zone II)

e. The design bases employed for sizing the filters, fans, and associated duct-work are:

    1. Each filter train is sized and specified for treating incoming air at 60,000 cfm and 150°F, which exceeds the accident temperature service requirements.

2. The system capacity is maintained with all filters fully loaded (dirty).

3. For HEPA filters, maximum free velocity does not exceed 375 fpm, with maximum airflow resistance of 1 inch wg. when clean and minimum efficiency of 99.97% by DOP test method.

4. The charcoal adsorber is rated for 95.0% trapping of radioactive iodine as elemental iodine (I_2) and 95.0% trapping of radioactive iodine as methyl iodide (CH_3I) when passing through charcoal (2 inch bed depth) at 70% relative humidity. The air residence time in the 2 inch charcoal bed is not less than 0.25 seconds.

6.5.1.3.2 System Description

There are two redundant RERS trains in each reactor enclosure. Each of the RERS trains consists of a bank of prefilters, two banks of HEPA filters (upstream and downstream of the charcoal adsorber), a vertical two inch deep charcoal adsorber bed (with fire detection temperature sensors and a water spray system for fire protection), and associated dampers, ducts, instruments, and controls. The RERS is shown schematically on drawing M-76. Specific RERS component design parameters are provided in Table 6.5-1.

The equipment and materials conform to the applicable requirements and recommendations of the guides, codes, and standards listed in Section 3.2. Conformance with Regulatory Guide 1.52 is discussed in Table 6.5-2.

Each redundant RERS train has a constant capacity of 60,000 cfm, and each is capable of treating the required amount of air from the Unit 1 or Unit 2 reactor enclosure volume being recirculated. Components for each RERS are designed as discussed in the following paragraphs.

The fan performance and motor selection are based on maximum system pressure drop, that is, a pressure drop based on maximum pressure drops across the component filters (3 inches wg. for the first bank of HEPA filters and 4 inches wg. for the second bank). The air flow is maintained at a constant rate by flow control dampers.

The charcoal adsorber is a gasketless, welded seam type filled with impregnated activated charcoal that meets the requirements in table 5-1 of ANSI N509 (1980) and Regulatory Guide 1.52 except that laboratory analysis of carbon samples is performed in accordance with ASTM D3803-1989. The bank holds a total of approximately 13,000 pounds of charcoal having an ignition temperature of not less than 626°F. The charcoal adsorber is capable of removing not less than 95.0% of elemental iodine and 95.0% of methyl iodide at 70% relative humidity.

There are no demisters provided for the RERS. The absence of water droplets in the RERS air stream during reactor enclosure isolation is assured based on the following:

a. The reactor enclosure relative humidity will not exceed 77% during normal operation. This relative humidity will decrease to below 70% post-LOCA due to the increase in heat to the structure.

b. ESF system leakage will be held to a minimum because LGS will follow the guidelines of NUREG-0737 Item III.D.1.1, i.e., provide periodic surveillance tests to minimize system leakage.

c. The RERS is not required to mitigate the consequences of a HELB or a moderate energy line break. Therefore this line break is not considered a source of water that could enter the RERS air stream.

d. The RERS will not communicate with the refueling area during reactor enclosure isolation or refueling area isolation. Therefore humidity from the fuel pool is not considered a source of water that could enter the RERS air stream. As indicated in Table 6.5-2, the SGTS, which will drawdown the refueling area upon refueling area isolation, will be provided with a prefilter in accordance with Regulatory Guide 1.52.

A water spray system within the charcoal bed is provided. The spray system is connected to the fire protection system. A valve is mounted outside the charcoal adsorber. A continuous type thermistor is provided on the leaving air side of the charcoal bed. A rise in the charcoal bed area temperature results in the following:

a. The first temperature setpoint (200°F) actuates an alarm in the control room. The filter train is removed from service until the cause of the alarm has been determined. The operator shall investigate to determine if a fire has occurred and introduce the fire protection water to the charcoal plenum, if necessary, as listed in item c.

b. The second temperature setpoint (250°F) also actuates an alarm in the control room. The operator shall continue to investigate to determine if a fire has occurred and introduce the fire protection water, if necessary, as listed in item c. The RERS charcoal temperature sensor system power trouble alarm is allied with this alarm window.

c. The third temperature setpoint (550°F) actuates an alarm in the control room. The operator shall investigate to determine if a fire has occurred and introduce the fire protection water to the charcoal plenum, if necessary, as follows: The operator manually opens the valve, thus introducing the fire protection water to the charcoal plenum. A drain valve is provided to drain the water from the filter plenum.

Six test canisters are provided for each charcoal adsorber. These canisters contain the same depth of the same charcoal that is in the adsorber. The canisters are mounted so that a parallel flow path is created between each canister and the adsorber. Periodically one of the canisters can be removed and laboratory tested to verify the adsorbent efficiency. Alternate means of sampling (slotted-tube method) may also be used for obtaining representative samples of used activated charcoal per the requirements specified in ANSI N509-1980.

Access doors, with 20x50 inch openings, are provided in each filter compartment in the RERS plenum.

The RERS filter plenum housing is of all-welded construction.

Interior lights with external light switches are provided between all train components to facilitate inspection, testing, and replacement of components.

Each charcoal train is continuously purged with 1 cfm of dry instrument air; however, any amount of dry air continuously purged through the adsorbers and HEPA filters will entrain moisture and maintain moisture levels at a minimum because the duct-work is gas-tight and there is no internal humidity

source. (The periodic operation of the ESF atmosphere cleanup train could introduce additional moisture into the system and increase moisture levels above those normally maintained.)

The RERS is actuated either automatically (safety-related mode) or manually for routine system operability testing (nonsafety-related mode). The automatic actuation is originated by the reactor enclosure isolation signal (Section 6.5.1.3.1.d).

During normal operation the RERS trains are maintained in a lead/lag mode of operation. Upon receipt of an automatic isolation signal the RERS train in lead will automatically start to accomplish the system functions. The RERS train in lag will remain in standby. In the event of a single active failure associated with the operating RERS train, the RERS train in standby will automatically start, following a time delay, to perform the system functions and will operate for the duration of the Design Bases Event.

6.5.1.3.3 Design Evaluation

The RERS is designed for filtration of contaminated air in the reactor enclosure following a postulated accident or abnormal occurrence which could result in abnormally high airborne radiation in the reactor enclosure. Equipment is powered from Class 1E buses and all power circuits meet IEEE 279 and IEEE 308 requirements to ensure uninterruptible operation in the event of loss of normal offsite ac power. Redundant components are provided where necessary to ensure that a single failure will not impair or preclude system operation. Operating the RERS trains in a lead/lag mode will assure compliance with the design bases since a single RERS train is sufficient to perform all of the required RERS safety functions and the time delay associated with the shutdown of the lead RERS train and standby start of the lag RERS train will have a negligible effect on the Reactor Enclosure differential pressure, the post-LOCA mixing function and the on-site/off-site dose analyses. The RERS is designed to seismic Category I requirements as discussed in Section 3.7 to ensure that the system remains intact and functional if there is an SSE. Components and materials of the RERS have been selected to assure availability of the system under postulated accident conditions. A RERS failure mode and effect analysis is presented in Table 6.5-6.

An analysis was conducted to calculate the maximum post-LOCA time period for which the relative humidity at the inlet of the RERS charcoal filters could exceed 70%. It was found that within 15 minutes after isolation of the reactor enclosure secondary containment, the relative humidity will decrease from an initial maximum condition of 76.2% to below 70%. The following conservative rationale was used for this analysis:

a. The reactor enclosure supply air system uses unconditioned outdoor air to provide once-through ventilation to cool the reactor enclosure during normal plant operation.

b. On a design basis summer day of 95°F (Db), the reactor enclosure ventilation system is designed to maintain the reactor enclosure at a nominal 104°F. The outdoor air is sensibly heated from 95°F to 104°F as it passes through the reactor enclosure supply fans and from internal reactor enclosure heat loads such as the primary containment, MCCs, load control centers, motors, lights, cable trays, and piping.

c. Assuming outdoor air conditions of 95°F (Db) and 95°F (Wb) (100% relative humidity) exist, the same air when heated to 104°F (Db) will have a relative humidity of 76.2%. This is the basis for the initial reactor enclosure relative humidity conditions when isolation occurs due to a LOCA.

d. Based on the ASHRAE 1981 Handbook of Fundamentals, less than 1% of the total hours during the months of June through September will exceed a 93°F (Db) or 77°F (Wb) in Philadelphia. Therefore the outdoor air conditions used in this analysis are improbable.

e. Other outdoor air conditions at lower dry-bulb and wet-bulb temperatures, which are more probable from a meteorological standpoint, can also result in an initial reactor enclosure relative humidity condition exceeding 70%. However, the initial relative humidity for these cases will be less than 76.2% because cooler air contains less moisture and the 9°F temperature rise from operating equipment has a greater effect on lowering the relative humidity.

f. After isolation occurs, an increase in the bulk reactor enclosure temperature from 104°F to 107°F will lower the relative humidity to 70% in accordance with basic psychrometric principles. At lower reactor enclosure temperatures, the initial relative humidity is closer to 70%, and a smaller temperature rise after isolation is needed to lower the relative humidity to 70%.

g. Only internal reactor enclosure heat loads that were determined to exist for the duration of the transient were considered to provide air heat-up. The heat load from seismic Category II motors was considered to decay instantly because loss of their internal motor ventilating fans would prevent efficient residual heat removal from the motor casings. The lighting load was also considered to decay to zero instantly because the small mass and therefore residual heat stored in this equipment would be small.

h. The heat loss of the air into the cooler exterior and interior walls and floor slabs of the reactor enclosure was calculated using a conservative heat transfer model.

i. The cooling effect of outdoor air inleakage into the reactor enclosure due to SGTS operation was considered.

j. Because the bulk reactor enclosure temperature 15 minutes post-LOCA will always exceed any outdoor air temperature by at least 12°F (107°F versus 95°F for worst case analysis), the relative humidity will not rise above 70% for the duration of RERS operation.

k. Internal sources of moisture resulting from operation of the ECCS pumps were evaluated. The additional moisture was found to be small and will not have a significant effect on relative humidity.

The RERS charcoal filter efficiency is not expected to be adversely affected by this temporary condition. Although the initial relative humidity of the reactor enclosure is 76.2% at the time of the LOCA, the RERS does not operate for the first 3 minutes. Therefore, the time period in which the relative humidity exceeds 70% and the RERS operates is between 3 minutes and 15 minutes when the average relative humidity will be approximately 73%. Reference 6.5-2 recommends a charcoal efficiency for methyl iodine removal of 95% for relative humidities of 85% and less as a conservative design basis. It also states that "Trapping of elemental radioiodine involves physical adsorption only, and the efficiency of nearly any good grade of activated carbon, impregnated or not, will be at least 99% (DF = 100) under any combination of temperature and humidity that would be encountered in

a nuclear air cleaning system." Evidence that these efficiency values are realistic and conservative has been identified in the following sources:

a. The ANSI N509 (1980) activated carbon performance test requirements and acceptance values are more stringent than the recommended efficiency values of Reference 6.5-2. LGS RERS charcoal is being supplied in accordance with the ANSI N509 requirements.

b. Figure 4.6 of Reference 6.5-3 plots the test results of 65 different methyl iodine penetration tests as a function of relative humidity. In no cases was the penetration found to be greater than 4% when the relative humidity was less than 85%. Figure 4.7 of Reference 6.5-3, based on 7 different tests, indicates a generally low penetration (less than 1%) for elemental iodine for all relative humidity conditions.

It was also determined that demisters were not necessary for the RERS. This conclusion is based on the following analysis of a postulated situation in which water droplets are assumed to be formed from system leakage and the possible migration paths of this leakage to the RERS filters.

The estimated leakage from the drywell/suppression pool to the reactor enclosure is limited by several mechanisms. These are:

a. The limit of 0.5% per day air leakage imposed by the containment leak test Technical Specification, the periodic integrated leak rate test, and individual valve leak tests. The 0.5% per day leak rate corresponds to approximately 1.4 cfm, which dictates only pinhole-size leak paths. These small leak paths serve to condense moisture and preclude droplet formation.

b. The programs of preventive maintenance implemented by NUREG-0737, Item III.D.1.1 to minimize system leakage. This program includes helium leak detection for gaseous systems and liquid detection/inspection for liquid-containing systems.

c. The postulated passive failure of an RHR pump seal and resulting release of liquid. The licensee’s preventive maintenance program will maintain normal plant leaks to low flow dripping type leakages. Any leakages with spraying water droplets will be identified and corrected as part of the maintenance program. However, for the purpose of this discussion, a postulated passive failure of an RHR pump seal is assumed (SRP 15.6.5, Appendix B). This assumption results in a 5 gpm leak of suppression water at less than 212°F (Figure 6.2-9) and may produce water spray into the air. Because the water is below the boiling point, the airborne water will fall to the floor and subsequently into the floor drains with little or no flashing.

   If water should be sprayed from the passive failure, it can be shown that any droplets formed travel less than 20 feet, based on analyses of spray systems where the nozzles are designed to maximize the development of water droplets (Reference 6.5-1). These analyses have shown that 1000 micron droplets would travel no more than 20 feet in a horizontal direction with an initial velocity of 3000 ft/sec. The travel distance from the RHR pump seal to the local RERS exhaust vents is approximately 29 feet vertically and 10 feet horizontally. No droplets will reach the exhaust duct.

   Another factor virtually eliminating the potential for water droplets to travel as far as 20 feet is the effect of the unit coolers in the ECCS rooms. These coolers have flow

rates of 9000 cfm to 22,000 cfm. The major objective of the unit coolers is to ensure cool ambient air in the RHR room and to condense excess water vapor. The RHR pump rooms have unit coolers, each operating at 21,800 cfm. The unit cooler air flow competes with the 310 cfm RERS exhaust air flow. Over 95% of the moisture in the air will go through the unit coolers and not into the duct-work.

If it is hypothetically and nonmechanistically assumed that airborne droplets are available, those water droplets entering the exhaust duct must make an immediate 90° turn. A 155 fpm (1.8 mph) RERS exhaust air velocity is not sufficient to overcome the force of gravity to impart a vertical upward velocity to any water droplets. Over 400 feet of RERS ducting containing valves and dampers and numerous bends and turns (at least 15) exist between the exhaust and the prefilters. This tortuous path results in droplets either falling back or impacting on the walls of the ducting where it will evaporate due to the less than 100% humidity in the air flow.

Furthermore, any water droplets suspended in the small air flow (310 cfm) from the RHR room are diluted by 59,700 cfm entering the RERS from other parts of the reactor enclosure. Because the calculated maximum humidity is less than 76.2%, water droplets carried with the air stream would be evaporated.

Even if water droplets were to reach the RERS filters, the droplets must first pass through the prefilter and the HEPA filters before impacting the charcoal medium. Both of these filters are more efficient at removing water droplets from air than demisters. Water removed would be evaporated in the air due to the maximum humidity being less than 76.2%.

Given these physical conditions and the lack of a significant source of water droplets, there is no need to install a demister on the RERS.

These contributions to the DBA/LOCA are considered in the Section 15.6.5 analysis and in SRP 15.6.5, Appendices A and B.

d. Deleted

6.5.1.3.4 Tests and Inspections

Tests and inspections are described in the applicable items (2, 3, and 7 through 13) in Table 9.4-4. Conformance with Regulatory Guide 1.52 is discussed in Table 6.5-2. The system is preoperationally tested in accordance with the requirements of Chapter 14 and periodically tested in accordance with the requirements of Chapter 16.

6.5.1.3.5 Instrumentation

The RERS can be actuated manually from the control room by tripping the reactor enclosure isolation system. Each RERS train is designed to function automatically upon receipt of a reactor enclosure isolation signal. The status of system equipment, which is an indication of pertinent system pressure drops and temperatures, is displayed in the control room during both normal and accident operation.

All instrumentation required during and after accident conditions is designed to seismic Category I requirements. Instrumentation conformance with Regulatory Guide 1.52 is discussed in Tables 6.5-2 and 6.5-8.

The following alarms are annunciated in the control room:

a. Fan trouble (including valve circuit trouble and charcoal temperature detection system trouble)

b. Charcoal filter high temperature alarms

ESF atmosphere cleanup systems are accessible during normal operation and during anticipated transients. ESF atmosphere cleanup systems operate only after an accident or during drywell purge. This allows operation on all ESF atmosphere cleanup systems, which ensures that prefilters and HEPA filters are either changed on high pressure readings or checked on abnormal readings.

6.5.1.3.6 Materials

The materials of construction used in or on the RERS are given in Table 6.5-7.

Materials used in or on the RERS are selected to ensure that system operability is not affected by radiation, temperature, or other environmental effects. Environmental qualification of the RERS is discussed in Section 3.11.

Filter materials used will not decompose due to radiation during the specified useful life of the filter.

6.5.2 CONTAINMENT SPRAY SYSTEM

The containment spray cooling subsystem, which is one of the five modes of operation of the RHR system, is not designed to perform a fission product removal function following a DBA. The containment cooling subsystem is described in Section 6.2.2.

6.5.3 FISSION PRODUCT CONTROL SYSTEMS

6.5.3.1 Primary Containment

The primary containment structure is in the form of a truncated cone (the drywell) over a cylindrical section (the suppression chamber). Its pressure-suppression concept is the GE Mark II design. The primary containment is made of reinforced concrete, and it is lined with welded steel plate and provided with a steel domed head. The structural design of the primary containment is discussed in Section 3.8. Plan and elevation views of the primary containment are shown in Figures 3.8-1 through 3.8-8.

The primary containment walls, liner plate, mechanical penetrations, isolation valves, hatches, and locks function to limit release of radioactive materials, subsequent to postulated accidents, so that the resulting offsite doses are less than the dose limits of 10 CFR 50.67. Primary containment parameters affecting fission product release accident analyses are given in Section 6.2.1. Fission product removal systems are discussed in Section 6.5.1. Operation of the primary containment purge system during normal conditions is described in Section 9.4.5.1. This system isolates as described in Section 6.2.4. As discussed in Section 6.2.5, a low volume containment purge capability is provided as a backup to the containment hydrogen recombiner system. If placed into operation, the ESF filtration systems (RERS and SGTS) would process the low volume purge exhaust flow prior to its release.

6.5.3.2 Secondary Containment

The secondary containment completely encloses both primary containments and is provided to contain leakage from the primary containments so that any such leakage can be processed by filtration systems prior to release to the environment. The secondary containment boundary is formed by the exterior walls of the reactor enclosures and the refueling area, with the exception of the fan rooms on el 313' and el 331'. These fan rooms are not within the secondary containment, and the interior walls which separate them from the remainder of the reactor enclosure form a portion of the secondary containment boundary. The design of the secondary containment is discussed in Section 3.8.4, and plan and elevation views of the reactor enclosure are shown in drawings M-116, M-117, M-118, M-119, M-120, M-121, M-122, M-123, M-131, M-132, M-133, M-134, M-135, M-136, M-137, and M-138.

Two systems are provided for removal of fission products from reactor enclosure air following a DBA. These systems are the RERS and the SGTS, both of which are described in Section 6.5.1. Drawdown of the reactor enclosures by the SGTS following a postulated accident to establish a negative relative pressure with respect to the outside is discussed in Section 6.2.3.

The SGTS also provides for the drawdown of the refueling area to a negative relative pressure with respect to the outside following a fuel handling accident. As described in the LGS Technical Specifications, SGTS is only required to be aligned to the refueling area during handling of recently irradiated fuel and during water inventory control actions.

Section 9.4.2.1.3 gives details of secondary containment isolation modes (REIS, RAIS) versus the various secondary containment isolation signal inputs.

6.5.4 ICE CONDENSER AS A FISSION PRODUCT CLEANUP SYSTEM

LGS does not have an ice condenser system.

Position k	Not applicable. No outdoor air intake	Not applicable. No outdoor air intake	Conforms

Table 6.5-2 (Cont'd)

REGULATORY POSITION	(SGTS)	(RERS)	CREFAS
Position l	Does not conform. Allowable leak rate: (1) filter housing, 0.1% of rated flow at 125% negative pressure, which complies with the 1973 original version of Regulatory Guide 1.52; (2) fan discharge gas-tight duct-work, 0.1% scheduled air flow, multiplied by ratio of the volume of duct being tested to the total volume of the duct run; (3) fan suction duct, 1% of scheduled air flow, multiplied by ratio of the volume of duct being tested to the total volume of the duct run. The system is considered not to be in a high radiation zone.	Does not conform. Allowable leak rate: (1) filter housing, 0.05% of rated flow at 125% negative design pressure, which complies with the 1973 original version of Regulatory Guide 1.52; (2) gas-tight duct-work, 0.1% of scheduled air flow, multiplied by ratio of volume of duct being tested to the total volume of the duct run; (3) standard duct, 1% of scheduled air flow, multiplied by ratio of the volume of duct being tested to the total volume of the duct run. The system is considered not to be in a high radiation zone.	Does not conform. Allowable leak rate: (1) filter housing, 0.05% of rated flow at 125% negative pressure, which complies with the 1973 original version of Regulatory Guide 1.52; (2) duct-work, 0.1% of scheduled air flow, multiplied by ratio of the volume of duct being tested to the total volume of the duct run. The system is considered not to be in a high radiation zone.
C.3. Component Design Criteria and Qualification Testing			
Position a	Not applicable. Demisters are not included.	(Same as SGTS)	(Same as SGTS)
Position b	Partially conforms. Two automatic reset cut-outs set at 180°F and 260°F.	Not applicable. Heaters are not included.	Conforms
Position c	Conforms[3]	Conforms	Conforms

Table 6.5-2 (Cont'd)

REGULATORY POSITION	(SGTS)	(RERS)	CREFAS
Position d	Partially conforms. HEPA filters meet requirements in this paragraph. However, testing will not be performed in ERDA test facilities. Shop tests and field tests are considered adequate.	(Same as SGTS)	(Same as SGTS)
Position e	Conforms	Conforms	Conforms
Position f	Partially conforms. HEPA filters are arranged 3 wide by 4 high and are serviced by a stepladder.	Does not conform. Because of space restrictions(1), the system is rated at 60,000 cfm. HEPA filters are arranged 8 wide by 5 high. Platforms are provided in the plenum to service the filter.	Partially conforms. Filter arrangement meets general guideline, except that service aisles between filter banks are narrower than recommended.
Position g	Partially conforms. Housing design generally conforms with ANSI N509 (1976) section 5.6, except that view ports are not included.	(Same as SGTS)	(Same as SGTS)
Position h	Conforms	Conforms	Conforms
Position i	Partially Conforms(2) (5)	Conforms(2)	Conforms(2)
Position j	Conforms	Conforms	Conforms
Position k	Conforms	Conforms	Conforms
Position l	Conforms	Conforms	Conforms
Position m	Conforms	Conforms	Conforms

	Position p	Conforms	Conforms	Conforms
C.4.	Maintenance			
	Position a	Conforms	Conforms	Conforms
	Position b	Conforms	Does not conform. Because of space restrictions(1), distance between filter banks is less than recommended.	(Same as RERS)
	Position c	Partially conforms. There are 4 charcoal test canisters provided rather than 6.	Conforms	Conforms
	Position d	Does not conform. SGTS trains continuously purged when the filters are not in use with dry instrument air to prevent build-up of moisture.	(Same as SGTS)	(Same as SGTS)
	Position e	Conforms	Conforms	Conforms
C.5.	In-Place Testing Criteria			
	Position a	Conforms(4)	Conforms(4)	Conforms(4)
	Position b	Conforms(4)	Conforms(4)	Conforms(4)
	Position c	Partially conforms. (4) HEPA filters are tested to re-quirements of this paragraph. However, testing will be performed at least once per 48 months rather than 18 months.	(Same as SGTS)	(Same as SGTS)
	Position d	Partially conforms.(4) Acti-vated carbon adsorber sections are tested to re-quirements of this paragraph. However, testing will be performed at least once per 24 months rather than 18 months.	(Same as SGTS)	(Same as SGTS)

Table 6.5-2 (Cont'd)

REGULATORY POSITION		(SGTS)	(RERS)	CREFAS
C.6.	Laboratory Testing Criteria for Activated Carbon[2]			
	Position a	Partially conforms. The Laboratory analysis of new and used carbon samples is performed in accordance with ASTM D3803-1989.	(Same as SGTS)	(Same as SGTS)
	Position b	Partially conforms. Activated carbon adsorber sections are tested to requirements of this paragraph. However, testing will be performed at least once per 24 months rather than 18 months. Additionally, the laboratory analysis of carbon samples is performed in accordance with ASTM D3803-1989.	(Same as SGTS)	(Same as SGTS)

(1) The LGS air filter systems were designed before the issuance of Regulatory Guide 1.52 in 1973. The filter design details have been studied in accordance with the regulatory guide and it was found that the filter performs satisfactorily although the design is not in strict conformance with the regulatory guide.

(2) Each original or replacement batch of impregnated activated charcoal used in the adsorber section meets the qualification and batch test results of ANSI N509 (1980). Laboratory tests of charcoal samples meeting the requirements of Position C.6 of Regulatory Guide 1.52 can be performed in accordance with ANSI N509 (1980) except that the laboratory analysis of carbpon samples is performed in accordance with ASTM D3803-1989.

(3) The prefilters in the RERS act as prefilters for the SGTS during reactor enclosure isolation. The prefilters in the SGTS duct from the refueling area act as prefilters for the SGTS during refueling area isolation.

(4) To ANSI/ASME N510 (1980) testing criteria.

(5) The air residence time in the 8 inch bed is 0.68 seconds considering a maximum total post inleakage rate from Zones I, II, and III of 5764 cfm.

Table 6.5-3

STANDBY GAS TREATMENT SYSTEM FAILURE MODES AND EFFECTS ANALYSIS

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Emergency	Power supply	Total LOOP	None. All units are powered from separate standby diesel generators.	Alarm in the control room	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Exhaust fans	Loss of one fan	The standby fan automatically starts.	Low flow indication in the control room	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Electric heaters	Loss of electric heater	Efficiency of of charcoal adsorber may decrease if the relative humidity is above 70%. The operator may manually switch to the standby train.	Temperature indication in the control room	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Upstream & downstream HEPA filters	High differential pressure across the filter bank.	The fan recirculation dampers modulate in sequence to maintain airflow. However, if the system flow rate drops below the setting of the fan flow switch, the standby fan automatically starts and the filter train is manually switched to standby train	Low flow indication in the control room	No loss of safety function

.

Table 6.5-3 (Cont'd)

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Emergency (LOCA or LOCA & LOOP)	Charcoal adsorbers	High-high-high temperature	At ignition temperature setting the fire protection system is manually actuated.	Temperature indication in the control room.	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	RERS to SGTS transfer valves	Valve fails to open	None. Valves are redundant and parallel. Normally closed valves fail open.	SGTS flow indication in the control room	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Fans inlet dampers	Damper fails closed	None. These dampers are redundant - standby unit will operate.	Flow indication and damper position indication in the control room	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Charcoal filter inlet valves and outlet valves	Valve fails closed	None. The valves are redundant - the standby unit will operate.	Flow indication in the control room	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Fans recirculation dampers	Dampers fail closed	None. These dampers are designed to fail closed. If the damper fails, this will increase a demand for more makeup air, and fans will attempt to deliver maximum flow.	Flow indication in the control room.	No loss of safety function
Emergency (LOCA or LOCA & LOOP)	Refueling Area to SGTS transfer valve	Valve fails open[1]	None. The refueling area is automatically isolated. The SGTS will drawdown both the reactor enclosure and refueling area.	Flow indication in the control room	No loss of safety function
Emergency (Fuel Handling Accident)	Refueling Area to SGTS transfer valve	Valve fails to open	None.Valves are redundant and parallel. Normally closed valves fail open.	SGTS flow indication in the control room	No loss of safety function

Table 6.5-3 (Cont'd)

PLANT OPERATING MODE	SYSTEM COMPONENT	COMPONENT FAILURE MODE	EFFECT OF FAILURE ON THE SYSTEM	FAILURE MODE DETECTION	EFFECT OF FAILURE ON PLANT OPERATION
Emergency (Fuel Handling Accident)	RERS to SGTS transfer valve	Valve fails open[1]	None. The corresponding reactor enclosure is automatically The SGTS will drawdown the refueling area and that Unit's reactor enclosure.	Flow indication in the Control isolated.	No loss of safety function Room
Emergency (Unit LOCA or LOOP)	The other Unit RERS to SGTS transfer valve	Valve fails open[1]	None. The other Unit reactor enclosure is automatically isolated. The SGTS will drawdown both reactor enclosures.	Flow indication in the Control Room	No loss of safety function

Note: The SGTS is a common system.

(1) Any combination of valve failures which result in either a 2 or 3 zone isolation will not affect SGTS operation. The SGTS has a design flow of 8400 cfm which is adequate to restore and maintain the required pressure in both reactor enclosures and common refueling area.

System inlet to outlet	-	Summation of pressure drop across total system, high alarm signal.	Provided	Provided	Provided

(1) Regulatory Guide 1.52, ANSI-N509, and SRP Table 6.5.1-1 were originally issued after the LGS system design and therefore were not specifically considered in the design.

(2) The SGTS flow rate is variable to draw down and maintain the reactor enclosure/refueling area at a negative 0.25 in wg. Local flow indication does not provide meaningful information in terms of system operability. Flow indication is provided in the control room where this information, in addition to the reactor enclosure/refueling area pressure differential indicators, is available for operator evaluation of system performance.

(3) Low flow switch operates on loss of flow only.

Table 6.5-8 (Cont'd)

(4) Maximum SGTS flow occurs only during drawdown. As thermodynamic equilibrium is approached within the reactor enclosure and/or refueling area during isolation, the SGTS flow decreases to the design inleakage rate.

(5) The RERS does not operate during normal plant operation. The RERS flow is recirculated within the reactor enclosure during isolation and is not directly released to the environment.

(6) Outdoor air requirements are governed by the control room leak-tightness needed to maintain a positive pressure. High flow through the filtration system due to the failure of FD-C-78-011A in an open position will result in additional recirculation flow rather than additional unfiltered outdoor air. Control room pressure differential is indicated in the control room.

(7) Electric heater does not operate continuously during EFA system operation. Local temperature and humidity indicator controllers are provided to assess system operation.

(8) Local panels are not continuously manned to observe alarm signals.

(9) The Emergency Fresh Air system air is made up of approximately 90% recirculation air from the control room and 10% outdoor air to maintain the control room at a positive pressure. If the heater fails to operate, the temperature of the resultant air mixture will be similar to the control room even during winter conditions. Therefore, a low temperature alarm is not essential. The Emergency Fresh Air heaters are provided with automatic and manual high temperature cutouts to prevent overheating of the heater elements. Radiation monitors are provided downstream of the Emergency Fresh Air system filters and will alarm on high radiation in the event of unacceptable air quality.

(10) ESF systems do not operate continuously, and routine system testing will ensure that filter changeout requirements will be met.

(11) General trouble alarm for local panel OOC926 when any deluge valve is opened.

6.6 PRESERVICE/INSERVICE INSPECTION OF CLASS 2 AND 3 COMPONENTS

The construction permits for the LGS Units 1 and 2 were issued in June 1974. Based on this date, 10CFR50.55a required that the PSI program for the Class 2 and 3 components meet the examination requirements set forth in ASME Section XI, 1971 edition with addenda through Winter 1972 or alternatively, the examination requirements of the subsequent editions and addenda, subject to the limitations and modifications listed in 10CFR50.55a. The LGS PSI programs followed the alternative requirements.

Specifically, the Unit 1 Class 2 and 3 component PSI program (except operability testing of safety-related pumps and valves) meets the requirements of ASME Section XI, 1974 edition with addenda through Summer 1975, as modified by Appendix III of the Winter 1975 Addenda and paragraph IWA-2232 of the Summer 1976 Addenda.

At the time the LGS PSI program commenced, the latest edition of the code permissible for use was the Summer 1975 Addenda. In an effort to take advantage of improved UT methods, Appendix III of the Winter 1975 Addenda and paragraph IWA-2232 of the Summer 1976 were used. Although these items are not specifically referenced by 10CFR50.55a, they are equivalent to the comparable portions of the subsequently approved ASME Section XI of Summer 1978 Addenda as long as Section XI Appendix III indications greater than 50% DAC are recorded. The LGS ISI procedures do record such indications.

Supplement 7 of Appendix III permits the use of Appendix III for austenitic piping welds with certain modifications. It is our position, consistent with the PSI/ISI industry, that Appendix III (at 50% DAC recording) is more appropriate for austenitic piping weld examination than Article 5 of ASME Section V. Thus for austenitic piping welds:

a. All of the Supplement 7 modifications are being used.

b. Examination sensitivity is ensured through the calibration process.

c. Where one-sided access only occurs and penetrations cannot be confirmed, a one-sided access limitation is noted in the data package for that weld.

When using Section XI, Appendix III for either ferritic or austenitic piping welds, the following applies:

a. All indications showing signal amplitudes equal to or in excess of 20% of the reference response are evaluated to the extent that the level II or level III examiner can determine their true nature.

b. The owner evaluates and takes corrective action for the disposition of any indication investigated and found to be other than geometrical or metallurgical in nature.

The Unit 2 Class 2 and 3 component PSI program and Units 1 and 2 programs for the preservice testing of safety-related pumps and valves meet the requirements of the Section XI Code, 1980 edition with addenda through Winter 1981.

For certain ASME Section XI requirements that have been determined to be impractical in the course of inspecting the components, the licensee has submitted and will submit requests for relief from the requirements to the NRC in accordance with the provisions of 10CFR50.55a.

In accordance with 10CFR50.55a, throughout the service life, Class 2 and 3 components (including supports) will meet the ISI requirements, except design and access provisions and preservice examination requirements, set forth in the ASME Section XI edition and addenda that become effective, to the extent practical within the limitations of design, geometry, and materials of construction of the components. In accordance with 10CFR50.55a, inservice examinations of components, inservice tests to verify operational readiness of safety-related pumps and valves, and system pressure tests conducted during the initial 10 year inspection interval will comply with ASME Section XI edition and addenda in effect 12 months prior to the date of issuance of the operating license. In accordance with 10CFR50.55a, the initial 10 year inspection interval commences with commercial operation. The successive 10 year inspection intervals will comply with ASME Section XI edition and addenda in effect 12 months prior to the start of the 10 year inspection interval.

6.6.1 COMPONENTS SUBJECT TO EXAMINATION

LGS piping was originally designed to ANSI B31.7. For inservice inspection, ANSI B31.7 Classes II and III are considered equivalent to ASME Section III, Classes 2 and 3. The PSI/ISI program includes figures showing the systems or portions of systems within the scope of the Section XI Code. The applicable PSI/ISI programs are described in References 6.6-1 through 6.6-7. Any necessary requests for relief are addressed in these documents.

There is a Risk Informed Categorization and Treatment Program at Limerick which is based on 10 CFR 50.69. This regulation provides an alternative approach for establishing requirements for treatment of SSCs using a risk-informed method of categorizing SSCs according to their safety significance. Specifically, for SSCs categorized as low safety significant, alternate treatment requirements may be implemented rather than treatments chosen by the ISI program. Refer to Section 13.5.5 for further information.

6.6.2 ACCESSIBILITY

a. Sufficient space is provided for personnel and equipment so that examinations of Class 2 and Class 3 piping and components can be performed, as required by the Code.

   1. Piping welds - The access provided for Class 2 system components depends on whether ultrasonic, surface, or visual examinations are performed.

   2. Pumps and valves - Space is provided to disassemble and reassemble the pump or valve. For visual examination, sufficient lighting and access space is provided to permit examination of the inner surface. For ultrasonic examination, access for equipment is provided, depending on the specific design of the weld.

   3. Supports - Access provisions for supports requiring examination are provided and depend on the specific type and design detail of the support.

   4. Pressure welds - Access is provided for the inspection of pressure-retaining welds, vessel supports, and pressure-retaining bolting.

b. Capability for the removal and temporary storage of structural members, shielding components, and insulation is provided.

c. Hoists and other handling machinery necessary to support ISI are provided.

d. Equipment and personnel for alternative examinations that may be required will be provided.

e. Repair and replacement operations are provided for system components and parts, where necessary.

6.6.3 EXAMINATION TECHNIQUES AND PROCEDURES

a. The techniques and procedures for surface, visual, and volumetric examinations are in compliance with IWA-2200 of the Section XI Code.

b. Alternate examination methods are acceptable, provided that the results are equal or superior to the methods of IWA-2200. The acceptance criteria for alternate examination methods are in accordance with IWA-3100 of the Section XI Code.

6.6.4 INSPECTION INTERVALS

The examinations required by IWC-2400 for Class 2 system components and by IWD-2400 for Class 3 system components will be performed on the basis of a 10 year interval, hereafter known as the inspection interval.

6.6.5 EXAMINATION CATEGORIES AND REQUIREMENTS

The PSI/ISI program provides a listing of the Class 2 and 3 components or parts including the Section XI Code item number, examination category, the required method of examination, and the extent and frequency of examination. The applicable PSI/ISI programs are identified in References 6.6-1 through 6.6-7.

6.6.6 EVALUATION OF EXAMINATION RESULTS

The standards for evaluation of results and repair procedures are in accordance with Articles IWB-3000 and IWA-4000. Where acceptance standards are still in preparation, IWA-3100 shall apply. The ISI program for the first and successive inspection intervals will use the articles in IWC and IWD as they are issued and approved. Summary reports for the RPV and piping PSI were submitted 90 days after commercial operation, in accordance with subarticle IWA-6220.

6.6.7 SYSTEM PRESSURE TESTS

The system pressure tests will be performed in accordance with the general requirements of IWA-5000 and the specific requirements of IWC-5000 and IWD-5000 for Class 2 and 3 components, respectively.

6.6.8 AUGMENTED INSERVICE INSPECTION TO PROTECT AGAINST POSTULATED PIPING FAILURES

Class 2 and 3 components will receive augmented inservice inspection in accordance with the documents listed below to the extent specified in the applicable PSI/ISI programs identified in References 6.6-1 through 6.6-7.

a. NUREG-0313, Revision 1, July 1980, "Technical Report on Material Selection and Processing Guidelines for BWR Coolant Pressure Boundary Piping" (see resolution of USI A-42, Section 1.12.2). Revision 1 of this NUREG is applicable prior to issuance of Generic Letter 88-01.

   In accordance with Generic Letter 88-01, the criteria of NUREG-0313, Revision 2, January 1988 are applicable for LGS Units 1 and 2. The ISI Program for weldments in piping shall be performed in accordance with the NRC staff positions and criteria addressed in Generic Letter 88-01 and BWRVIP-75-A, "BWR Vessel and Internals Project Technical Basis for Revisions to Generic Letter 88-01 Inspection Schedule." Details for schedule, methods, personnel, and sample expansion shall be included as augmented inspection requirements. Response to the Generic Letter 88-01 was provided per letter from S.J. Kowalski (PECo) to F.J. Miraglia, Jr. (NRC), dated August 2, 1988. The ISI Program for weldments in piping shall be performed in accordance with the NRC staff positions and criteria addressed in Generic Letter 88-01. Details for schedule, methods, personnel, and sample expansion shall be included as augmented inspection requirements.

b. BTP MEB 3-1 (NUREG-0800) addresses high energy piping between containment isolation valves and first outboard restraint for which no breaks are postulated

In addition, high energy fluid system piping between containment isolation valves will receive an augmented examination as follows:

a. Protective measures and structures are located, to the greatest extent possible, so as not to prevent access for inservice inspections.

b. High energy fluid system piping between containment isolation valves is required to be either 100% volumetrically examined (both circumferential and longitudinal welds) during each examination interval or examined in accordance with the Risk Informed Inservice Inspection Program as applied to these welds.

c. High energy piping requiring ISI receives a baseline (preservice) examination to establish the integrity of the original condition of the welds.

d. Augmented examination for high energy piping is maintained out to outboard restraints.

e. Welds between outboard containment isolation valves and piping restraints will be included in the PSI and the ISI plans.

6.7 MSIV LEAKAGE ALTERNATE DRAIN PATHWAY

The MSIV Leakage Alternate Drain Pathway prevents a direct release of fission products that could leak through the closed MSIVs after a LOCA. The pathway provides control by providing a hold-up volume for the MSIV leakage before release to the atmosphere. This is accomplished by directing the leakage through existing Main Steam Drain Lines to the High Pressure Shell of the Main Condenser.

6.7.1 DESIGN BASES

6.7.1.1 Safety Criteria

The following criteria represent pathway design, safety, and performance requirements imposed on the MSIV Leakage Alternate Drain Pathway.

a. The MSIV Leakage Alternate Drain Pathway is evaluated to have sufficient capacity and capability to control the leakage from the MSIVs, consistent with containment leakage limits imposed for the conditions associated with a postulated design basis LOCA. Specifically, a complete severance of a recirculation line does not permit an offsite dose to exceed the requirements of 10CFR50.67.

b. The MSIV Leakage Alternate Drain Pathway has been evaluated to demonstrate that the main system piping and equipment are seismically rugged and meet the requirements of 10CFR Part 100, Appendix A.

c. The MSIV Leakage Alternate Drain Pathway is capable of performing its safety function following a LOCA with Loss of Offsite Power. The Pathway is not single failure proof, but there are alternate unanalyzed pathways which will serve to direct any MSIV leakage to allow for reducing the offsite dose.

d. The MSIV Leakage Alternate Drain Pathway is manually actuated, and designed to permit actuation within about 20 minutes, but no earlier than 10 minutes, after a postulated design basis LOCA. This time period is considered to be consistent with loading requirements of the Class 1E electrical buses and with reasonable times for operator action.

6.7.1.2 Regulatory Acceptance Criteria

The piping and the components of the MSIV Leakage Alternate Drain Pathway have been evaluated to confirm the capability of the main steam piping and condenser to serve as an alternate leakage pathway. Seismic verification walkdowns have been performed to assure that the MSIV, the steam drain lines, the condenser and interconnecting piping and equipment that are not seismically analyzed fall within the bounds of the design characteristics of the seismic experience database as discussed in reference 1.

6.7.2 SYSTEM DESCRIPTION

The MSIV Leakage Alternate Drain Pathway is credited in the Radiological Dose Calculations for Limerick Generating Station. The pathway serves as a "hold-up" volume for processing of a potential release of fission products that could leak through the closed MSIV's during a Loss of Coolant Accident (LOCA). This pathway limits the calculated doses from the MSIV Leakage to within the requirements of 10CFR50.67 for offsite releases and GDC 19 for local area access. The system has been evaluated to adequately handle the Technical Specification allowed MSIV leakage.

The design boundaries of the MSIV Leakage Alternate Drain Pathway are defined as follows. The designated boundary (block) valves (HV-1(2)08, HV-1(2)09, HV-1(2)11, HV-1(2)50, Main Turbine Stop Valves (MSTV), and Main Turbine Bypass Valves (MTBV)) will function to contain the MSIV leakage in the drain pathway. The boundary valves also identify the functional and design boundary of the "MSIV Leakage Alternate Drain Pathway." All other lines which interface with the designated drain pathway are shown in the applicable drawings and UFSAR Figures (drawings M-01, M-41, M-49, M-55, and Figure 10.4-4) will either be described below as a drain pathway, or lead back through Seismic Category I/IIA piping back into containment (primary or secondary) and as such do not represent potential leakage pathways.

There are three potential leakage pathways. These pathways are as follows:

1) Flow from all four Main Steam lines directly after the outboard MSIVs, through 2 inch EBB-1(2)05, into 3 inch EBB-1(2)05, into 3 inch EBD-1(2)08, into 4 inch EBD-1(2)08, discharging into the H.P. Condenser.

2) Flow from the above seat drain on the Main Stop Valves through 1 inch EBD-*, into 2 inch EBD-1(2)15, into 4 inch EBD-1(2)08, discharging into the H.P. Condenser.

3) Flow from all four Main Steam lines directly before the Main Stop Valves through 1 inch EBB-1(2)01(2,3,4), into 2 inch EBD-1(2)14, into 2 inch EBD-1(2)15, into 4 inch EBD-1(2)08, discharge into the H.P. Condenser.

Although all three drain pathways are capable of directing leakage to the H.P. Condenser the only credited drain line is item 1). This is based on the fact that the other drain lines are either not sized properly to ensure adequate flow or require the opening of non-class 1E valves. The primary drain pathway has one normally closed valve in the line (HV-041-1(2)F021). This valve is required to be opened to establish the drain pathway.

The remainder of the system shown in attachment 1 of reference 2, identifies the total scope of the potential pathways which was evaluated during a seismic walkdown, and was in a Design Analysis contained in reference 1 for "Seismic Ruggedness" specified in reference 2.

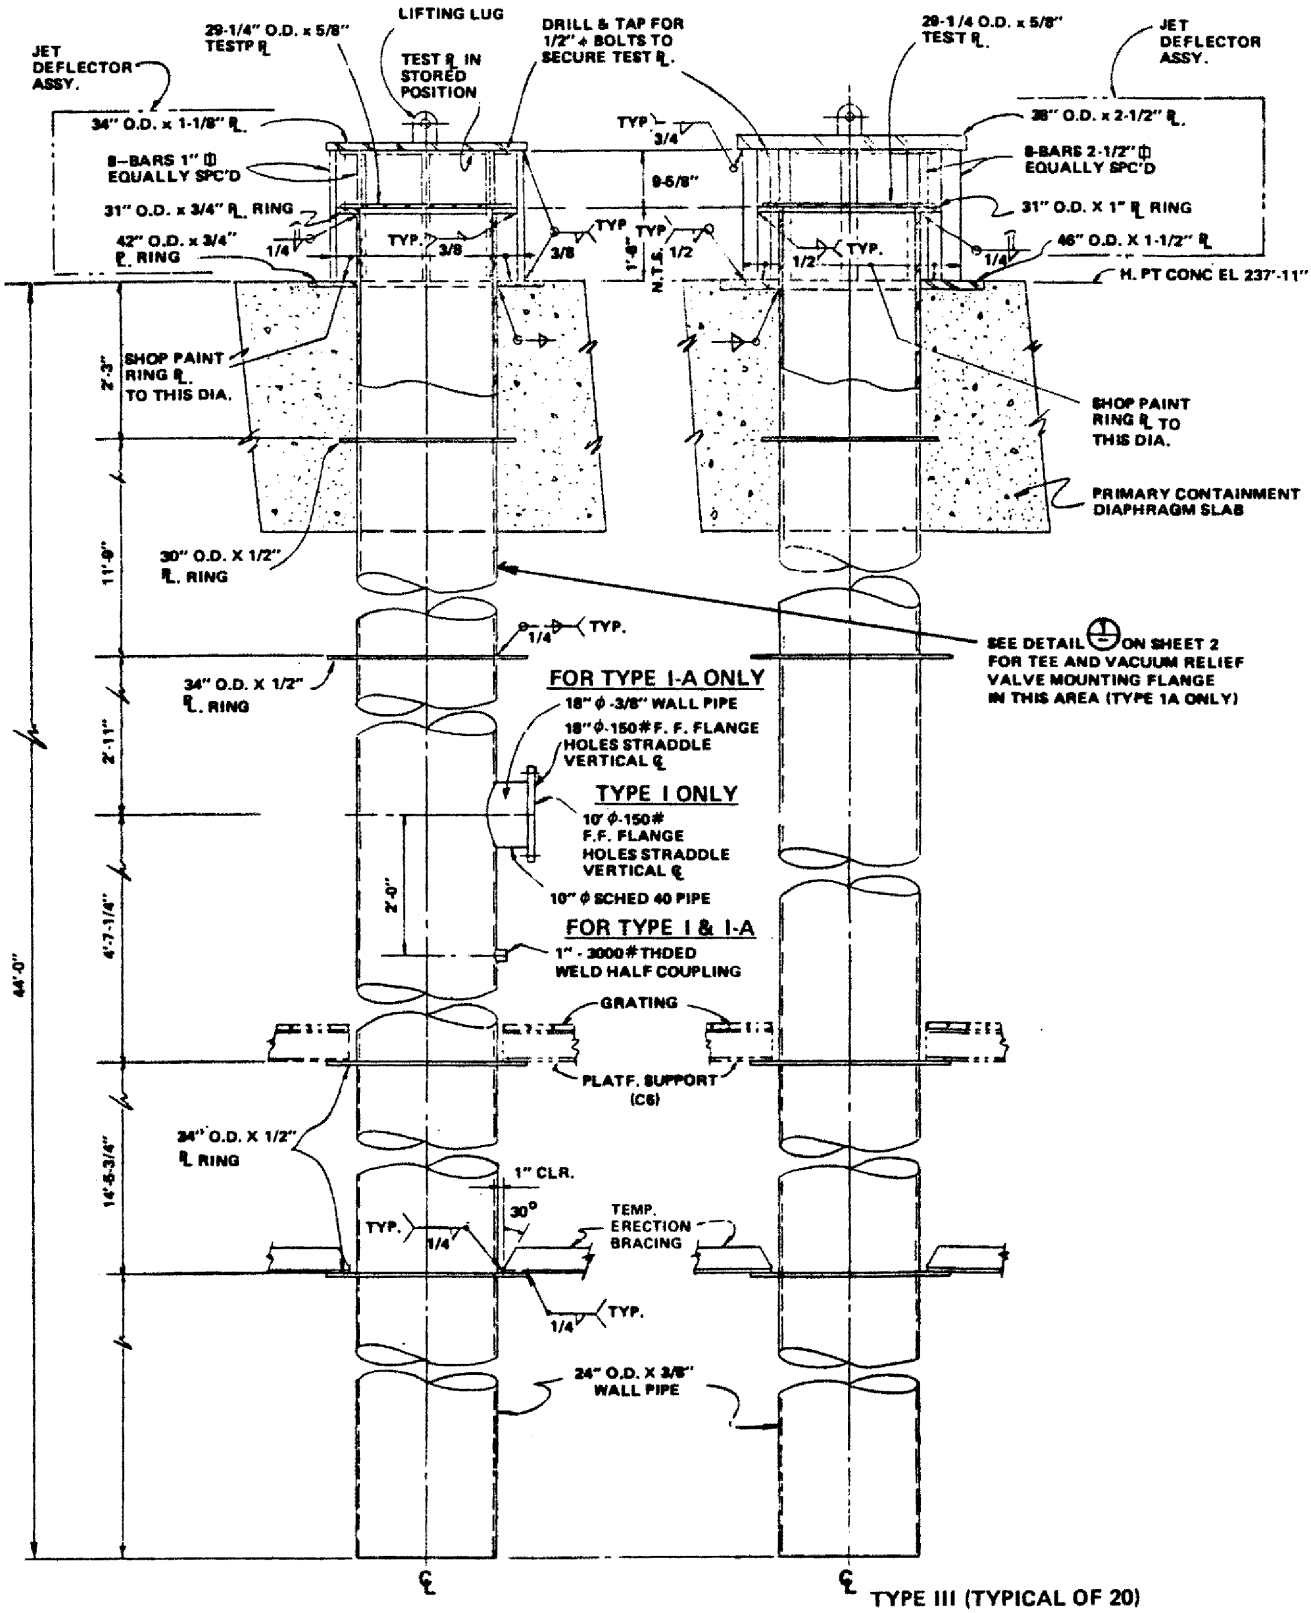
6.7.3 SYSTEM EVALUATION

An evaluation of the capability of the MSIV Leakage Alternate Drain Pathway to control the release of radioactivity from the MSIVs during and following a LOCA has been conducted. A summary of the evaluation is contained in reference 2. In addition, the results of the radiological evaluations are contained in section 15.6.5.

6.7.4 INSTRUMENTATION REQUIREMENTS

There are no specific instrumentation requirements for this pathway since there are no automatic actions required. The operational requirements of the pathway only require the capability to reposition one valve identified in section 6.7.2 .

6.7.5 Inspection And Testing



The valves required to be repositioned are tested in accordance with the requirements of the Inservice Testing Program.

6A.0 INTRODUCTION

NOTE: The subcompartment differential pressure inputs values and analysis results presented in this section for the recirculation line and feedwater line breaks are based on the original design basis conditions. The blowdown mass and energy releases for the recirculation line and feedwater line breaks were reanalyzed at power rerate conditions. Based on the power rerate analyses, the original analyzed load bounds rerate conditions. Therefore, the shield wall design is not affected by power rerate. The drywell head region pressurization analysis presented in this section was reanalyzed for power rerate conditions. The resulting pressure differential at power rerate conditions is well below pressure differential for the drywell head region.

Differential pressure analyses were performed for the RPV shield annulus and the drywell head region.

The RPV shield annulus, which is 48.95 feet high and 1.70 feet wide at the top, has the 28 inch recirculation pumps suction lines passing through it. The mass and energy release rates from a postulated recirculation outlet line break constitute the most severe transient in the reactor shield annulus. Therefore, this pipe break is selected when analyzing loading of the shield wall and the RPV support skirt for pipe breaks causing annulus pressurization. The estimation of mass and energy release is based on the guidelines set forth in GE's "Generic Annulus Pressurization Mass-Energy Release Methodology" (MFN178-78) and "Technical Description Annulus Pressurization Load Adequacy Evaluation" (NEDO-24548/78NED302). Table 6A-1 presents the full mass and energy release data estimated by applying the finite break opening time/instantaneous break opening time approaches. Because the break location is more than three-fourths of the distance through the penetration, it is conservatively assumed that 50% of the blowdown is released into the annulus, and the remaining 50% is vented to the drywell atmosphere. Table 6A-2 provides, as a function of time, the mass flux and areas used for each side of the break. Physical parameters pertinent to the blowdown rate estimation are noted in the table.

In addition to the analyses for the recirculation outlet line break in the annulus, similar analyses using the same methodology for blowdown rate estimation are performed for a postulated feedwater line break in the annulus. Table 6A-3 presents the mass and energy release rates generated by only applying the very conservative instantaneous break opening time method. Also, it is conservatively assumed in the analyses that the full blowdown is completely released into the annulus. The mass flux as a function of time and areas used for each side of the break are presented in Table 6A-4. Pertinent physical parameters are noted in the table.

Because the main steam lines are not inside the annulus and the recirculation inlet lines are smaller than the outlet lines, the annulus pressurization analyses for these two cases are not needed.

In considering the drywell head region, the maximum blowdown rate stems from a break in the RHR head spray line. The blowdown mass and energy release rates for this line are calculated using Moody Critical Flow of 2800 $lb_m/sec\text{-}ft^2$ and an enthalpy of 1192 Btu/lb_m for the original power level. Pressurization consequences at 3527 MWt are based on the original effects and a multiplier. This multiplier is calulated from the effects of the 3527 MWt on the blowdown mass and energy release rates.. Table 6A-5 shows the blowdown schedule for a 6 inch Schedule 80 line break with an effective break area of 0.181 ft^2. Since this line could singularly pressurize the drywell head region, it is chosen for analysis in a postulated break. The head spray line does not

exist for Unit 2 and has been removed from Unit 1. However, the analysis is still applicable since it envelopes loads from rupture of any other pipe in this region.

All differential pressure analyses were performed according to the analytical techniques described in Reference 6A-1. These adjusted pressures are combined with the other appropriate loads (e.g., seismic and jet impingement) to develop design loads for the affected structures and components. Subcompartment venting is used to ensure that the differential pressures developed will remain below the structural capability of compartment walls.

Mass and energy release rates using the NEDO-20533 methodology for a recirculation line break are shown in Table 6.2-10. Short-term release rates based on NEDO-24548 are shown in Table 6A-1. Comparison of these two tables indicates that mass flow rates and enthalpy calculated using NEDO-24548 are less than the conservative values produced using assumptions consistent with NEDO-20533.

Recirculation line break blowdown data used for containment analysis are based on assumptions and calculations made specifically for the LGS units. These assumptions and calculations are discussed in NEDO-10320 (Reference 6.2-5), which follows the methodology outlined in NEDO-20533. This model has been shown to be quite conservative for long-term containment analysis.

However, for the special cases required to analyze pressurization of the annulus due to a recirculation line or feedwater line break, a more detailed model is used. The NEDO-24548 model for short-term mass and energy release includes the effects of inventory and subcooling for flow rates during the first 5 seconds. Credit may also be taken for a finite break opening time. Blowdown rates from NEDO-24548, which calculates the maximum quasi-steady mass flux based on the Moody steady slip flow model with subcooling, are also considered to be conservative estimates of the mass and energy released from the vessel.

6A.1 BIOLOGICAL SHIELD ANNULUS SUBCOMPARTMENT MODELING PROCEDURES AND ANALYSIS

NOTE: The subcompartment differential pressure inputs values and analysis results presented in this section for the recirculation line and feedwater line breaks are based on the original design basis conditions. The blowdown mass and energy releases for the recirculation line and feedwater line breaks were reanalyzed at power rerate conditions. Based on the power rerate analyses, the original analyzed loads bound rerate conditions. Therefore, the shield wall design is not affected by power rerate. The drywell head region pressurization analysis presented in this section was reanalyzed for power rerate conditions. The resulting pressure differential at power rerate conditions is well below pressure differential for the drywell head region.

An analysis was performed of the pressure distribution around the RPV after a recirculation line break. The general layout of the shield annulus is shown in Figures 3.8-1 through 3.8-8 and in 6A-1. Figure 6A-2 is a schematic of the RPV shield annulus model. The model consists of six major levels. Each level is subdivided into twelve 30° segments to form a total of 72 nodes inside the annulus plus an additional node for the rest of the drywell.

The guidelines of GE's "Generic Annulus Pressurization Load Adequacy Evaluation" (NEDO-24548/78NED302) were followed in treating the entire drywell region (volume number 73) as a single compartment in the RPV shield annulus subcompartment analysis. Treating the drywell region as a single compartment reduces the drywell pressure response due to venting from the annulus, resulting in the greatest ΔP across the shield wall.

The 235,200 ft^3 size of the drywell region used in the analysis is a "free volume." The volume occupied by equipment, structures, and floors (i.e.; obstructions) contained within the drywell was excluded from the "free volume" estimate.

In general, the arrangement of the pipes in the annulus determines the most representative level division, since they constitute the only significant flow restrictions. This 73 node model is considered detailed enough to conservatively predict the maximum pressure loads on the compartment structure. Therefore, a nodalization sensitivity study is not needed.

For the purpose of determining peak pressure in the reactor vessel shield annulus, all insulation is assumed to move flush against the biological shield wall while still maintaining its original thickness. The volume of the insulation is excluded from the net volume of each subcompartment, and the projected area of the insulation that blocks the venting path is also excluded from the free venting area used in the analysis.

Venting to the drywell atmosphere is achieved only through the top of the biological shield annulus. For conservatism, venting through the reactor shield wall is not considered.

Initial conditions used in this analysis are 15.45 psia, 135°F, and 30% relative humidity. Bases for these initial conditions are discussed in the drywell head region subcompartment analysis (Section 6A.2).

Tables 6A-6 and 6A-7 give the subcompartment volumes, flow areas, length/area (L/A) ratio, and flow coefficients (including origins) used in the analysis.

The resultant pressure distributions are shown in Figure 6A-3 for the recirculation outlet line break and Figure 6A-4 for the feedwater line break. The subcompartment pressures existing in each subcompartment at the time of peak differential pressure across the RPV are also shown in these figures. Additionally, the load forcing functions that include both peak and transient loadings on the RPV and the reactor shield wall are presented in Figures 6A-5 and 6A-6 for the recirculation outlet break and in Figures 6A-7 and 6A-8 for the feedwater line break. This forcing function represents the time-dependent resultant force on the structure and originates from the vector sum of the product of compartment pressure and area for each of the many nodes used to represent the surface.

The components of these nodal areas are calculated in the following manner:

$$(A_x)_i = R_i H_i \operatorname{Sin}(\theta_{1_i} - \theta_{2_i}) \qquad \text{(EQ. 6A-1)}$$

$$(A_y)_i = R_i H_i \operatorname{Cos}(\theta_{2_i} - \theta_{1_i}) \qquad \text{(EQ. 6A-2)}$$

where:

R_i = Radius of the ith geometry node, in

H_i = Height of the ith geometry node, in

$\theta_{1_i} + \theta_{2_i}$ = Swept angle of geometry node i

Therefore, the force generated by a pressure, (P), acting on a nodal area (A) has the following components:

$(F_x)_i = P_j (A_x)_i$ (EQ. 6A-3)

$(F_y)_i = P_j (A_y)_i$ (EQ. 6A-4)

The compartment pressure transients resulting from a break in the reactor shield annulus generate a nodal force distribution over exposed surfaces. The resultant of this nodal force distribution is presented in Figures 6A-5, 6A-6, 6A-7 and 6A-8. This nodal force distribution is included in the analysis of nonaxisymmetric loadings on the containment internal structures, which is discussed in Sections 3.8.3.3 and 3.8.3.4.

Blowdown jet loads that include jet impingement and reaction forces against the reactor vessel are also analyzed for the feedwater line break for reference and comparison. Note that these analyses are based on the very conservative assumptions that the first pipe restraint nearest the nozzle fails. For this break, approximately 9.5" pipe center line offset limited by the shield plug opening produces a net break area of 88.53 in^2, which consequently results into a total maximum jet load against the vessel and a maximum reaction force of 158,500 lb_f and 93,230 lb_f, respectively. Note that this blowdown jet load is relatively small compared with the peak load contributed by the unbalanced reactor annulus pressurization due to the same break.

6A.2 DRYWELL HEAD REGION SUBCOMPARTMENT ANALYSIS

The design basis pressure differential between the drywell head region and the rest of the containment is a structural requirement of the drywell head. A pressure analysis of the drywell head region for a postulated head spray line break was performed. The effects of a 6 inch RHR head spray line break bound those of a 2 inch core vent line, which is the only other line that runs through the drywell head region.

Figure 6A-9 illustrates the basic arrangement of the head region. Venting from the head region is accomplished through ventilation openings as shown in Figure 6A-9. These vent openings provide a total of 18.64 ft^2 of vent area with a flow coefficient of 0.64 to relieve pressure buildup caused by the postulated break. Figure 6A-10 is the schematic flow diagram with vent flow areas and discharge coefficient used in the drywell head venting analysis.

For the drywell head region subcompartment analysis, the possibility that insulation from the RPV could break loose and block the vent paths was not considered because the postulated rupture of the RHR head spray line is outside the insulation above the top of the RPV. The jet from the vessel side of the break is above the top of the insulation, which precludes the metallic insulation sections from breaking loose due to the outward flow of the jet. Forces on the insulation from flow from the other side of the break as well as from the subsequent pressurization in the drywell head region would be inward toward the RPV, rather than outward toward the vent paths.

There is only a small amount of insulation on the drywell head region lines. In the event that this insulation should fail to remain on the pipe due to direct jet impingement, the vent paths leading from the drywell region would not become blocked for the following reasons. The openings of each of the six vents and two exhaust lines from the drywell head region are above the floor and have a ¾ inch mesh screen installed over them. To block the vent paths, a substantial amount of insulation would need to fall directly onto the vent path opening and break through the screen. This is considered improbable because there is only a small amount of pipe insulation in this region and not all of the failed insulation would fall on any one vent path opening.

To determine peak pressure in the drywell head, all insulation is assumed to remain in place. Initial conditions of 15.4 psia, 135°F, and 20% relative humidity are used in this analysis.

The initial conditions used for both the RPV shield annulus and drywell head region analyses reflect conservative assumptions to minimize the total heat capacity of the subcompartment, which satisfies SRP Section 6.2.1.2, Item II.B.1. The COPDA (NE699/D2) subcompartment analysis code is designed to handle realistic conditions. Recommended minimum relative humidity for COPDA, which is described in Reference 6A-1, is in the range of 25% to 30%. The available heat capacity at P=15.45 psia, T=135°F, and RH=30% is less than 3% greater than the heat capacity at 14.8 psia, 135°F, and RH=0%, and will not significantly affect the results of the analysis.

The initial pressure of 15.45 psia (0.75 psig) is the nominal drywell pressure under normal operating conditions for this unit. The pressure alarm setpoints are at 14.8 psia (0.1 psig) and 16.2 psia (1.5 psig). The heat capacity gain due to the higher initial pressure of 0.75 psig is less than 0.2% compared to the heat capacity available for T=135°F, RH=30%, and P=14.8 psia.

The drywell air cooling system is designed to limit the maximum average bulk temperature in the drywell to 135°F, with local maxima not exceeding 150°F (Section 9.4.5.2). For a given relative humidity, an increase in the initial temperatures is accompanied by an increase in the steam partial pressure. Consequently, the heat capacity in the compartment increases due to a greater steam mass. For this reason, the maximum bulk temperature of 135°F is used rather than the 150°F local maximum.

For the RPV shield annulus subcompartment analysis, it should be noted that Reference 6A-2 concludes that loads from such annulus pressurization analyses are insensitive to minor variations in initial (P), (T), and (ϕ).

The pressure transient of this analysis is presented in Figure 6A-11. It can be seen that the maximum pressure in the drywell head region is 25.91 psia and occurs 0.82 seconds after the head spray line break. The maximum pressure of 25.91 psia includes an increase of 2.61 psia as a result of power rerate. Considering the containment pressure to be atmospheric (no drywell air displaced into the rest of containment), a differential of 11.2 psid is obtained between the drywell head and the rest of containment. This pressure differential is well below the design pressure differential of 16.0 psid.

NOTE: The information presented in this table is based on original plant conditions. The values in the table do provide a reasonable representation of the general blowdown characteristics.

Table 6A-2 (Cont'd)

---

(1) Listed below are pertinent physical parameters used in the blowdown estimation:

A	=	3.644	ft^2	Minimum cross-sectional area between vessel and break
D	=	2.154	ft	Pipe I.D. at the break location
h_o	=	527.85	Btu/lb_m	Vessel enthalpy
L_I	=	2.917	ft	Inventory length
P_o	=	1031.2	psia	Vessel pressure
P_{sat}	=	908	psia	Saturation pressure
ν	=	0.02127	ft^3/lb_m	Specific volume of the fluid initially in the pipe
V	=	135	ft^3	Inventory volume

(2) The postulated break location is at the nozzle safe-end to the pipe weld, which is located about 4.5 inches from the drywell side of the shield wall. A double-ended guillotine break was assumed. This is conservative because there is insufficient clearance for complete separation of the pipe and nozzle.

NOTE: The information presented in this table is based on original plant conditions.

TIME (s)	MASS FLOW (lb_m/s)	ENTHALPY (Btu/lb_m)
0.0	0	404.5
0.0001	20348	404.5
0.0217	20348	404.5
0.0218	18454	404.5
1.0	18454	404.5

NOTE: The information presented in this table is based on original plant conditions. The values in the table do provide a reasonable representation of the general blowdown characteristics.

Table 6A-4

FEEDWATER LINE BREAK BLOWDOWN MASS FLUX TIME HISTORY[1]

TIME (s)	MASS FLUX ($lb_m/s/ft^2$)	EFFECTIVE BREAK AREA (ft^2)
VESSEL SIDE:		
0.0001	18250	0.3717
0.0217	18250	0.3717
0.0218	18250	0.2679
1.0	18250	0.2679
SUPPLY PIPE SIDE[2]		
0.0001	18250	0.7433
1.0	18250	0.7433

(1) Listed below are some pertinent physical parameters used in the blowdown estimation

A	=	0.7433 ft^2		Minimum cross-sectional area between vessel and break
D	=	0.9728 ft		Pipe I.D. at the break location
h_o	=	404.5		Btu/lb_m Vessel enthalpy
L_l	=	12	ft	Inventory length
P_o	=	1053	psia	Vessel pressure
P_{sat}	=	326	psia	Saturation pressure
ν	=	0.01888	ft^3/lb_m	Specific volume of the feedwater
V	=	2.79	ft^3	Inventory volume

(1) The most restricted flow area on the feedwater supply pipe side is the break area itself. Full break area steady-state blowdown from this side is conservatively assumed to be reached immediately after the pipe rupture.

NOTE: The information presented in this table is based on original plant conditions. The values in the table do provide a reasonably represent the general characteristics of the blowdown mass flux time history.

Table 6A-5

HEAD SPRAY LINE BREAK[1][2]

TIME (s)	STEAM FLOW lb_m/s	STEAM ENTHALPY (Btu/lb)
0.0	506.8	1192
20.0	506.8	1192

(1) Head spray line break is based on 6 inch Schedule 80 pipe with Moody Blowdown corresponding to 2800 $lb_m/sec\text{-}ft^2$. Overall containment response is that of a "small break accident."

(2) This table is based on the original design basis power. the effects of rerate power conditions blowdown are shown in Figure 6A-11.

CHAPTER 7 - INSTRUMENTATION AND CONTROL SYSTEMS

TABLE OF CONTENTS

7.1 INTRODUCTION

7.1.1 Identification of Safety-Related Systems
7.1.1.1 General
7.1.1.2 Identification of Individual Systems
7.1.1.3 Classification
7.1.1.3.1 Safety-Related Systems
7.1.1.3.2 Power Generation Systems
7.1.1.3.3 General Functional Requirements of Design Basis
7.1.1.3.4 Specific Regulatory Requirements

7.1.2 Identification of Safety Criteria
7.1.2.1 General
7.1.2.1.1 Reactor Protection System - Instrumentation and Controls
7.1.2.1.2 Primary Containment and Reactor Vessel Isolation Control System - Instrumentation and Controls
7.1.2.1.3 Emergency Core Cooling System - Instrumentation and Controls
7.1.2.1.4 Neutron Monitoring System - Instrumentation and Controls
7.1.2.1.5 Refueling Interlocks - Instrumentation and Controls
7.1.2.1.6 Reactor Manual Control System - Instrumentation and Controls
7.1.2.1.7 Reactor Vessel Instrumentation
7.1.2.1.8 Recirculation Flow Control System - Instrumentation and Controls
7.1.2.1.9 Feedwater Control System - Instrumentation and Controls
7.1.2.1.10 Pressure Regulator and Turbine-Generator System - Instrumentation and Controls
7.1.2.1.11 Process Radiation Monitoring System - Instrumentation and Controls
7.1.2.1.12 Area Radiation Monitoring System
7.1.2.1.13 Deleted
7.1.2.1.14 Habitability and Control Room Isolation System - Instrumentation and Controls
7.1.2.1.15 Service Water Systems - Instrumentation and Controls
7.1.2.1.16 Containment Atmospheric Control System - Instrumentation and Controls
7.1.2.1.17 Reactor Core Isolation Cooling System - Instrumentation and Controls
7.1.2.1.18 Standby Liquid Control System - Instrumentation and Controls
7.1.2.1.19 Radwaste Systems - Instrumentation and Controls
7.1.2.1.20 Reactor Water Cleanup System - Instrumentation and Controls
7.1.2.1.21 Class 1E Power Systems
7.1.2.1.22 Leak Detection Systems - Instrumentation and Controls
7.1.2.1.23 Reactor Shutdown Cooling Mode of the RHR System - Instrumentation and Controls
7.1.2.1.24 Fuel Pool Cooling and Cleanup System - Instrumentation and Controls
7.1.2.1.25 Reactor Enclosure Recirculation System - Instrumentation and Controls
7.1.2.1.26 Standby Gas Treatment System - Instrumentation and Controls
7.1.2.1.27 Deleted
7.1.2.1.28 Safety-Related Display Instrumentation
7.1.2.1.29 Containment Instrument Gas System - Instrumentation and Controls

7.1.2.1.30 Containment Spray Mode of the RHR System - Instrumentation and Controls
7.1.2.1.31 Remote Shutdown System - Instrumentation and Controls
7.1.2.1.32 Suppression Pool Cooling Mode of the RHR System - Instrumentation and Controls
7.1.2.1.33 Safety-Related Equipment Area Cooling Ventilation Systems
7.1.2.1.34 Drywell Unit Coolers - Instrumentation and Controls
7.1.2.1.35 Control Enclosure Chilled Water System - Instrumentation and Controls
7.1.2.1.36 High Pressure/Low Pressure System Interlocks
7.1.2.1.37 Safety/Relief Valve Position Indication System - Instrumentation and Controls
7.1.2.1.38 Fire Protection and Suppression System
7.1.2.1.39 Reactor Enclosure Isolation System
7.1.2.1.40 Nonsafety-Related Equipment Area Cooling Ventilation Systems
7.1.2.1.41 Safeguard Piping Fill System
7.1.2.1.42 Refueling Area Isolation System
7.1.2.1.43 Redundant Reactivity Control System
7.1.2.1.44 Rod Worth Minimizer (Unit 2)
7.1.2.1.45 Plant Monitoring System (Unit 2)
7.1.2.1.46 Emergency Response Facility Data System (Unit 1)
7.1.2.2 Independence of Redundant Safety-Related Systems
7.1.2.2.1 Introduction
7.1.2.2.2 Mechanical Systems Separation Criteria
7.1.2.2.3 Electrical Systems Separation Criteria
7.1.2.3 Physical Identification of Safety-Related Equipment
7.1.2.4 Instrument Errors
7.1.2.5 Conformance to Regulatory Guides
7.1.2.5.1 Regulatory Guide 1.6 (March 1971) - Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems (Safety Guide 6)
7.1.2.5.2 Regulatory Guide 1.7 (November 1978) - Control of Combustible Gas Concentrations in Containment Following a Loss-of-Coolant Accident
7.1.2.5.3 Regulatory Guide 1.9 (March 1971) - Selection of Diesel Generator Set Capacity for Standby Power Supplies (Safety Guide 9)
7.1.2.5.4 Regulatory Guide 1.11 (March 1971) - Instrument Lines Penetrating Primary Reactor Containment (Safety Guide 11)
7.1.2.5.5a Regulatory Guide 1.21 (June 1974) - Measuring, Evaluating, and Reporting Radioactivity in Solid Wastes and Releases of Radioactive Materials in Liquid and Gaseous Effluents from Light-Water-Cooled Nuclear Power Plants
7.1.2.5.5b Regulatory Guide 1.22 (February 1972) - Periodic Testing of Protection System Actuation Functions (Safety Guide 22)
7.1.2.5.6 Regulatory Guide 1.29 (September 1978) - Seismic Design Classification
7.1.2.5.7 Regulatory Guide 1.30 (August 1972) - Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment (Safety Guide 30)
7.1.2.5.8 Regulatory Guide 1.32 (February 1977) - Criteria for Safety-Related Electric Power Systems for Nuclear Power Plants
7.1.2.5.9 Regulatory Guide 1.40 (March 1973) - Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of Water-Cooled Nuclear Power Plants
7.1.2.5.10 Regulatory Guide 1.45 (May 1973) - Reactor Coolant Pressure Boundary Leakage Detection Systems

7.1.2.5.11 Regulatory Guide 1.47 (May 1973) - Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems
7.1.2.5.12 Regulatory Guide 1.53 (June 1973) - Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems
7.1.2.5.13 Regulatory Guide 1.56 (July 1978) - Maintenance of Water Purity in Boiling Water Reactors
7.1.2.5.14 Regulatory Guide 1.62 (October 1973) - Manual Initiation of Protective Actions
7.1.2.5.15 Regulatory Guide 1.63 (July 1978) - Electric Penetration Assemblies in Containment Structures for Light-Water-Cooled Nuclear Power Plants
7.1.2.5.16 Regulatory Guide 1.68 (August 1978) - Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors
7.1.2.5.17 Regulatory Guide 1.70 (November 1978) - Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants
7.1.2.5.18 Regulatory Guide 1.73 (January 1974) - Qualification Tests of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants
7.1.2.5.19 Regulatory Guide 1.75 (September 1978) - Physical Independence of Electric Systems
7.1.2.5.20 Regulatory Guide 1.80 (June 1974) - Preoperational Testing of Instrument Air Systems
7.1.2.5.21 Regulatory Guide 1.89 (November 1974) - Qualification of Class 1E Equipment for Nuclear Power Plants
7.1.2.5.22 Regulatory Guide 1.96 (May 1975) - Design of Main Steam Isolation Valve Leakage Control Systems for Boiling Water Reactor Nuclear Power Plants
7.1.2.5.23 Regulatory Guide 1.97 (December 1980) - Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following and Accident
7.1.2.5.24 Regulatory Guide 1.100 (August 1977) - Seismic Qualification of Electric Equipment for Nuclear Power Plants
7.1.2.5.25 Regulatory Guide 1.105 (November 1976) - Instrument Setpoints
7.1.2.5.26 Regulatory Guide 1.118 (June 1978) - Periodic Testing of Electric Power and Protection Systems
7.1.2.5.27 Regulatory Guide 1.139 (May 1978) - Guidance for Residual Heat Removal
7.1.2.6 Conformance to 10CFR50, Appendix A, General Design Criteria
7.1.2.6.1 GDC 1 - Quality Standards and Records
7.1.2.6.2 GDC 2 - Design Bases for Protection Against Natural Phenomena
7.1.2.6.3 GDC 3 - Fire Protection
7.1.2.6.4 GDC 4 - Environmental and Dynamic Effects Design Bases
7.1.2.6.5 GDC 5 - Sharing of Structures, Systems, and Components
7.1.2.6.6 GDC 10 - Reactor Design
7.1.2.6.7 GDC 12 - Suppression of Reactor Power Oscillations
7.1.2.6.8 GDC 13 - Instrumentation and Control
7.1.2.6.9 GDC 15 - Reactor Coolant System Design
7.1.2.6.10 GDC 19 - Control Room
7.1.2.6.11 GDC 20 - Protection System Functions
7.1.2.6.12 GDC 21 - Protection System Reliability and Testability
7.1.2.6.13 GDC 22 - Protection System Independence
7.1.2.6.14 GDC 23 - Protection System Failure Modes
7.1.2.6.15 GDC 24 - Separation of Protection and Control Systems
7.1.2.6.16 GDC 25 - Protection System Requirements for Reactivity Control Malfunctions
7.1.2.6.17 GDC 26 - Reactivity Control System Redundancy and Capability

7.1.2.6.18 GDC 27 - Combined Reactivity Control Systems Capability
7.1.2.6.19 GDC 28 - Reactivity Limits
7.1.2.6.20 GDC 29 - Protection Against Anticipated Operational Occurrences
7.1.2.6.21 GDC 30 - Quality of Reactor Coolant Pressure Boundary
7.1.2.6.22 GDC 33 - Reactor Coolant Makeup
7.1.2.6.23 GDC 34 - Residual Heat Removal
7.1.2.6.24 GDC 35 - Emergency Core Cooling
7.1.2.6.25 GDC 37 - Testing of Emergency Core Cooling System
7.1.2.6.26 GDC 38 - Containment Heat Removal
7.1.2.6.27 GDC 40 - Testing of Containment Heat Removal System
7.1.2.6.28 GDC 56 - Primary Containment Isolation
7.1.2.6.29 GDC 57 - Closed System Isolation Valves
7.1.2.6.30 GDC 60 - Control of Releases of Radioactive Materials to the Environment
7.1.2.6.31 GDC 61 - Fuel Storage and Handling and Radioactivity Control
7.1.2.6.32 GDC 63 - Monitoring Fuel and Waste Storage
7.1.2.6.33 GDC 64 - Monitoring Radioactivity Releases
7.1.2.7 Conformance to Industry Codes and Standards
7.1.2.7.1 IEEE 279 (1971) - Criteria for Protection Systems for Nuclear Power Generating Stations
7.1.2.7.2 IEEE 308 (1971 and 1974) - Criteria for Class 1E Electrical Systems for Nuclear Power Generating Stations
7.1.2.7.3 IEEE 317 (1972) - Electric Penetration Assemblies in Containment Structures for Nuclear Power Generating Stations
7.1.2.7.4 IEEE 323 (1971) - IEEE Trial Use Standard: General Guide for Qualifying Class 1 Electric Equipment for Nuclear Power Generating Stations
7.1.2.7.5 IEEE 336 (1971) - Installation, Inspection, and Testing Requirements for Instrumentation and Electric Equipment During the Construction of Nuclear Power Generating Stations
7.1.2.7.6 IEEE 338 (1971, 1975, and 1977) - Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems
7.1.2.7.7 IEEE 344 (1971 or 1975) - Guide for Seismic Qualification of Class 1 Electric Equipment for Nuclear Power Generating Stations
7.1.2.7.8 IEEE 379 (1972 or 1977) - Guide for the Application of the Single Failure Criterion to Nuclear Power Generating Station Protection Systems
7.1.2.7.9 IEEE 382 (1972) - Trial Use Guide for Type Test of Class 1 Electric Valve Operators for Nuclear Power Generating Stations
7.1.2.7.10 IEEE 383 (1974) - Standard for Type Test of Class 1E Electric Cables, Field Splices, and Connections for Nuclear Power Generating Stations
7.1.2.7.11 IEEE 384 (1974 or 1977) - Criteria for Separation of Class 1E Equipment and Circuits
7.1.2.8 Conformance to Branch Technical Positions
7.1.2.8.1 BTP ICSB 3
7.1.2.8.2 BTP ICSB 21
7.1.2.8.3 BTP ICSB 22
7.1.2.8.4 BTP ICSB 26
7.1.2.9 Technical Design Bases
7.1.2.10 Safety System Settings
7.1.2.11 Operating Experience Assessment
7.1.2.11.1 Bulletin 80-06, Engineered Safety Feature Reset Controls
7.1.2.11.2 Information Notice 79-22, Qualification of Control Systems

7.1.2.11.3 Bulletin 79-27, Loss of Non-Class 1E Instrumentation and Control Power Systems Bus During Operation

7.1.3 Protection System Inservice Testability

7.3.2.15.4 Emergency Switchgear and Battery Rooms Cooling System - Instrumentation and Controls
7.3.2.15.5 Emergency Core Cooling Systems Pump Compartment Unit Coolers - Instrumentation and Controls
7.3.2.15.6 Auxiliary Equipment Room Ventilation System - Instrumentation and Controls
7.3.2.15.7 Safety-Related Equipment Area Cooling Ventilation Systems Additional Design Considerations Analyses
7.3.2.16 Drywell Unit Coolers - Instrumentation and Controls
7.3.2.16.1 DUC General Functional Requirements Conformance
7.3.2.16.2 DUC Specific Regulatory Requirements Conformance
7.3.2.16.3 DUC Additional Design Considerations Analyses
7.3.2.17 Refueling Area Isolation System - Instrumentation and Controls
7.3.2.17.1 RAIS General Functional Requirements Conformance
7.3.2.17.2 RAIS Specific Regulatory Requirements Conformance

7.4 SYSTEMS REQUIRED FOR SAFE SHUTDOWN

7.4.1 Description
7.4.1.1 Reactor Core Isolation Cooling System - Instrumentation and Controls

7.4.1.1.1 RCIC System Identification
7.4.1.1.2 RCIC Power Sources
7.4.1.1.3 RCIC Equipment Design
7.4.1.1.4 RCIC Environmental Considerations
7.4.1.1.5 RCIC Operational Considerations
7.4.1.1.6 RCIC - IEEE 279 - Design Basis
7.4.1.2 Standby Liquid Control System - Instrumentation and Controls
7.4.1.2.1 SLCS System Identification
7.4.1.2.2 SLCS Power Sources
7.4.1.2.3 SLCS Equipment Design
7.4.1.2.4 SLCS Environmental Considerations
7.4.1.2.5 SLCS Operational Considerations
7.4.1.2.6 SLCS - IEEE 279 - Design Basis
7.4.1.3 Reactor Shutdown Cooling Mode of the RHR System - Instrumentation and Controls
7.4.1.3.1 RHR-SCM System Identification
7.4.1.3.2 RHR-SCM Power Sources
7.4.1.3.3 RHR-SCM Equipment Design
7.4.1.3.4 RHR-SCM Environmental Considerations
7.4.1.3.5 RHR-SCM Operational Considerations
7.4.1.3.6 RHR-SCM - IEEE 279 - Design Basis
7.4.1.4 Remote Shutdown System
7.4.1.4.1 RSS Identification
7.4.1.4.2 RSS Description
7.4.1.4.3 RSS Procedure
7.4.1.4.4 RSS Controls and Instrumentation - Equipment, Panels, and Displays
7.4.1.4.5 RSS - IEEE 279 - Design Basis
7.4.1.5 Emergency Service Water System - Instrumentation and Controls
7.4.1.6 Residual Heat Removal Service Water System - Instrumentation and Controls
7.4.1.7 Class 1E Power Systems
7.4.1.8 Shutdown Ventilation Systems
7.4.1.8.1 RCIC System Pump Compartment Unit Coolers - Instrumentation and Controls
7.4.1.8.2 RHR System Pump Compartment Unit Coolers
7.4.1.8.3 Remote Shutdown System Ventilation System

7.4.2 Analysis
7.4.2.1 Reactor Core Isolation Cooling System - Instrumentation and Controls
7.4.2.1.1 RCIC General Functional Requirements Conformance
7.4.2.1.2 RCIC Specific Regulatory Requirements Conformance
7.4.2.2 Standby Liquid Control System - Instrumentation and Controls
7.4.2.2.1 SLCS General Functional Requirements Conformance
7.4.2.2.2 SLCS Specific Regulatory Requirements Conformance
7.4.2.3 Reactor Shutdown Cooling Mode of the RHR System - Instrumentation and Controls
7.4.2.3.1 RHR-SCM General Functional Requirements Conformance
7.4.2.3.2 RHR-SCM Specific Regulatory Requirements Conformance
7.4.2.4 Remote Shutdown System - Instrumentation and Controls
7.4.2.4.1 RSS General Functional Requirements Conformance
7.4.2.4.2 RSS Specific Regulatory Requirements Conformance
7.4.2.5 Emergency Service Water System - Instrumentation and Controls

7.4.2.6 Residual Heat Removal Service Water System - Instrumentation and Controls
7.4.2.7 Class 1E Power Systems
7.4.2.8 Shutdown Ventilation Systems
7.4.2.8.1 RCIC System Pump Compartment Unit Coolers - Instrumentation and Controls
7.4.2.8.2 RHR System Pump Compartment Unit Coolers
7.4.2.8.3 Remote Shutdown System Ventilation System
7.4.2.9 Additional Design Consideration Analyses
7.4.2.9.1 Loss of Plant Instrument Air
7.4.2.9.2 Loss of Cooling Water to Vital Equipment
7.4.2.9.3 Plant Load Rejection
7.4.2.9.4 Turbine Trip

7.5 INFORMATION SYSTEMS IMPORTANT TO SAFETY

7.5.1 Description
7.5.1.1 General
7.5.1.2 Normal Operation
7.5.1.3 Transient Occurrences
7.5.1.4 Accident Conditions
7.5.1.4.1 Initial Accident Event
7.5.1.4.2 Postaccident Monitoring
7.5.1.4.3 Additional Instrumentation for Regulatory Guide 1.97 Variables

7.5.2 Analysis
7.5.2.1 General
7.5.2.2 Normal Operation
7.5.2.3 Transient Occurrences
7.5.2.4 Accident Conditions
7.5.2.4.1 Initial Accident Event
7.5.2.4.2 Postaccident Monitoring
7.5.2.4.3 Safe Shutdown Displays
7.5.2.5 General Functional Requirements Conformance
7.5.2.5.1 Specific Regulatory Requirements Conformance

7.6 ALL OTHER INSTRUMENTATION SYSTEMS REQUIRED FOR SAFETY

7.6.1 Description
7.6.1.1 Process Radiation Monitoring Systems - Instrumentation and Controls
7.6.1.1.1 Main Steam Line Radiation Monitoring System - Instrumentation and Controls
7.6.1.1.2 Reactor Enclosure Ventilation Exhaust Radiation Monitoring System - Instrumentation and Controls
7.6.1.1.3 Refueling Area Ventilation Exhaust Radiation Monitoring System - Instrumentation and Controls
7.6.1.1.4 Control Room Ventilation Radiation Monitoring System - Instrumentation and Controls
7.6.1.1.5 Control Room Emergency Fresh Air Radiation Monitoring System - Instrumentation and Controls
7.6.1.1.6 Primary Containment Post-LOCA Radiation Monitoring System - Instrumentation and Controls

7.6.1.1.7 Residual Heat Removal Service Water Radiation Monitoring System - Instrumentation and Controls
7.6.1.1.8 North Stack Effluent Radiation Monitoring System - Instrumentation and Controls
7.6.1.2 High Pressure/Low Pressure Systems Interlocks - Instrumentation and Controls
7.6.1.2.1 HPLPSI Function Identification
7.6.1.2.2 HPLPSI Power Sources
7.6.1.2.3 HPLPSI Equipment Design
7.6.1.2.4 HPLPSI Environmental Considerations
7.6.1.2.5 HPLPSI Operational Considerations
7.6.1.3 Leak Detection System - Instrumentation and Controls
7.6.1.3.1 LDS Identification
7.6.1.3.2 LDS Power Sources
7.6.1.3.3 LDS Equipment Design
7.6.1.4 Neutron Monitoring System - Instrumentation and Controls
7.6.1.4.1 NMS Identification
7.6.1.4.2 NMS Power Sources
7.6.1.4.3 Intermediate Range Monitor System
7.6.1.4.4 Local Power Range Monitor System
7.6.1.4.5 Average Power Range Monitor System
7.6.1.5 Safety/Relief Valve Positions Indication System - Instrumentation and Controls
7.6.1.5.1 SRVPI System Identification
7.6.1.5.2 SRVPI Power Supplies
7.6.1.5.3 SRVPI Initiating Circuits
7.6.1.5.4 SRVPI Logic and Sequencing
7.6.1.5.5 SRVPI Bypasses and Interlocks
7.6.1.5.6 SRVPI Redundancy and Diversity
7.6.1.5.7 SRVPI Testability
7.6.1.5.8 SRVPI Environmental Considerations
7.6.1.5.9 SRVPI Operational Considerations
7.6.1.6 Containment Instrument Gas System - Automatic Depressurization System Control - Instrumentation and Controls
7.6.1.6.1 CIGS-ADS Description
7.6.1.6.2 CIGS-ADS Initiating Circuits
7.6.1.6.3 CIGS-ADS Logic
7.6.1.6.4 CIGS-ADS Bypasses
7.6.1.6.5 CIGS-ADS Interlocks
7.6.1.6.6 CIGS-ADS Redundancy and Diversity
7.6.1.6.7 CIGS-ADS Actuated Devices
7.6.1.7 Safeguard Piping Fill System - Instrumentation and Controls
7.6.1.7.1 SPFS Description
7.6.1.7.2 SPFS Initiating Circuits
7.6.1.7.3 SPFS Logic
7.6.1.7.4 SPFS Bypasses and Interlocks
7.6.1.7.5 SPFS Redundancy and Diversity
7.6.1.7.6 SPFS Actuated Devices
7.6.1.8 Redundant Reactivity Control System - Instrumentation and Controls
7.6.1.8.1 RRCS System Identification
7.6.1.8.2 RRCS Power Sources
7.6.1.8.3 RRCS Equipment Design

7.6.2 Analysis

7.6.2.1 Process Radiation Monitoring Systems - Instrumentation and Controls
7.6.2.1.1 Main Steam Line Radiation Monitoring System
7.6.2.1.2 Reactor Enclosure Ventilation Exhaust Radiation Monitoring System
7.6.2.1.3 Refueling Area Ventilation Exhaust Radiation Monitoring System
7.6.2.1.4 Control Room Ventilation Radiation Monitoring System
7.6.2.1.5 Control Room Emergency Fresh Air Radiation Monitoring System
7.6.2.1.6 Primary Containment Post-LOCA Radiation Monitoring System
7.6.2.1.7 RHR Service Water Radiation Monitoring System
7.6.2.1.8 North Stack Effluent Radiation Monitoring System
7.6.2.2 High Pressure/Low Pressure Systems Interlocks - Instrumentation and Controls
7.6.2.2.1 HPLPSI General Functional Requirements Conformance
7.6.2.2.2 HPLPSI Specific Regulatory Requirements Conformance
7.6.2.3 Leak Detection System - Instrumentation and Controls
7.6.2.3.1 LDS General Functional Requirements Conformance
7.6.2.3.2 LDS Specific Regulatory Requirements Conformance
7.6.2.4 Neutron Monitoring System - Instrumentation and Controls
7.6.2.4.1 Intermediate Range Monitor System
7.6.2.4.2 Local Power Range Monitor System
7.6.2.4.3 Average Power Range Monitor System
7.6.2.5 Safety/Relief Valve Position Indication System - Instrumentation and Controls
7.6.2.5.1 SRVPI General Functional Requirements Conformance
7.6.2.5.2 SRVPI Specific Regulatory Requirements Conformance
7.6.2.6 Containment Instrument Gas System - ADS Control - Instrumentation and Controls
7.6.2.6.1 CIGS-ADS General Functional Requirements Conformance
7.6.2.6.2 CIGS-ADS Specific Regulatory Requirements Conformance
7.6.2.7 Safeguard Piping Fill System - Instrumentation and Controls
7.6.2.7.1 SPFS General Functional Requirements Conformance
7.6.2.7.2 SPFS Specific Regulatory Requirements Conformance
7.6.2.8 Redundant Reactivity Control System - Instrumentation and Controls
7.6.2.8.1 RRCS General Functional Requirements Conformance
7.6.2.8.2 RRCS Specific Regulatory Requirements Conformance
7.6.2.9 Additional Design Considerations Analyses
7.6.2.9.1 General Plant Safety Analyses
7.6.2.9.2 Cold Water Slug Injection
7.6.2.9.3 Refueling Accidents
7.6.2.9.4 Overpressurization of Low Pressure System
7.6.3 References

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

7.7.1 Description
7.7.1.1 Reactor Vessel Instrumentation
7.7.1.1.1 RVI Identification
7.7.1.1.2 RVI Power Sources
7.7.1.1.3 RVI Equipment Design

CHAPTER 7 - INSTRUMENTATION AND CONTROL SYSTEMS

7.1 INTRODUCTION

This chapter presents the specific detailed design and performance information relative to the instrumentation and control aspects of the safety-related and power generation systems used throughout the plant. The design and performance considerations relative to these systems' safety function and their mechanical aspects are described elsewhere in this UFSAR.

See Section 1.7 for a listing of elementary diagrams and schematic diagrams and Section 1.2 for equipment layout drawings.

7.1.1 IDENTIFICATION OF SAFETY-RELATED SYSTEMS

7.1.1.1 General

Instrumentation and control systems supplied by GE are designated as either power generation systems or safety-related systems, depending on their function. Some portions of a system may have a safety function while other portions of the same system may be classified as power generation. A description of the system of classification can be found in Section 15.9.2.2.2.

The systems presented in Chapter 7 are also classified according to Regulatory Guide 1.70 (Rev 3), namely, RPS, ESF systems, safe shutdown systems, safety-related display instrumentation, other systems required for safety, and control systems not required for safety. Table 7.1-1 lists the systems under each of these classifications and identifies the designer and/or the supplier. Table 7.1-2 identifies instrumentation and control systems that are identical to those of a nuclear power plant of similar design that has recently received NRC design or operation approval through the issuance of either a construction permit or an operating license. Differences and their effect on safety-related systems are also identified in Table 7.1-2. "First-of-a-kind" instruments including any microprocessors, multiplexers or computer systems used in or providing inputs to safety-related systems are identified in Table 7.1-8.

7.1.1.2 Identification of Individual Systems

A brief descriptive statement is given for each system.

1. The RPS instrumentation and controls initiate an automatic reactor shutdown via control rods (scram) if monitored system variables exceed pre-established limits. This action prevents fuel damage and limits system pressure, thus restricting the release of radioactive material.

2. The PCRVICS instrumentation and controls initiate closure of various automatic isolation valves if monitored system variables exceed pre-established limits. This action limits the loss of coolant from the RCPB and the release of radioactive materials from the RCPB, the primary containment, and the reactor enclosure.

3. The ECCS instrumentation and controls provide initiation and control of systems that provide core cooling. These systems are the HPCI system, the ADS, the core spray system, and the LPCI mode of the RHR system.

4. The NMS instrumentation and controls use incore neutron detectors to monitor core neutron flux. The NMS provides logic signals to the RPS when a condition necessitating a reactor shutdown is detected. Average neutron flux and Simulated Thermal Power are used as the overpower indicator during power operation and intermediate range detectors are used as overpower indicators during startup and shutdown. Oscillations in the local neutron flux are used as the indicator of thermal-hydraulic instability caused power oscillations**.** The NMS also provides power level indication during planned operation. Source range detectors are used to provide neutron flux information during reactor startup and low flux level operations. The TIP system gathers axial neutron flux information via a gamma-sensitive detector and uses this data to calibrate the LPRMS. The RBM system provides a signal to prevent control rod movement when local high neutron flux is sensed by the LPRMs.

   The NMS consists of the following six major systems:

   a. SRM system

   b. IRM system

   c. LPRM system

   d. APRM system (includes OPRM function)

   e. TIP system

   f. RBM system

5. The RI instrumentation and controls serve as a backup to procedural core reactivity control during refueling operation. These interlocks prevent the withdrawal of control rods and the movement of refueling equipment when permissive conditions are not satisfied.

6. The RMCS instrumentation and controls allow the operator to manipulate control rods and determine their positions. Various interlocks are provided in the control circuitry to prevent multiple operator errors or equipment malfunctions from requiring the action of the RPS.

7. The RVI monitors and transmits information to the reactor operator concerning key reactor vessel operating variables.

8. The RFCS instrumentation and controls regulate the speed of the reactor recirculation pumps (through ASDs) to vary the coolant flow rate through the core.

9. The FCS instrumentation and controls regulate the feedwater system flow rate so that proper reactor vessel water level is maintained. The system is arranged to permit single-element (reactor vessel water level only), three-element (reactor vessel water level, main steam flow, and feedwater flow), or manual operation.

10. The PRTGS instrumentation and controls work together to allow proper generator and reactor response to load demand changes. If the generator electrical load is lost, the turbine-generator speed-load controls initiate rapid closure of the turbine

governor valves (coincident with fast opening of the bypass valves) to prevent excessive turbine overspeed.

11. The PRMS instrumentation and controls:

The process radiation monitoring systems are those radiation monitoring systems other than the area monitoring system, the portable monitors, and the offsite monitors. The PRMS serve one or more of the following purposes:

a. Maintain surveillance over process liquid and gas lines that may serve as discharge routes for radioactive materials for the monitoring and/or controlling radioactive releases from the plant.

b. Maintain surveillance and/or control of ventilation systems for either maintaining the habitability of area that are vital for safe plant operation and shutdown or monitoring the quantity of radioactive effluents released to the environment.

c. Maintain surveillance and/or control of those process lines of power generating equipment whose malfunction is indicated by an abnormal increase in radiation levels.

The following is a listing of the safety-related PRMS:

a. Main steam line radiation monitoring system

b. Reactor enclosure ventilation exhaust radiation monitoring system

c. Refueling area ventilation exhaust radiation monitoring system

d. Control room ventilation radiation monitoring system

e. Control room emergency fresh air radiation monitoring system

f. Primary containment post-LOCA radiation monitoring system

g. Residual heat removal service water radiation monitoring system

The following is a listing of the nonsafety-related PRMS:

a. South stack effluent radiation monitoring system

b. Radwaste equipment rooms ventilation radiation monitoring system

c. Charcoal treatment system process exhaust radiation monitoring system

d. Recombiner rooms, hydrogen analyzer compartments, and equipment drain sump vent radiation monitoring system

e. Steam exhaust discharge and vacuum pump exhaust radiation monitoring system

f. Radwaste enclosure ventilation exhaust radiation monitoring system

g. Air ejector/holdup pipe discharge radiation monitoring system

h. Primary containment leak detection radiation monitoring system

i. Hot maintenance shop ventilation exhaust radiation monitoring system

j. Liquid radwaste discharge radiation monitoring system

k. Service water radiation monitoring system

l. Reactor enclosure cooling water radiation monitoring system

m. North stack effluent radiation monitoring system

Some of the above safety and nonsafety-related PRMSs provide postaccident monitoring capabilities in accordance with Regulatory Guide 1.97. These systems are identified in Section 7.5.

12. Area radiation monitoring system:

The purpose of the ARMS is to indicate and record gamma radiation levels in areas where radioactive materials might be present, stored, handled, or inadvertently introduced. Alarm capability is provided in case these radiation levels rise above permissible limits.

13. Deleted

14. The HCRIS instrumentation and controls provide means to isolate the control room from radiation or chlorine entering through the control room ventilation system. The emergency fresh air system provides a means for pressurizing the control room with clean air during radiation isolation. The control room HVAC system provides the proper environment for the control room and adjacent areas.

15. The service water systems instrumentation and controls provide cooling water to vital equipment as follows:

a. ESW to the diesel generators, RHR pumps, ECCS room coolers, and control room chillers

b. RHRSW to the RHR heat exchangers

16. CAC system instrumentation and controls:

a. The CGCS monitors and controls the concentration of combustible gases (hydrogen and oxygen) in the containment during normal operation and after a LOCA.

b. The PCVR subsystem monitors the drywell and suppression chamber pressure to limit the amount by which suppression chamber pressure can exceed drywell pressure.

17. The RCIC system instrumentation and controls provide initiation and control of a system that provides makeup water to the reactor vessel to remove decay heat from the reactor core in the event of reactor isolation from the main condenser system and loss of coolant flow from the reactor feedwater system.

18. The SLCS instrumentation and controls provide initiation of a reactivity control system that can shut the reactor down from rated power if all withdrawn control rods cannot be inserted to achieve reactor shutdown. The SLCS instrumentation and controls also support the manual initiation of SLCS to control suppression pool pH post LOCA.

19. The radwaste system instrumentation and controls support the manual processing and disposing of the radioactive process wastes generated during power operation. The radwaste control system includes liquid, gaseous, and solid radwaste subsystems.

20. The RWCU system instrumentation and controls support manual operation of system equipment to maintain high reactor water purity and reduce concentrations of fission products in the reactor water.

21. The Class 1E power system instrumentation and controls provide for reliable operation of the Class 1E power systems during normal and accident conditions. These power systems consist of:

    a. 4 kV ac power system fed from offsite source with diesel generator backup

    b. dc power system fed from offsite source with battery backup

22. The LDS instrumentation and controls use various temperature, pressure, level, and flow sensors to detect and indicate water and steam leakage in selected reactor systems and to annunciate and provide isolation signals (in certain cases) to limit leakage from the RCPB when limiting leakage conditions exist.

23. The RHR-SCM instrumentation and controls provides manual initiation of cooling to remove the decay and sensible heat from the reactor vessel during shutdown so that the reactor can be refueled and serviced.

24. The FPCC system instrumentation and controls support manual operation of the system that cools the fuel pool.

25. The RERS instrumentation and controls provide initiation and control of a system which filters and mixes the reactor enclosure and refueling floor ventilation air during isolation conditions.

26. The SGTS instrumentation and controls provide the means to control reactor enclosure and refueling floor pressure at a negative value with reference to the outside atmosphere during an isolation of the reactor enclosure.

27. Deleted

28. The SRDI is provided to inform the reactor operator when a manual safety action should be taken or is required. Instrumentation is also provided to give the reactor operator the capability to track process variables pertinent to safety during expected operational perturbations and following postulated accidents.

29. The CIGS instrumentation and controls support a system that provides the necessary compressed gas for the operation of the ADS SRVs, and for the operation of pneumatic devices located inside the drywell and suppression chamber.

30. The RHR-CSM instrumentation and controls support the manual initiation of the portion of the RHR system that is provided to condense steam in the containment under postaccident conditions.

31. The RSS instrumentation and controls provide the capability to ensure safe shutdown of the reactor when the control room is uninhabitable.

32. The RHR-SPCM instrumentation and controls support the manual initiation of the portion of the RHR system that is provided to effect post-LOCA cooling of the suppression pool water.

33. The safety-related equipment area cooling ventilation systems are as follows:

    a. The SGTS filter room and access area unit coolers instrumentation and controls provide support to the system that provides cooling to SGTS filter room and access areas.

    b. The DGEVS instrumentation and controls provide support to the system that provides ventilation to the diesel generator enclosures and equipment.

    c. The SPPSVS instrumentation and controls provide support to the system that provides ventilation for the ESW pumps and RHRSW pumps located in the spray pond pump house.

    d. The ESBRCS instrumentation and controls provide support to the system that provides ventilation and cooling to the emergency switchgear rooms, inverter rooms, battery rooms, and the chiller equipment rooms in the control structure.

    e. The ECCS and RCIC pump compartment unit coolers instrumentation and controls provide support to the system that provides cooling to the core spray, HPCI, RHR, and RCIC pump rooms.

f. The AERVS instrumentation and controls provides support to the system that provides ventilation and cooling to the auxiliary equipment room, computer room, remote shutdown room, and control enclosure fan rooms.

34. The DUC instrumentation and controls provide support to the system that provides atmosphere mixing in the primary containment after a LOCA and cooling during normal operation.

35. The CECWS instrumentation and controls provide support to the system that provides chilled water to the control room air supply fan cabinets, the auxiliary equipment room air supply fan cabinets, the SGTS room and access area unit coolers, and emergency switchgear and battery room air supply fan cabinets.

36. HPLPSI instrumentation and controls prevent over pressurization of the low pressure systems that interface with the RCPB.

37. SRVPI system instrumentation and controls use acoustic sensors to provide the operator with reliable OPEN/NOT-OPEN status of the SRVs.

38. The FPSS instrumentation and controls provide fire protection and suppression for the cable area of the PGCC and adjacent areas in the auxiliary equipment room.

39. The REIS instrumentation and controls provide signals to isolate the reactor enclosure secondary containment and starts the RERS and SGTS under emergency conditions.

40. Nonsafety-related equipment area cooling ventilation systems:

a. Reactor enclosure ventilation system instrumentation and controls provide support to the system that provides ventilation to the reactor enclosure during normal plant operation.

b. Turbine enclosure ventilation system instrumentation and controls provide support to the system that provides ventilation to the turbine enclosure and to el 180', el 200', el 217', and el 254' in the control structure.

c. Radwaste enclosure ventilation system instrumentation and controls provide support to the system that provides ventilation to the radwaste enclosure.

d. Chemistry laboratory expansion ventilation system instrumentation and control provided to the system that provides ventilation to the chemical laboratories.

e. Hot maintenance shop ventilation system instrumentation and controls provide support to the system that provides ventilation to the hot maintenance shop.

e. Miscellaneous enclosure ventilation systems instrumentation and controls provide support to the systems that provide ventilation to the circulating water pump structure, water treatment enclosure, Schuylkill River pump structure, Perkiomen Creek pump structure, sewage treatment enclosure,

auxiliary boiler enclosure, boiler fuel transfer enclosure, lube oil structure, chlorine and acid feed enclosure, and the administration building.

41. The SPFS instrumentation and controls provide support to a system which ensures that the ECCS and RCIC piping is maintained full of water when the systems are in standby mode. The SPFS also discharges to the feedwater lines to provide a seal on the isolation valves in the event of a feedwater line break outside containment.

42. The RRCS is a system designed to mitigate the potential consequences of an anticipated transient without scram event. The system consists of control panels, detection and actuation logic, and the necessary interface logic for input to the recirculation system, feedwater system, SLCS, RWCU system, and the ARI function of the CRD.

43. The RAIS instrumentation and controls provide signals to isolate the refueling area and start the SGTS under emergency conditions.

44. The RWM monitors and enforces adherence to established rod insert and withdraw sequences at low power levels. This function prevents the operator from establishing control rod patterns that are not consistent with the prescribed sequence by initiating the appropriate rod insert block and rod withdrawal block. When RWM is inoperable both insert and withdraw rod blocks are enforced unless the RWM is bypassed.

45. The PMS is a centralized, integrated system which performs the process monitoring and calculations that are necessary for the effective evaluation of normal and emergency power plant operation. The PMS acquires and records process data (e.g., temperatures, pressures, flows, status indicators) to produce displays, logs, and plots of current or historical plant performance.

46. The ERFDS is a part of the PMS and performs the process monitoring and calculations defined as being necessary for the effective evaluation of normal and emergency power plant operation. The PMS acquires and records process data for ERFDS including temperatures, pressures, flows, and status indicators. This data is processed to produce meaningful displays, logs, and plots of current or historical plant performance and is presented to plant personnel in the plant main control room or other user definable locations.

7.1.1.3 Classification

7.1.1.3.1 Safety-Related Systems

Safety-related systems provide actions necessary to ensure safe shutdown, protect the integrity of radioactive material barriers, or prevent the release of radioactive material in excess of allowable limits. These safety-related systems may consist of components, groups of components, systems, or groups of systems. ESF systems are included in this category. ESF systems function to mitigate the consequences of DBAs.

7.1.1.3.2 Power Generation Systems

Power generation systems are not required to ensure safe shutdown, protect the integrity of radioactive material barriers, or prevent the release of radioactive material in excess of allowable limits. The instrumentation and control portions of these systems, may, by their actions, prevent the plant from exceeding preset limits that would otherwise initiate action of the safety-related systems.

7.1.1.3.3 General Functional Requirements of Design Basis

Plant systems may have both a safety design basis and a power generation design basis, depending on their function. The safety design basis states in functional terms the unique design requirements that establish limits for the operation of the system. The general functional requirements portion of the safety design basis presents those requirements that have been determined to be sufficient to ensure the adequacy and reliability of the system from a safety viewpoint. Many of these requirements have been incorporated into various codes, criteria, and regulatory requirements.

7.1.1.3.4 Specific Regulatory Requirements

The plant systems have been examined with respect to specific regulatory requirements that are applicable to the subject instrumentation and controls systems. These regulatory requirements include:

a. Conformance to regulatory guides

b. Conformance to 10CFR50, Appendix A, "General Design Criteria"

c. Conformance to industry codes and standards

The specific regulatory requirements applicable to each system's instrumentation and controls are specified in Table 7.1-3.

7.1.2 IDENTIFICATION OF SAFETY CRITERIA

7.1.2.1 General

Design bases and criteria for instrumentation and control equipment design are based on the need to have the system perform its intended function while meeting the requirements of applicable general design criteria, regulatory guides, industry standards, and other documents.

7.1.2.1.1 Reactor Protection System - Instrumentation and Controls

7.1.2.1.1.1 RPS Safety Design Bases

The RPS is designed to meet the following functional requirements:

a. The RPS initiates a reactor scram with precision and reliability to prevent or limit fuel damage following abnormal operational transients.

b. The RPS initiates a scram with precision and reliability to prevent damage to the RCPB as a result of excessive internal pressure, that is, to prevent nuclear system pressure from exceeding the limit allowed by applicable industry codes.

c. To limit the uncontrolled release of radioactive materials from the RCPB, the RPS precisely and reliably initiates a reactor scram on gross failure of this barrier.

d. To detect conditions that threaten the fuel assembly or RCPB, the RPS inputs are derived from variables that are true, direct measures of operational conditions.

e. The RPS responds correctly to the sensed variables over the expected range of magnitudes and rates of change.

f. A sufficient number of sensors are provided to monitor essential variables that have spatial dependence.

g. The following bases ensure that the RPS is designed with sufficient reliability:

1. If failure of a control or regulating system causes a plant condition that requires a reactor scram but also prevents action by necessary RPS channels, the remaining portions of the RPS meet safety design basis (g.6).

2. The loss of one or both power supplies does not prevent a reactor scram.

3. Once initiated, an RPS action goes to completion. The return-to-normal operation requires deliberate operator action.

4. There is sufficient physical separation between redundant instrumentation and control equipment monitoring the same variable to prevent environmental factors, electrical transients, or physical events from impairing the ability of the system to respond correctly.

5. Ground motions of a SSE magnitude as amplified by building and supporting structures do not impair the ability of the RPS to initiate a reactor scram.

6. No single failure within the RPS prevents proper RPS action, when required, to satisfy safety design bases (a), (b), and (c) above.

7. Any one intentional bypass, maintenance operation, calibration operation, or test to verify operational availability does not impair the ability of the RPS to respond correctly.

8. The system is designed so that the required number of sensors for any monitored variable exceeding the scram setpoint initiates an automatic scram.

h. The following bases reduce the probability that RPS operational reliability and precision are degraded by operator error:

1. Access to trip settings, component calibration controls, test points, and other terminal points is under the control of plant procedures.

2. Manual bypass of instrumentation and control equipment components is under the control of the control room operator. If the ability to trip some

essential part of the system has been manually bypassed, this fact is continuously annunciated in the control room.

7.1.2.1.1.2 RPS Specific Regulatory Requirements

The specific requirements applicable to the RPS instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.1.3 RPS Power Generation Design Bases

The RPS has one objective, which is availability. The setpoints, power sources, and controls and instrumentation are arranged so as to preclude spurious scrams.

7.1.2.1.2 Primary Containment and Reactor Vessel Isolation Control System - Instrumentation and Controls

7.1.2.1.2.1 PCRVICS Safety Design Bases

The following safety design bases are implemented in the PCRVICS:

a. To limit the release of radioactive materials to the environment, the PCRVICS precisely and reliably initiates timely isolation of penetrations through the primary containment whenever the values of monitored variables exceed preselected operational limits.

b. To provide assurance that important variables are monitored with a precision sufficient to fulfill safety design basis requirements (a), the PCRVICS responds correctly to the sensed variables over the expected design range of magnitudes and rates of change.

c. To ensure that important variables are monitored to fulfill safety design basis (a), a sufficient number of sensors is provided for monitoring essential variables.

d. To ensure that conditions indicative of a failure of the RCPB are detected to fulfill safety design basis (a), PCRVICS inputs are derived from variables that are accurate, direct measures of existing plant conditions.

e. The time required to close the MSIVs is short, to limit the radiological consequences and loss of coolant from a steam line break outside containment. However, the time required to close the MSIVs is long enough so that inadvertent isolation of steam lines does not cause a transient as severe as that resulting from closure of the turbine stop valves coincident with failure of the turbine bypass system. This ensures that the MSIV closure speed is compatible with the ability of the RPS to protect the fuel assemblies and the RCPB.

f. The following safety design bases are specified for the systems controlling automatic isolation valves to ensure that the closure of automatic isolation valves is initiated when required to fulfill safety design basis (a):

1. Any single failure, maintenance operation, calibration operation, or test to verify operational availability does not impair the functional ability of the isolation control system.

2. The system is designed so that a specified number of sensors for any monitored variable exceeding the isolation setpoint initiate automatic isolation.

3. Where a plant condition that requires isolation can be caused by a failure or malfunction of a control or regulating system, and the same failure or malfunction prevents action by one or more isolation control system channels designed to provide protection against the unsafe condition, the remaining portions of the isolation control system meet the requirements of safety design bases (a), (b), (c), and (f.1).

4. The power supplies for the PCRVICS are arranged so that the loss of one supply cannot prevent automatic isolation when required.

5. The system is designed so that, once initiated, automatic isolation action goes to completion. The return-to-normal operation after isolation action requires deliberate operator action.

6. There is sufficient electrical and physical separation of wiring and piping between instrument channels monitoring the same essential variable to prevent environmental factors, electrical faults, and physical events from impairing the ability of the system to respond correctly.

7. Earthquake ground motions of SSE magnitude do not impair the ability of the primary containment and reactor vessel isolation control system to initiate automatic isolation.

g. The following safety design basis is specified to ensure that the isolation of main steam lines is accomplished:

   The isolation valves in each of the main steam lines do not rely on electrical power to achieve closure. Valve closure power is from diverse stored energy sources.

h. To reduce the probability that the operational reliability of the PCRVICS is degraded by operator error, the following safety design bases are specified for automatic isolation valves:

   1. Access to all trip settings, component calibration controls, test points, and other terminal points for equipment associated with essential monitored variables is under the control of the plant procedures.

   2. The means for bypassing instrument channels, trip logics, or system components are under the control of the control room operator. If the ability to trip some essential part of the system has been bypassed, this fact is continuously annunciated in the control room.

i. The system provides the operator with a means to take manual isolation action that is independent of the automatic isolation. If there is a failure of the RCPB, it is possible for the operator to manually initiate isolation of the primary containment and reactor vessel from the control room.

j. The following bases are specified to provide the operator with the means to assess the condition of the PCRVICS and to identify conditions indicative of a failure of the RCPB.

1. The PCRVICS is designed to provide the operator with information pertinent to the status of the system.

2. Means are provided for prompt identification of instrument channel and trip system responses.

k. It is possible to check the operational availability of each instrument channel and trip logic during reactor operation.

7.1.2.1.2.2 PCRVICS Specific Regulatory Requirements

The specific regulatory requirements applicable to the PCRVICS instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.2.3 PCRVICS Power Generation Design Bases

There are no power generation design bases for the PCRVICS.

7.1.2.1.3 Emergency Core Cooling System - Instrumentation and Controls

7.1.2.1.3.1 ECCS Safety Design Bases

The ECCS control and instrumentation is designed to meet the following functional safety design bases:

a. Automatically initiate and control the ECCS to prevent fuel cladding temperatures from reaching 2200°F.

b. Respond to a need for emergency core cooling, regardless of the physical location of the malfunction or break that causes the need.

c. The following safety design bases are specified to limit dependence on operator judgement in times of stress:

1. The ECCS responds automatically so that no action is required of plant operators within 10 minutes after a LOCA.

2. The performance of the ECCS is indicated by control room instrumentation.

3. Facilities for manual control of the ECCS are provided in the control room.

7.1.2.1.3.2 ECCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the controls and instrumentation for the ECCS are shown on Table 7.1-3.

7.1.2.1.3.3 ECCS Power Generation Design Bases

There are no power generation design bases for this system.

7.1.2.1.4 Neutron Monitoring System - Instrumentation and Controls

7.1.2.1.4.1 Source Range Monitor Subsystem

7.1.2.1.4.1.1 SRM Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.4.1.2 SRM Specific Regulatory Requirements

There are no specific regulatory requirements for this system.

7.1.2.1.4.1.3 SRM Power Generation Design Bases

The SRM subsystem meets the following power generation design bases:

a. Neutron sources and neutron detectors together result in a signal-to-noise ratio of at least 2:1 and a count rate of at least three counts per second with all control rods fully inserted before initial power operation.

b. The SRM is able to perform the following functions:

    1. Indicate a measurable increase in output signal from at least one detecting channel before reactor period reaches 20 seconds duration during the worst possible startup rod withdrawal conditions

    2. Indicate substantial increases in output signals with the maximum permitted number of SRM channels out of service during normal reactor startup operations

    3. Ensure that the SRM channels are on scale when the IRM first indicates neutron flux during a reactor startup

    4. Provide a measure of the time rate of change of the neutron flux (reactor period) for operational convenience

    5. Generate interlock signals to block control rod withdrawal if the count rate exceeds a preset value or falls below a preset limit (if the IRMs are not above the second range) or if certain electronic failures occur

c. Perform its function in the maximum normal thermal and radiation environment

d. Ensure that loss of a single power bus does not disable the monitoring and alarming functions of all the available monitors

7.1.2.1.4.2 Intermediate Range Monitor Subsystem

7.1.2.1.4.2.1 IRM Safety Design Bases

The IRM generates a trip signal that can be used while operating in the intermediate range to prevent fuel damage resulting from anticipated or abnormal operational transients that occur. The independence and redundancy incorporated in the design of the IRM is consistent with the safety design bases of the RPS.

7.1.2.1.4.2.2 IRM Specific Regulatory Requirements

The specific regulatory requirements applicable to the controls and instrumentation for the IRM are given in Table 7.1-3 for the NMS.

7.1.2.1.4.2.3 IRM Power Generation Design Bases

The IRM generates an interlock signal to block rod withdrawal if the IRM reading exceeds a preset value or if the IRM is not operating properly. The IRM is designed so that overlapping neutron flux indications exist with the SRM and APRM subsystems.

7.1.2.1.4.3 Local Power Range Monitor Subsystem

7.1.2.1.4.3.1 LPRM Safety Design Bases

The LPRM is designed to provide a sufficient number of LPRM signals to satisfy the APRM safety design bases.

7.1.2.1.4.3.2 LPRM Specific Regulatory Requirements

The specific regulatory requirements applicable to the controls and instrumentation for the LPRM are given in Table 7.1-3 for the NMS.

7.1.2.1.4.3.3 LPRM Power Generation Design Bases

The LPRM supplies the following:

a. Signals to the APRM that are proportional to the local neutron flux at various locations within the reactor core

b. Signals to alarm high or low local neutron flux

c. Signals proportional to the local neutron flux to drive indicating meters and auxiliary devices to be used for operator evaluation of power distribution, local heat flux, minimum critical power ratio, and fuel burnup rate

d. Signals to the RBM to indicate changes in local relative neutron flux during the movement of control rods

7.1.2.1.4.4 Average Power Range Monitor Subsystem

7.1.2.1.4.4.1 APRM Safety Design Bases

Under the worst permitted input LPRM bypass conditions, the APRM is capable of generating a trip signal in response to average neutron flux increases or thermal-hydraulic instability caused power oscillations in time to prevent fuel damage. The independence and redundancy incorporated into the design of the APRM are consistent with the safety design bases of the RPS.

7.1.2.1.4.4.2 APRM Specific Regulatory Requirements

The specific regulatory requirements applicable to the controls and instrumentation for the APRM are given in Table 7.1-3 for the NMS.

7.1.2.1.4.4.3 APRM Power Generation Design Bases

The APRM provides the following functions:

a. A continuous indication of average reactor power (neutron flux) from a few percent to 125% of rated reactor power

b. Interlock signals for blocking further rod withdrawal to avoid an unnecessary scram actuation

c. A reference power level for the RBM subsystem

7.1.2.1.4.5 Traversing Incore Probe Subsystem

7.1.2.1.4.5.1 TIP Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.4.5.2 TIP Specific Regulatory Requirements.

There are no specific regulatory requirements applicable to this system.

7.1.2.1.4.5.3 TIP Power Generation Design Bases

The TIP subsystem meets the following power generation design bases:

a. It provides a signal proportional to the axial neutron flux distribution at the radial locations of the LPRM detectors. This signal is of high precision to allow reliable calibration of LPRM gains.

b. It provides an accurate indication of the position of the flux measurement to allow pointwise or continuous measurement of the axial neutron flux distribution.

7.1.2.1.4.6 Rod Block Monitor Subsystem

7.1.2.1.4.6.1 RBM Safety Design Bases

There are no safety design bases for the RBM subsystem.

7.1.2.1.4.6.2 RBM Specific Regulatory Requirements

Specific regulatory requirements applicable to this subsystem are given in Table 7.1-3.

7.1.2.1.4.6.3 RBM Power Generation Design Bases

The RBM subsystem meets the following power generation design bases:

a. Prevents local fuel damage that may result from a single rod withdrawal error under the worst permitted conditions of RBM bypass

b. Provides a signal used by the operator to evaluate the change in the local relative power level during control rod movement

7.1.2.1.5 Refueling Interlocks - Instrumentation and Controls

7.1.2.1.5.1 RI Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.5.2 RI Specific Regulatory Requirements

The specific regulatory requirements applicable to the controls and instrumentation for refueling interlocks are given in Table 7.1-3.

7.1.2.1.5.3 RI Power Generation Design Bases

Refueling interlocks meet the following power generation design bases:

a. During fuel movements in or over the reactor core, they prevent control rod withdrawal.

b. No more than one control rod is withdrawn from its fully inserted position at any time when the reactor is in the refueling mode.

c. They prevent the operation of fuel loaded refueling equipment over the core whenever any control rod is withdrawn.

When fuel is being moved from the core to the spent fuel pool during refueling, the refueling interlocks may be disabled for core cells from which the four fuel assemblies have been removed if the conditions contained in Technical Specifications 3.9.10.2 are met and compensating administrative controls are established.

7.1.2.1.6 Reactor Manual Control System - Instrumentation and Controls

7.1.2.1.6.1 RMCS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.6.2 RMCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the controls and instrumentation for the RMCS are given in Table 7.1-3.

7.1.2.1.6.3 RMCS Power Generation Design Basis

The RMCS is designed to meet the following power generation design basis:

a. Enforce adherence to predetermined control rod withdrawal and insertion sequences

b. Provide the operator with the means to achieve prescribed control rod patterns

c. Inhibit control rod motion following receipt of rod block trip signals

d. Provide information pertinent to the position and motion of the control rods to the control room.

7.1.2.1.7 Reactor Vessel Instrumentation

7.1.2.1.7.1 RVI Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.7.2 RVI Specific Regulatory Requirements

There are no specific regulatory requirements applicable to this system.

7.1.2.1.7.3 RVI Power Generation Design Bases

RVI is designed to provide the reactor operator with sufficient indication of reactor vessel coolant temperature, reactor vessel water level, reactor vessel pressure, and nuclear system leakage to maintain proper normal operating conditions. These instruments augment safety-related information so that the operator can startup, operate, shutdown, and service the reactor in an efficient manner.

7.1.2.1.8 Recirculation Flow Control System - Instrumentation and Controls

7.1.2.1.8.1 RFCS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.8.2 RFCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the RFCS are given in Table 7.1-3.

7.1.2.1.8.3 RFCS Power Generation Design Bases

The RFCS is designed to allow manual recirculation flow rate adjustment of reactor power level.

7.1.2.1.9 Feedwater Control System - Instrumentation and Controls

7.1.2.1.9.1 FCS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.9.2 FCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the FCS are given in Table 7.1-3.

7.1.2.1.9.3 FCS Power Generation Design Bases

The reactor FCS regulates the feedwater flow over the entire power range of the reactor to maintain adequate water level in the reactor vessel and to prevent unnecessary initiation of safety-related systems due to low water level.

7.1.2.1.10 Pressure Regulator and Turbine-Generator System - Instrumentation and Controls

7.1.2.1.10.1 PRTGS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.10.2 PRTGS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are given in Table 7.1-3.

7.1.2.1.10.3 PRTGS Power Generation Design Bases

The operation of the reactor demands that a pressure regulator concept be applied to maintain a constant turbine inlet pressure.

The turbine pressure regulator, to maintain constant turbine inlet pressure, operates the steam bypass valves so that a portion of nuclear boiler rated flow can be bypassed for transient steam flow loads above that which can be accepted by the turbine and for the startup and shutdown phase. The PRTGS accomplishes the following control functions:

a. Control turbine speed and turbine acceleration

b. Operate the steam bypass system to keep reactor pressure within limits and avoid large power transients

c. Control main turbine control valve pressure within the proportional band setting of the pressure regulator

7.1.2.1.11 Process Radiation Monitoring System - Instrumentation and Controls

7.1.2.1.11.1 Main Steam Line Radiation Monitoring System

7.1.2.1.11.1.1 MSL-RMS Safety Design Bases

The MSL-RMS is designed to meet the following safety design bases:

a. Detect a gross release of fission products from the fuel under any anticipated operating combination of main steam lines

b. Promptly indicate a gross release of fission products from the fuel

7.1.2.1.11.1.2 MSL-RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this subsystem are shown in Table 7.1-3.

7.1.2.1.11.1.3 MSL-RMS Power Generation Design Bases

The MSL-RMS is designed to display in the control room an indication of gross gamma radiation level at the main steam tunnel.

7.1.2.1.11.2 Reactor Enclosure Ventilation Exhaust Radiation Monitoring System

7.1.2.1.11.2.1 REVE-RMS Safety Design Bases

This system is designed to meet the following design bases:

a. Detect a gross release of radioactive material into the reactor enclosure ventilation duct

b. Promptly indicate a gross release of radioactive material

c. Provide, on detection of a gross release of radioactive material:

1. A trip signal for the reactor enclosure fans and closure of the valves to the vent exhaust system

2. A trip signal to isolate the primary containment atmosphere purge and vent lines and start the SGTS

3. An annunciation alarm signal in the control room

7.1.2.1.11.2.2 REVE-RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are shown in Table 7.1-3.

7.1.2.1.11.2.3 REVE-RMS Power Generation Design Bases

The system provides the following:

a. Recorder indication in the control room of the gross gamma radiation level

b. An alarm annunciation in the control room

7.1.2.1.11.3 Refueling Area Ventilation Exhaust Radiation Monitoring System

7.1.2.1.11.3.1 RAVE-RMS Safety Design Bases

This system is designed to meet the following design bases:

a. Detect a gross release of radioactive material into the refueling area ventilation duct

b. Promptly indicate a gross release of radioactive material

c. Provide on detection of a gross release of radioactive material:

1. A trip signal for the refueling area fans and closure of the valves to the ventilation exhaust system

2. A trip signal to isolate the primary containment atmosphere purge and vent lines and start the SGTS

3. An alarm annunciation in the control room

7.1.2.1.11.3.2 RAVE-RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are shown in Table 7.1-3.

7.1.2.1.11.3.3 RAVE-RMS Power Generation Design Bases

This system is designed to display an alarm in the control room and record gross releases of radioactive material from the refueling area duct. The control trip capability is stated above.

7.1.2.1.11.4 Control Room Ventilation Radiation Monitoring System

7.1.2.1.11.4.1 CRV-RMS Safety Design Bases

This system is designed to meet the following design bases:

a. Detect the presence of a hazardous quantity of radioactive material infiltrating the control room ventilation duct

b. Promptly indicate the presence of hazardous amounts of radioactivity

c. Provide, on detection of hazardous amounts of radioactive material:

1. A trip signal to close the control room ventilation intake dampers

2. A trip signal to start the control room emergency fresh air system

7.1.2.1.11.4.2 CRV-RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are given in Table 7.1-3.

7.1.2.1.11.4.3 CRV-RMS Power Generation Design Bases

The system provides continuous indication and recording of the concentration of radioactive material entering the control room under all conditions of plant operation, including accidents. It provides annunciation alarms in the control room.

7.1.2.1.11.5 Control Room Emergency Fresh Air Radiation Monitoring Systems

7.1.2.1.11.5.1 CREFA-RMS Safety Design Bases

This system is designed to detect the presence of residual radiation in the effluent from the HEPA/charcoal filters during operation of the CREFAS.

7.1.2.1.11.5.2 CREFA-RMS Specific Regulatory Requirements

This system satisfies the requirement that the control room ventilation system is monitored at all times for radioactivity. If there is closure of the control room ventilation intake dampers, the control room radiation monitoring system becomes inoperative, so it becomes necessary to transfer surveillance to an active station. The specific regulatory requirements of this system are shown in Table 7.1-3.

7.1.2.1.11.5.3 CREFA-RMS Power Generation Design Bases

During operation of the CREFAS, the monitoring system provides continuous indication and recording of the concentration of radioactive material entering the control room. It provides annunciation alarms in the control room.

7.1.2.1.11.6 Primary Containment Post-LOCA Radiation Monitoring System

7.1.2.1.11.6.1 PCPL-RMS Safety Design Bases

This system is designed to maintain surveillance of the gross gamma radioactivity of the primary containment atmosphere under postaccident conditions.

7.1.2.1.11.6.2 PCPL-RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are shown in Table 7.1-3.

7.1.2.1.11.6.3 PCPL-RMS Power Generation Design Bases

This monitoring system becomes operational during and after accident conditions when shutdown occurs. As such, it does not serve any power generation design basis. However, indications of radiation levels are transmitted to the control room for readout, recording, and alarm annunciation at preset levels.

7.1.2.1.11.7 Residual Heat Removal Service Water Radiation Monitoring System

7.1.2.1.11.7.1 RHRSW-RMS Safety Design Bases

This system is designed to meet the following safety design bases:

a. Detect the presence of significant amounts of radioactivity in the RHRSW downstream of the RHR heat exchangers

b. Promptly indicate the release of radioactive material to the spray pond

c. Provide a trip signal to the RHRSW Pumps on detection of the presence of significant amounts of radioactive material.

7.1.2.1.11.7.2 RHRSW-RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are given in Table 7.1-3.

7.1.2.1.11.7.3 RHRSW-RMS Power Generation Design Bases:

This system provides the following:

a. Recorder indication in the control enclosure of the radioactivity level in the RHRSW

b. Annunciates alarms in the control room.

7.1.2.1.11.8 Nonsafety-Related Radiation Monitoring Systems

The following process radiation monitoring systems are classified as power generation systems in that they do not serve safety-related functions. The postaccident monitoring functions of some of these systems are discussed in Section 7.5.

a. South stack effluent (ventilation)

b. Radwaste equipment rooms ventilation

c. Charcoal treatment system process exhaust (gas)

d. Recombiner rooms, hydrogen analyzer compartments, and equipment drain sump vent (ventilation)

e. Steam exhauster discharge and vacuum pump exhaust (gas)

f. Radwaste enclosure ventilation exhaust (ventilation)

g. Air ejector offgas

h. Primary containment leak detector (gas)

i. Hot maintenance shop ventilation exhaust (ventilation)

j. Liquid radwaste discharge (liquid)

k. Service water (liquid)

l. Reactor enclosure cooling water (liquid)

m. North stack effluent (ventilation)

With the exception of items (g) and (j), these monitoring systems have no control functions. The above systems are described in Section 11.5.

7.1.2.1.11.8.1 Nonsafety-Related RMS Safety Design Bases

There are no safety design bases for these systems. The postaccident design bases of some of the systems are described in Section 7.5.

7.1.2.1.11.8.2 Nonsafety-Related RMS Specific Regulatory Requirements

The specific regulatory requirements applicable to these systems are shown in Table 7.1-3.

7.1.2.1.11.8.3 Nonsafety-Related RMS Power Generation Design Bases

These systems provide the following:

a. Except for the hot maintenance shop monitor, the systems provide an indication in the control room of the radiation levels measured in each application. All indications of the hot maintenance shop monitor are local.

b. Except for the hot maintenance shop monitor, the systems provide recorder signals to the control room.

c. Alarm annunciation is provided if high or downscale trip signals are transmitted to the control room. Alarm annunciator signals from the hot maintenance shop monitor are local.

d. The liquid radwaste discharge monitor trip signal closes the liquid radwaste discharge valve if there is a high signal. Data from this monitor are transmitted to the radwaste enclosure control room rather than to the main control room.

7.1.2.1.12 Area Radiation Monitoring System

7.1.2.1.12.1 ARMS Safety Design Bases

The ARMS is not a safety-related system and provides no control function.

7.1.2.1.12.2 ARMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are given in Table 7.1-3.

7.1.2.1.12.3 ARMS Power Generation Design Bases

The system provides continuous indication and recording of gamma radiation intensities in those areas where radioactive materials may be present, handled, or inadvertently introduced. It provides annunciation alarms both locally and in the control room if preset limits of radiation are exceeded. Local alarms and readouts are located either adjacent to the detectors or at the entrance-ways to those areas that might prove hazardous to personnel.

7.1.2.1.13 Deleted

7.1.2.1.14 Habitability and Control Room Isolation System - Instrumentation and Controls

7.1.2.1.14.1 HCRIS Safety Design Bases

The system is designed to meet the following safety design bases:

a. During a radiation accident, isolate the main air intake and pressurize the control room with clean, filtered air

b. During a chlorine accident, isolate the control room and provide cleanup of the control room atmosphere by recirculation

7.1.2.1.14.2 HCRIS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.14.3 HCRIS Power Generation Design Bases

This system is designed to provide a safe and comfortable environment for the control room personnel.

7.1.2.1.15 Service Water Systems - Instrumentation and Controls

7.1.2.1.15.1 Emergency Service Water - Instrumentation and Controls

7.1.2.1.15.1.1 ESW Safety Design Bases

The system is designed to meet the following safety design bases:

a. During and after transient and accident conditions, the system provides cooling for the control room chillers and diesel generators, serves safety-related pump-motor units needing water cooling, and maintains cooling of safety-related equipment via space coolers.

b. During loss of fuel pool cooling, the system provides makeup water to maintain the water level in the fuel pool.

7.1.2.1.15.1.2 ESW Specific Regulatory Requirements

The specific regulatory requirements applicable to the ESW system are shown in Table 7.1-3.

7.1.2.1.15.1.3 ESW Power Generation Design Bases

The system is designed to provide cooling for recirculation pump motors and oil coolers and the RECW system heat exchangers.

7.1.2.1.15.2 Residual Heat Removal Service Water System - Instrumentation and Controls

7.1.2.1.15.2.1 RHRSW Safety Design Bases

The system is designed to meet the following safety design bases:

a. During normal shutdown, the RHRSW system provides cooling for the RHR system heat exchangers.

b. During and after transient and accident conditions, the system provides cooling for the RHR system heat exchangers.

c. After an accident, the RHRSW system provides water for flooding the reactor core, and spraying the primary containment, if required.

7.1.2.1.15.2.2 RHRSW Specific Regulatory Requirements

The specific regulatory requirements applicable to the RHRSW system are shown in Table 7.1-3.

7.1.2.1.15.2.3 RHRSW Power Generation Design Bases

There are no power generation design bases for this system.

7.1.2.1.16 Containment Atmospheric Control System - Instrumentation and Controls

7.1.2.1.16.1 Combustible Gas Control System

7.1.2.1.16.1.1 CGCS Safety Design Bases

The system provides the means to measure and control the concentration of hydrogen and oxygen in the primary containment atmosphere following postulated accidents to ensure that the primary containment integrity is maintained.

The system monitors the concentration of hydrogen and oxygen in the primary containment atmosphere during normal operation and following postulated accidents. Limits are established on abnormal concentrations of hydrogen and oxygen so that corrective action can be taken before unacceptable results occur. The unacceptable results are as follows:

a. A threat of significant compromise to the primary containment structure

b. A threat of significant compromise to the equipment inside the primary containment

7.1.2.1.16.1.2 CGCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the CGCS instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.16.1.3 CGCS Power Generation Design Bases

The system is designed to provide the means to measure and control the amount of oxygen to ensure containment inerting.

7.1.2.1.16.2 Primary Containment Vacuum Relief System - Instrumentation and Controls

7.1.2.1.16.2.1 PCVR Safety Design Bases

The PCVR is designed to meet the following safety design bases:

a. Operate automatically to allow air from the suppression chamber to enter the drywell when a differential pressure exceeds a pre-established limit

b. Check the operational availability of each valve and the disc position indication system for each valve during reactor operation

7.1.2.1.16.2.2 PCVR Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.16.2.3 PCVR Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.17 Reactor Core Isolation Cooling System - Instrumentation and Controls

7.1.2.1.17.1 RCIC Safety Design Bases

The system is designed to meet the following safety design bases:

a. Sufficient coolant can be maintained in the reactor vessel in case of an isolation with a loss of main feedwater flow.

b. Provisions are made for automatic and remote manual operation of the system.

c. Components of the RCIC system are designed to satisfy seismic Category I design requirements.

d. The power supply for the system is from immediately available energy sources of high reliability.

e. Provision is made so that periodic testing can be performed during plant operation.

7.1.2.1.17.2 RCIC Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are given in Table 7.1-3.

7.1.2.1.17.3 RCIC Power Generation Design Bases

There are no power generation design bases for this system.

7.1.2.1.18 Standby Liquid Control System - Instrumentation and Controls

7.1.2.1.18.1 SLCS Safety Design Bases

This system is capable of shutting the reactor down from full power to cold shutdown and maintaining the reactor in a subcritical state at atmospheric temperature and pressure conditions by pumping sodium pentaborate, a neutron absorber, into the reactor. This system is also capable of maintaining suppression pool pH at a level of 7.0 or greater following a LOCA.

7.1.2.1.18.2 SLCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are given in Table 7.1-3.

7.1.2.1.18.3 SLCS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.19 Radwaste Systems - Instrumentation and Controls

7.1.2.1.19.1 Liquid Radwaste System

7.1.2.1.19.1.1 LRS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.19.1.2 LRS Specific Regulatory Requirements

Specific regulatory requirements applicable to the system are listed in Table 7.1-3.

7.1.2.1.19.1.3 LRS Power Generation Design Bases

The instrumentation and control system is designed to provide dependable measurement and control for the various liquid processing systems during normal and expected occurrence conditions.

7.1.2.1.19.2 Gaseous Radwaste System

7.1.2.1.19.2.1 GRS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.19.2.2 GRS Specific Regulatory Requirements

Specific regulatory requirements applicable to the system are listed in Table 7.1-3.

7.1.2.1.19.2.3 GRS Power Generation Design Bases

The instrumentation and control system is designed to perform the following:

a. Monitor and control the GRS

b. Detect, indicate, and alarm a system upset to provide sufficient time for corrective action

7.1.2.1.19.3 Solid Radwaste System

7.1.2.1.19.3.1 SRS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.19.3.2 SRS Specific Regulatory Requirements

No specific regulatory requirements are imposed on the SRS.

7.1.2.1.19.3.3 SRS Power Generation Design Bases

The instrumentation and control system is designed to:

a. Monitor and control the SRS

b. Detect, indicate, and alarm a system upset to provide sufficient time for corrective action

7.1.2.1.20 Reactor Water Cleanup System - Instrumentation and Controls

7.1.2.1.20.1 RWCU Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.20.2 RWCU Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are provided in Table 7.1-3.

7.1.2.1.20.3 RWCU Power Generation Design Bases

The purpose of the RWCU system is to provide continuous processing of the reactor water to maintain the purity within specified limits. The system also provides the means for removal of reactor water. Although the RWCU system is of importance to startup and long-term operation, the reactor may operate while the RWCU is out of service.

7.1.2.1.21 Class 1E Power Systems

7.1.2.1.21.1 Class 1E Power Systems Safety Design Bases

The safety design bases for the electrical power systems required to support the safety-related systems are described in Sections 8.1 and 8.3.

7.1.2.1.21.2 Class 1E Power Systems Specific Regulatory Requirements

The specific regulatory requirements applicable to the standby power systems are given in Sections 8.1 and 8.3.

7.1.2.1.21.3 Class 1E Power Systems Power Generation Design Bases

The power generation design bases for the standby power systems are described in Sections 8.1 and 8.3.1.

7.1.2.1.22 Leak Detection Systems - Instrumentation and Controls

7.1.2.1.22.1 LDS Safety Design Bases

The safety design bases for the LDS are as follows:

a. Signals are provided that initiate automatic isolation (or permit manual isolation) of abnormal leakage before the results of this leakage become unacceptable.

b. The unacceptable results of failure to detect leakage are as follows:

1. The potential for degradation of the RCPB in excess of specified limits

2. The potential for release of primary coolant fluid sufficient to cause unacceptable offsite radiological doses

3. The potential for a leakage rate in excess of the capability of operating equipment to maintain reactor vessel water level

4. A threat of significant compromise to the steam and power conversion system boundary

5. The potential for a leakage rate in excess of radiological limits

6. The potential for a leakage rate that negates the safety equipment function

7.1.2.1.22.2 LDS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are given in Table 7.1-3.

7.1.2.1.22.3 LDS Power Generation Design Bases

A means is provided to detect and indicate in the control room abnormal leakage from the RCPB, steam, and the power conversion system boundary.

7.1.2.1.23 Reactor Shutdown Cooling Mode of the RHR System - Instrumentation and Controls

7.1.2.1.23.1 RHR-SCM Safety Design Bases

The RHR-SCM is designed to meet the following functional design bases:

a. Instrumentation and controls are provided that enable the system to remove the residual heat (decay heat and sensible heat) from the reactor vessel during normal shutdown.

b. Manual controls of the RHR-SCM are provided in the control room, and manual controls for one loop are provided at the remote shutdown panel.

c. Performance of the RHR-SCM is indicated by control room instrumentation and instrumentation on the remote shutdown panel.

7.1.2.1.23.2 RHR-SCM Specific Regulatory Requirements

The specific requirements applicable to the RHR-SCM are shown in Table 7.1-3.

7.1.2.1.23.3 RHR-SCM Power Generation Design Bases

The RHR-SCM meets the following power generation design bases:

a. Cooling is provided for the reactor during the shutdown operation when the vessel pressure is below the prescribed limit.

b. The reactor water is cooled to a temperature that is practicable for refueling and servicing operation.

7.1.2.1.24 Fuel Pool Cooling and Cleanup System - Instrumentation and Controls

7.1.2.1.24.1 FPCC Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.24.2 FPCC Specific Regulatory Requirements

The specific regulatory requirements applicable to the FPCC are given in Table 7.1-3.

7.1.2.1.24.3 FPCC Power Generation Design Bases

The purpose of the FPCC instrumentation and controls is to maintain the shielding water in the spent fuel and equipment storage pools and the reactor water well below a desired temperature and at a degree of clarity necessary to refuel and service the reactor.

7.1.2.1.25 Reactor Enclosure Recirculation System - Instrumentation and Controls

7.1.2.1.25.1 RERS Safety Design Bases

During an isolation of the reactor enclosure the RERS filters and mixes the air in this area.

7.1.2.1.25.2 RERS Specific Regulatory Requirements

The specific regulatory requirements applicable to the RERS instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.25.3 RERS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.26 Standby Gas Treatment System - Instrumentation and Controls

7.1.2.1.26.1 SGTS Safety Design Bases

This system is designed to meet the following safety design bases:

a. During an isolation of the reactor enclosure and/or refueling area, the SGTS restores and maintains these areas at a negative pressure with reference to the outside atmosphere

b. Further filter the air drawn from the reactor enclosure recirculation system before exhausting it to the atmosphere

7.1.2.1.26.2 SGTS Specific Regulatory Requirements

The specific regulatory requirements applicable to the SGTS instrumentation and control are shown in Table 7.1-3.

7.1.2.1.26.3 SGTS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.27

Deleted

7.1.2.1.28 Safety-Related Display Instrumentation

7.1.2.1.28.1 SRDI Safety Design Bases

The necessary display instrumentation is available to the reactor operator in the control room for determining when conditions exist that require specified manual control actions and to monitor the results of these and automatic actions, and to identify and follow the source of the accident to the degree necessary for the operator to perform his/her role and to verify adequate core cooling and containment integrity.

7.1.2.1.28.2 SRDI Specific Regulatory Requirements

The specific regulatory requirements applicable to the SRDI are given in Table 7.1-3.

7.1.2.1.28.3 SRDI Power Generation Design Bases

The safety-related instruments that are also used for power generation are designed so that all the expected power operation actions and maneuvers can be reasonably accomplished by the reactor operator.

7.1.2.1.29 Containment Instrument Gas System - Instrumentation and Controls

7.1.2.1.29.1 CIGS Safety Design Bases

The CIGS is designed to provide a compressed gas supply for the ADS SRVs.

7.1.2.1.29.2 CIGS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.29.3 CIGS Power Generation Design Bases

See Section 9.3.

7.1.2.1.30 Containment Spray Mode of the RHR System - Instrumentation and Controls

7.1.2.1.30.1 RHR-CSM Safety Design Bases

The RHR-CSM is designed to meet the following safety design bases:

a. Instrumentation and controls are provided to sense drywell pressure and to enable the system to condense steam in the drywell and the suppression pool air volume during a transient or accident event.

b. All manual controls for the containment spray mode of the RHR system are provided in the control room.

c. Performance of the RHR-CSM is indicated by control room instrumentation.

7.1.2.1.30.2 RHR-CSM Specific Regulatory Requirements

Specific regulatory requirements applicable to the RHR-CSM are listed in Table 7.1-3.

7.1.2.1.30.3 RHR-CSM Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.31 Remote Shutdown System - Instrumentation and Controls

7.1.2.1.31.1 RSS Safety Design Bases

The capability to remotely shutdown the reactor is designed to meet the following functional design bases:

a. Instrumentation and controls are provided outside the control room to allow prompt hot shutdown of the reactor and to maintain safe conditions during hot shutdown.

b. Suitable procedures provide the capability for subsequent cold shutdown of the reactor.

7.1.2.1.31.2 RSS Specific Regulatory Requirements

Specific regulatory requirements applicable to the RSS are listed in Table 7.1-3.

7.1.2.1.31.3 RSS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.32 Suppression Pool Cooling Mode of the RHR System - Instrumentation and Controls

7.1.2.1.32.1 RHR-SPCM Safety Design Bases

Instrumentation and controls are provided to allow the reactor operator to manually initiate suppression pool cooling to ensure that the pool temperature does not exceed the pre-established pool temperature limit.

7.1.2.1.32.2 RHR-SPCM Specific Regulatory Requirements

The specific regulatory requirements applicable to this mode of operation are the same as listed in Table 7.1-3 for the RHR-SCM.

7.1.2.1.32.3 RHR-SPCM Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.33 Safety-Related Equipment Area Cooling Ventilation Systems

7.1.2.1.33.1 Standby Gas Treatment System Filter Room and Access Area Unit Coolers - Instrumentation and Controls

7.1.2.1.33.1.1 SGTS-UC Safety Design Bases

Instruments and controls are provided to enable the unit coolers to provide cooling to the areas around the SGTS filter to keep ambient conditions within the prescribed limits.

7.1.2.1.33.1.2 SGTS-UC Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.33.1.3 SGTS-UC Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.33.2 Diesel Generator Enclosure Ventilation System - Instrumentation and Controls

7.1.2.1.33.2.1 DGEVS Safety Design Bases

Instruments and controls are provided to enable the diesel generator fans to provide ventilation to the diesel generator cells to keep the ambient conditions within the prescribed limits.

7.1.2.1.33.2.2 DGEVS Specific Regulatory Requirements

The specific regulatory requirements applicable to the DGEVS instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.33.2.3 DGEVS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.33.3 Spray Pond Pump Structure Ventilation System - Instrumentation and Controls

7.1.2.1.33.3.1 SPPSVS Safety Design Bases

Instruments and controls are provided to enable the fan systems to maintain the environment of the spray pond pump structure within the prescribed limits.

7.1.2.1.33.3.2 SPPSVS Specific Regulatory Requirements

This specific regulatory requirements applicable to the SPPSVS instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.33.3.3 SPPSVS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.33.4 Emergency Switchgear and Battery Rooms Cooling System - Instrumentation and Controls

7.1.2.1.33.4.1 ESBRCS Safety Design Bases

Instruments and controls are provided to enable the cooling units to keep the ambient conditions of the affected areas within the prescribed limits and provide exhaust recirculation from the battery rooms.

7.1.2.1.33.4.2 ESBRCS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.33.4.3 ESBRCS Power Generation Design Bases

Instruments and controls are provided to enable the cooling units to keep the ambient conditions of the affected areas within the prescribed limits and provide exhaust from the battery rooms.

7.1.2.1.33.5 Emergency Core Cooling Systems (ECCS and RCIC) Pump Compartment Unit Coolers - Instrumentation and Controls

7.1.2.1.33.5.1 ECCS-UC Safety Design Bases

Instruments and controls are provided to enable the unit coolers to keep the ambient conditions of the affected areas, except for HPCI and RCIC within the prescribed limits.

7.1.2.1.33.5.2 ECCS-UC Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.33.5.3 ECCS-UC Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.33.6 Auxiliary Equipment Room Ventilation System - Instrumentation and Controls

7.1.2.1.33.6.1 AERVS Safety Design Bases

Instruments and controls are provided to enable the fan systems to maintain the environment in the auxiliary equipment room within the prescribed limits.

7.1.2.1.33.6.2 AERVS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.33.6.3 AERVS Power Generation Design Bases

Instruments and controls are provided to ensure adequate ventilation for the equipment in the auxiliary equipment room.

7.1.2.1.34 Drywell Unit Coolers - Instrumentation and Controls

7.1.2.1.34.1 DUC Safety Design Bases

Instruments and controls are provided to enable the unit coolers to provide atmosphere mixing in the primary containment.

7.1.2.1.34.2 DUC Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.34.3 DUC Power Generation Design Bases

Instruments and controls are provided to enable the unit coolers to provide cooling in the primary containment.

7.1.2.1.35 Control Enclosure Chilled Water System - Instrumentation and Controls

7.1.2.1.35.1 CECWS Safety Design Bases

Instruments and controls are provided to enable the chiller and its circulating pumps to supply chilled water to the cooling coils of the associated equipment.

7.1.2.1.35.2 CECWS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and controls are shown in Table 7.1-3.

7.1.2.1.35.3 CECWS Power Generation Design Bases

Instruments and controls are provided to enable the chiller and its circulating pumps to supply chilled water to the cooling coils of the associated equipment.

7.1.2.1.36 High Pressure/Low Pressure System Interlocks

7.1.2.1.36.1 HPLPSI Safety Design Bases

HPLPSI is not a system, but provides interlocks between pressure in the reactor coolant and pressure in the RHR system. Therefore safety design bases do not apply directly to HPLPSI.

7.1.2.1.36.2 HPLPSI Specific Regulatory Requirements

There are no specific regulatory requirements for the HPLPSI.

7.1.2.1.36.3 HPLPSI Power Generation Design Bases

There are no power generation design bases for the HPLPSI.

7.1.2.1.37 Safety/Relief Valve Position Indication System - Instrumentation and Controls

7.1.2.1.37.1 SRVPI Safety Design Bases

Indication and alarms, provided in the control room, alert the operator to, and identifies, OPEN/NOT-OPEN SRVs.

7.1.2.1.37.2 SRVPI Specific Regulatory Requirements

The specific regulatory requirements applicable to the SRVPI are shown in Table 7.1-3.

7.1.2.1.37.3 SRVPI Power Generation Design Bases

There are no power generation design bases for this system.

7.1.2.1.38 Fire Protection and Suppression System

7.1.2.1.38.1 FPSS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.38.2 FPSS Specific Regulatory Requirements

There are no specific regulatory requirements for this system.

7.1.2.1.38.3 FPSS Power Generation Design Bases

There are no power generation design bases for this system.

7.1.2.1.39 Reactor Enclosure Isolation System

7.1.2.1.39.1 REIS Safety Design Bases

The system is designed to meet the following safety design bases:

a. Instruments and controls are provided that enable the system to isolate the reactor enclosure secondary containment.

b. Manual controls for the isolation system are provided in the control room.

c. Performance of the isolation is indicated by control room instrumentation.

7.1.2.1.39.2 REIS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and control are shown in Table 7.1-3.

7.1.2.1.39.3 REIS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.40 Nonsafety-Related Equipment Area Cooling Ventilation Systems

7.1.2.1.40.1 Safety Design Bases

There are no safety design bases for the instrumentation and controls for these systems.

7.1.2.1.40.2 Specific Regulatory Requirements

There are no specific regulatory requirements for these systems' instruments and controls.

7.1.2.1.40.3 Power Generation Design Bases

Instruments and controls are provided to ensure adequate ventilation for equipment and personnel located in the areas serviced by the nonsafety-related equipment area cooling ventilation systems during normal plant operation.

7.1.2.1.41 Safeguard Piping Fill System

7.1.2.1.41.1 SPFS Safety Design Bases

The SPFS is designed to perform two functions:

a. Provide a safety-related backup source of makeup water to the ECCS and RCIC pump discharge lines to prevent drainage of the lines from back leakage through the discharge check valves in the event of failure of the primary source (condensate transfer system)

b. Provide a water seal in the feedwater lines to forestall the possibility of drainage of the feedwater lines and subsequent bypass leakage of containment atmosphere

7.1.2.1.41.2 SPFS Specific Regulatory Requirements

The specific regulatory requirements for this system are listed in Table 7.1-3.

7.1.2.1.41.3 SPFS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.42 Refueling Area Isolation System

7.1.2.1.42.1 RAIS Safety Design Bases

The system is designed to meet the following safety design bases:

a. Instruments and controls are provided that enable the system to isolate the refueling floor.

b. Manual controls for the isolation system are provided in the control room.

c. Performance of the isolation is indicated by control room instrumentation.

7.1.2.1.42.2 RAIS Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and control are shown in Table 7.1-3.

7.1.2.1.42.3 RAIS Power Generation Design Bases

There are no power generation design bases for this system.

7.1.2.1.43 Redundant Reactivity Control System

7.1.2.1.43.1 RRCS Safety Design Basis

The RRCS is designed to mitigate the potential consequences of an ATWS event. The RRCS provides signals to mitigate an ATWS event by:

a. Initiating an ARI which is redundant and diverse from the normal RPS

b. Tripping the recirculation pump

c. Providing feedwater runback function

d. Automatically initiating the SLCS.

7.1.2.1.43.2 RRCS Specific Regulatory Requirements

The regulatory requirements applicable to the RRCS are given in Table 7.1-3.

7.1.2.1.43.3 RRCS Power Generation Design Bases

This system has no power generation design bases.

7.1.2.1.44 Rod Worth Minimizer

7.1.2.1.44.1 RWM Safety Design Bases

There are no safety design bases for the RWM.

7.1.2.1.44.2 RWM Specific Regulatory Requirements

The specific regulatory requirements applicable to the system instrumentation and control are listed in Table 7.1-3.

7.1.2.1.44.3 RWM Power Generation Design Basis

The RWM monitors and enforces operator adherence to established startup, shutdown, and low power level control rod sequences.

7.1.2.1.45 Plant Monitoring System

7.1.2.1.45.1 PMS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.45.2 PMS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are listed in Table 7.1-3.

7.1.2.1.45.3 PMS Power Generation Design Bases

The PMS is a centralized, integrated system which performs the process monitoring and calculations defined as being necessary for the effective evaluation of power plant operation. The PMS acquires and records process data (e.g., temperatures, pressure, flows, and status indicators) to produce meaningful displays, logs, and plots of current and historical plant performance. The PMS has the following major functions:

a. Provide real-time and historical emergency response information necessary to meet and support SPDS requirements; that is, information to maintain adequate core cooling, shut down the reactor, cool the RPV to cold shutdown conditions, maintain primary containment integrity, and protect equipment in the primary containment.

b. Provide functions, such as scan, log, and alarm, certain NSSS programs, SOE, trend recorder, and BOP programs.

c. Provide information to personnel in the control room, the TSC, and the EOF.

d. Provide real-time and historical information during normal, startup, and emergency operation at high resolution recording speeds for event monitoring and analyses.

7.1.2.1.46 Emergency Response Facility Data System

7.1.2.1.46.1 ERFDS Safety Design Bases

There are no safety design bases for this system.

7.1.2.1.46.2 ERFDS Specific Regulatory Requirements

The specific regulatory requirements applicable to this system are listed in Table 7.1-3.

7.1.2.1.46.3 ERFDS Power Generation Design

The ERFDS is a part of the PMS and performs the process monitoring and calculations defined as being necessary for the effective evaluation of normal and emergency power plant operation. The PMS acquires and records process data for ERFDS including temperatures, pressures, flows, and status indicators. This data is processed to produce meaningful displays, logs, and plots of current or historical plant performance and is presented to plant personnel in the plant main control room or other user definable locations.

7.1.2.2 Independence of Redundant Safety-Related Systems

7.1.2.2.1 Introduction

This section defines separation criteria for safety-related mechanical and electrical equipment. Safety-related equipment to which the criteria apply is that equipment that is necessary to mitigate the effects of DBAs and is identified in Section 7.1.1. The objective of the criteria is to delineate the separation requirements necessary to achieve independence of safety-related equipment.

7.1.2.2.2 Mechanical Systems Separation Criteria

7.1.2.2.2.1 General

a. Separation of the affected mechanical systems and equipment is accomplished so that the substance and intent of the General Design Criteria of 10CFR50, Appendix A are fulfilled.

b. Consideration is given to the redundant and diverse requirements of the affected systems.

c. Consideration is given to the type, size, and orientation of possible breaks of the RCPB specified in Section 3.6.

d. A single active component failure is an occurrence which results in the loss of capability of a component to perform its intended safety functions. Multiple failures resulting from a single occurrence are considered to be part of the single failure. Fluid systems are considered to be designed against an assumed single failure if a single failure of any active component (assuming passive components function properly) does not result in a loss of capability of the system to perform its safety function.

e. The affected mechanical systems and equipment, along with their associated structures, are appropriately separated so that they are adequately protected against:

    1. The design basis LOCA dynamic effects outlined in Section 3.6

    2. Missiles as defined in Section 3.5

3. Fires and floods capable of damaging redundant mechanical safety equipment (Sections 9.5.1 and 3.4)

The need for and the adequacy of separation are determined in conjunction with the criteria specified in Sections 3.5 and 3.6.

7.1.2.2.2.2 Mechanical Systems Separation

a. Piping for a redundant safety system is run independently of its counterpart. Redundant piping supports, restraints, and mechanical components of the same system are not shared unless it can be shown that such sharing does not impair their ability to perform their safety functions.

b. Entrance penetrations to the containment are separated so that damage to or failure of one branch of a system does not render its redundant counterpart(s) inoperable.

c. Equipment for redundant safety systems or redundant groups of safety systems is separated so that damage to or failure of one division of a system does not render its redundant counterpart inoperable.

7.1.2.2.2.3 Mechanical Systems Physical Separation

a. Mechanical equipment, piping, and tubing for safety-related systems are separated so that no single credible event is capable of disabling sufficient equipment to prevent reactor shutdown, removal of decay heat from the core, long-term suppression pool cooling, isolation, and integrity of the containment. Separation is accomplished either by distance or by physical barriers such as walls and intervening structural components.

   A representation of the separation is shown in Tables 7.1-4, 7.1-5, and 7.1-6.

b. The equipment in each group is separated from that in the other group by the required practical distance.

c. Separation barriers are constructed between the functional groups as required to ensure that the environmental disturbances (such as fire, flood, pipe rupture phenomena, falling objects, etc.) affecting one functional group do not affect the remaining groups.

7.1.2.2.3 Electrical Systems Separation Criteria

7.1.2.2.3.1 General

The electrical separation criteria are described in Section 8.1.6.1.14, compliance with Regulatory Guide 1.75. In addition to the criteria described there, the following applies:

a. Panels and Racks

Panels and racks associated with the RPS or ESF are labeled with marker plates which distinctively identify the equipment as being in the protective system; the difference may be in color, or color of engraving-fill. The marker plates include identification of the proper division of the equipment included.

b. Junction or Pullboxes

Junction and/or pullboxes enclosing wiring for the RPS or ESF have identification similar to and compatible with the panels and racks.

c. Cables

Refer to Section 8.1.6.1.14.

d. Raceways

Refer to Section 8.1.6.1.14.

e. Sensory Equipment Grouping and Designation Letters

Redundant sensory equipment is identified by suffix letters in accordance with Table 7.1-4 for all de-energized-to-operate systems, including the RPS, and in accordance with Table 7.1-5 for the NMS. These tables also show the allocation of sensors to their separated divisions.

f. Isolation Devices

Three types of isolation devices are used in control and instrumentation circuits:

a. Auxiliary relays and control switches

b. Fiber optic couplers

c. Solid-state signal isolators

Auxiliary relays are the most widely used type of isolation device. Several relay types are used with both contact-to-contact and coil-to-contact isolation being used in both BOP and NSSS circuits. Relays and control switches are considered to be acceptable isolation devices if they have a minimum breakdown voltage of at least 600 V RMS between adjacent contacts. This level was chosen because the maximum credible voltage that could be impressed on a control circuit is 530 V ac based on a hot short occurring between a power and control cable in a cable tray.

To confirm the suitability of relays as isolation devices, tests were performed on the several relay types that are mort widely used at LGS. These tests are documented in PECo Test Report 48503, dated September 1, 1982. This test report was submitted to the NRC by letter from J.S. Kemper (PECo) to A. Schwencer (NRC) dated November 20, 1982 and shows that these relays perform satisfactorily in preventing a postulated failure in a non-Class 1E circuit from adversely affecting a Class 1E circuit.

Fiber optic couplers are used to isolate the inputs to the PMS, which is non-safety related, from certain safety-related instrument loops that it monitors. The fiber optic transducers are part of the input modules of the PMS, some of which are Class 1E. The safety related modules are mounted in panels that contain cables of only one division. These panels are located in the control structure from which the multiplexer output is transmitted via fiber optic cable to the TSC where the PMS CPUs are located. Any failure of the PMS would not be reflected back into the safety systems through the fiber optic link because this fiber optic cable has a typical dielectric breakdown of 1.4 MV per inch.

Fiber optic isolators are also used between the Class 1E postaccident radiation monitors and the computer-based RMMS.

The RRCS also uses fiber optic isolators for logic interface between Class 1E divisions and Class 1E/non-Class 1E inputs. Test data for the isolators in these systems was transmitted to the NRC by letter from J.S. Kemper (PECo) to A. Schwencer (NRC) dated December 14, 1983.

Solid-state isolators are used to provide isolation of Class 1E analog inputs to the Plant Monitoring System. Because the computer input cables are routed in raceways that contain only instrumentation cables, it can be shown by analysis that these isolators adequately prevent any failure in the computer or the instrumentation raceways from adversely affecting any safety-related system.

Solid-state isolators are used to isolate inputs from the NMS (except PRNM) and from the dc battery bus to the Plant Monitoring System.

The NMS (except PRNM) isolators consist of an operational amplifier with a 10 volt maximum output which is reduced to 160 mV maximum by a resistive network. A 30 mA fuse is then provided in series prior to taking the signal to the computer. The dc voltage transducer/isolator has been tested to ensure that either a short circuit, open circuit, or short to ground on the output terminals would not cause an unacceptable effect on the dc system.

The PRNM uses fiber optic isolators between divisions and to the Plant Monitoring System, optically coupled relays for isolation of outputs to non-divisional circuits, and magnetically coupled analog isolators for isolation of analog outputs. It has been shown by analysis that these methods in combination with the wire and cable routing within the system assure adequate isolation between redundant channels of the safety-related functions.

Solid-state analog isolators are also used in several HVAC analog control loops to provide isolation of cross-division signals. Test data for all solid-state isolators was transmitted to the NRC by letter from J.S. Kemper (PECo) to A. Schwencer (NRC) dated December 14, 1983.

7.1.2.2.3.2 Electrical Systems Separation Requirements

7.1.2.2.3.2.1 RPS and Normally Energized Portions of PCRVICS

The following general rules apply to RPS wiring. Portions of the NMS wiring are considered as part of the RPS.

a. RPS cable in raceways outside of the main protection system cabinets run in enclosed raceways used only for the RPS. Under-vessel neutron monitoring cables are not placed in any enclosure that unduly restricts their flexibility. Neutron monitoring cables (SRM, IRM, and APRM) may be run in the same raceway, provided that divisional separation is maintained.

b. Wiring to redundant sensors on a common process tap is run in separate raceways to separate destinations to meet the single failure criterion.

c. Wiring for sensors of more than one variable in the same trip channel may be run in the same raceway.

d. Wires from both RPS trip systems that trip actuators to a single group of scram solenoids may be run in a single conduit; however, a single conduit does not contain wires to more than one group of scram solenoids or any other wiring. Wiring for two solenoids on the same control rod may be run in the same conduit.

e. Cables through the primary containment penetrations are so grouped that failure of all cabling in a single penetration cannot prevent a scram (this applies specifically to the neutron monitoring cables and the MSIVs position switch cables).

f. Power supplies to systems that de-energize to operate (so-called "fail-safe" power supplies) require only separation that is deemed prudent to give reliability (continuity of operation). Therefore, the protection system power supplies and load circuit breakers are not required to comply with the separation requirements for safety reasons, even though the load circuits go to separated panels.

g. Wiring providing power for the movement of each RPS backup scram valve and the solenoids for the SDV vent and drain valves is routed in rigid conduit, and wires are separated from one another and from all other cables.

h. The RPS wiring is run and/or protected so that no common source or potentially damaging energy (e.g., electrical fire in non-RPS wireways, malfunction, misoperation of plant equipment, pipe rupture, etc.) could reasonably result in a loss of ability to scram when required.

7.1.2.2.3.2.2 <u>All Other Safety-Related Systems Electrical Systems Separation Criteria</u>

a. Separation is designed so that no single failure can prevent the performance of any safety-related function. Redundant (even dissimilar) systems may be required to perform the required function to satisfy the single failure criterion. Figures 7.1-1 through 7.1-4, and Table 7.1-6 show equipment separation into divisions and the allowable interconnections through isolating devices.

b. The inboard and outboard NSSS system isolation valves are backups for each other, so they must be independent of and protected from each other, to the extent that no single failure can prevent the operation of at least one valve of an inboard/outboard pair. Figure 7.1-3 illustrates the MSL isolation valve separation concept.

c. Isolation valve circuits require special attention because of their function in limiting the consequences of a pipe break outside the primary containment. Isolation valve

control and power circuits are protected from the pipelines that they are responsible for isolating, as follows:

1. Essential isolation valve wiring in the vicinity of the outboard valve (or downstream from the valve) is installed in conduit and routed to take advantage of the mechanical protection afforded by the valve operator or other available structural barriers not susceptible to disabling damage from the pipeline break. Additional mechanical protection (barriers) is interposed as necessary.

2. Isolation valve control and/or power wiring run in a raceway with other cables is protected from secondary effects of damage to those cables that might result from a pipe break in a line requiring isolation (i.e., short circuits that might overheat cables in an ESF raceway).

3. When the downstream piping from the containment is not seismic Category I, the isolation valve wiring in the vicinity of the inboard valve is in rigid conduit and routed so as to take advantage of the mechanical protection afforded by the valve operator or other available structural barriers not susceptible to disabling damage from a pipe line break. Additional mechanical protection (barriers) are interposed as necessary between wiring and potential sources of disabling mechanical damage consequential to a pipe break. Except for the requirements of this paragraph, wiring near the inboard valve does not require special treatment discussed in paragraphs (1) and (2) above.

4. MOVs that have a mechanical check valve backup for their isolation function are included in the division that embraces the system in which the valves are located rather than adhering strictly to the inboard/outboard divisional classification.

d. Steam Leakage Zone

Electrical equipment and raceways for systems listed in Section 7.1.1.2 are not located in a steam leakage zone insofar as is practicable, or they are designed for short-term exposure to the high temperature and humidity associated with a steam leak.

e. Suppression Pool Level Swell Zone

Any electrical equipment and/or raceways for the RPS or ESF located in this zone are designed to complete their function satisfactorily before being rendered inoperable due to exposure to the environment created by the level swell phenomena.

7.1.2.3 Physical Identification of Safety-Related Equipment

The physical identification of equipment is described in Section 8.1.

7.1.2.4 Instrument Errors

The design considers instrument performance, as well as engineering judgment and historical practices in the selection of instrumentation and controls and in the determination of setpoints. An adequate margin between safety limits and Limiting Safety System Settings is provided based on the appropriate combination of engineering judgment, historical practice, and allowances for instrument performance. The Limiting Safety System Settings are contained in the Technical Specifications. When computational techniques are employed, nominal trip setpoints and allowable values are determined by combining allowances for instrument channel performance, such as accuracy (e.g., reference accuracy, pressure effects, temperature affects, radiation effects, etc.), process measurement accuracy, primary element accuracy, instrument drift, calibration accuracies and other uncertainties as appropriate. The specific performance allowance and the environmental and process conditions used, are based on the design, application, functional and calibration requirements of the instrument channel. The surveillance frequency is factored into time based instrument performance parameters.

Process instrument setpoints for LGS Units 1 and 2 are controlled in plant documentation and logs. The setpoints include automatic trip, indication, interlock and alarm setpoints for plant instruments such as analog and digital switches, time delays and similar devices.

The setpoint values shown on the logic diagrams in Chapter 7 are intended to assist the reader in the understanding of the document.

Administrative process control and document instrument setpoints for LGS Units 1 & 2. The scope of these processes include trip, alarm, and initiation setpoints for plant instruments such as analog and digital switches, time delays and similar devices.

The setpoint values shown on the logic diagrams in Chapter 7 are intended to assist the reader in the understanding of the document.

7.1.2.5 Conformance to Regulatory Guides

The statements on the degree of conformance to various regulatory guides which follow are intended to demonstrate an overall safety system level of compliance. The applicability of the conformance statements to each system is found in Table 7.1-3. Each individual system analysis discussion defines any difference in the degree of conformance to a particular regulatory guide.

7.1.2.5.1 Regulatory Guide 1.6 (March 1971) - Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems (Safety Guide 6)

Independence is maintained between redundant standby (onsite) sources and between their distribution systems in compliance with Regulatory Guide 1.6. Further discussion is presented in Section 8.1.6.1.

7.1.2.5.2 Regulatory Guide 1.7 (November 1978) - Control of Combustible Gas Concentrations in Containment Following a Loss-of-Coolant Accident

Conformance with Regulatory Guide 1.7 is discussed in Section 6.2.5.4.

7.1.2.5.3 Regulatory Guide 1.9 (March 1971) - Selection of Diesel Generator Set Capacity for Standby Power Supplies (Safety Guide 9)

See Section 8.1.6.1 for a complete discussion of conformance with Regulatory Guide 1.9.

7.1.2.5.4 Regulatory Guide 1.11 (March 1971) - Instrument Lines Penetrating Primary Reactor Containment (Safety Guide 11)

Conformance to Regulatory Guide 1.11 is discussed in Section 6.2.4.

7.1.2.5.5a Regulatory Guide 1.21 (June 1974) - Measuring, Evaluating, and Reporting Radioactivity in Solid Wastes and Releases of Radioactive Materials in Liquid and Gaseous Effluents from Light-Water-Cooled Nuclear Power Plants

The LGS process and effluent radiological monitoring and sampling systems are designed to allow conformance to this guide, as discussed in Sections 11.5, 7.6 and 7.7. Evaluation and reporting procedures during operation will conform to this guide.

7.1.2.5.5b Regulatory Guide 1.22 (February 1972) – Periodic Testing of Protection System Actuation Functions (Safety Guide 22)

The LGS design is in conformance with this guide. With respect to paragraph D.3 of the guide, administrative controls are considered "positive means" to limit the expansion of a bypass to redundant or diverse systems. Collective annunciation of bypassing by manual means is considered to satisfy the guidelines. Additional details are provided below:

D.3a The indications of system inoperability provided under the guidelines of Regulatory Guide 1.47 are used by the operator to prevent, through administrative procedures, the bypassing of a redundant channel of a protection system. The conditions that render the system inoperable during test are annunciated. The conditions that automatically bring up the out-of-service alarm are identifiable to the operator in the control room by means of the out-of-service status light.

D.3b A manual out-of-service switch is provided to annunciate any bypass condition that does not automatically energize the system out-of-service annunciator. A single status light indicates that the annunciator has been manually actuated. Individual indication for each manually induced inoperability is not provided.

Details for each system are discussed in Sections 7.2, 7.3, 7.4 and 7.6.

7.1.2.5.6 Regulatory Guide 1.29 (September 1978) - Seismic Design Classification

LGS is in conformance with this Guide with respect to instrumentation and controls.

The instrumentation and control equipment required to meet seismic Category I requirements is identified in general in Table 3.2-1, and specifically in the system piping and instrumentation drawings.

7.1.2.5.7 Regulatory Guide 1.30 (August 1972) - Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment (Safety Guide 30)

Conformance to this guide is discussed in Section 8.1.6.1.

7.1.2.5.8 Regulatory Guide 1.32 (February 1977) - Criteria for Safety-Related Electric Power Systems for Nuclear Power Plants

Refer to Section 8.1.6.1 for a discussion of this guide.

7.1.2.5.9 Regulatory Guide 1.40 (March 1973) - Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of Water-Cooled Nuclear Power Plants

There are no continuous-duty motors installed inside the containment that are part of the instrumentation and control systems.

7.1.2.5.10 Regulatory Guide 1.45 (May 1973) - Reactor Coolant Pressure Boundary Leakage Detection Systems

The RCPB leakage detection systems are provided to detect and, to the extent practical, identify the location(s) of the source of reactor coolant leakage.

Conformance to Regulatory Guide 1.45 is discussed in Section 5.2.

7.1.2.5.11 Regulatory Guide 1.47 (May 1973) - Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems

In accordance with the requirements of Regulatory Guide 1.47, bypassed and inoperable status indication has been provided for all plant protection systems. These systems are listed below. Also listed are the conditions that cause annunciation of system inoperability.

Equipment monitored within a protection system is that equipment which, when bypassed on removed from service, will cause inoperability of a redundant portion of the protection system. Bypass or removal of equipment will automatically initiate the system level out-of-service annunciator and illuminate a status light on the system control panel indicating the cause of the out-of-service condition.

All auxiliary and supporting systems to protection systems are monitored as part of the protection system availability in accordance with Regulatory Guide 1.47. The inoperability of these support systems causes the actuation of the out-of-service annunciator for the protection systems that these systems support. A status light is provided to indicate that the inoperability of the support system is the cause of inoperability of the protection system.

The bypass indication system is designed and installed in a manner which precludes the possibility of adverse affects on the plant safety system. The bypass indication system is electrically isolated from the protection circuits so that the failure or bypass of a protective function is not a credible consequence of failures in the bypass indication system and the bypass indication system cannot reduce the independence between redundant safety systems.

Equipment that is bypassed or removed from service not more than once per year is not monitored. A manual out-of-service switch is provided for this equipment and for other equipment that cannot be monitored.

Regulatory Positions C.1, C.2, and C.3:

Automatic indication is provided in the main control room to inform the operator that a system is inoperable. Annunciation is provided to indicate that a system or part of a system is not operable. Individual lights indicate what part of the system is out of service. Manual actuation is provided to cover situations which cannot be automatically annunciated. For example, the reactor protection (trip) system, and the containment and reactor vessel isolation system have annunciators lighting

and sounding whenever one or more channels of an input variable are bypassed. Bypassing is not allowed in the trip logic or actuation logic.

Instruments which form part of a one-out-of-two-twice logic system can be removed from service for calibration. Removal of the instrument from service is indicated in the main control room by manual actuation of the system out-of-service annunciator.

Regulatory Position C.4:

All the annunciators can be tested by depressing the annunciator test switches on the control room bench boards and can be brought up by manual switches as discussed in Regulatory Positions C.1, C.2, and C.3.

The following discussion expands the explanation of conformance to Regulatory Guide 1.47 to reflect the importance of providing accurate information for the operator and of reducing the possibility for the indicating equipment to adversely affect its monitored safety system.

a. Individual indicator lights are arranged together on a control room panel to indicate what function of the system is out of service, bypassed or otherwise inoperable. All bypass and inoperability indicators both at a system level and component level are grouped only with items that will prevent a system from operating if needed.

b. As a result of design, preoperational testing, and startup testing, no erroneous bypass indication is anticipated.

c. These indication provisions serve to supplement administrative controls and aids the operator in assessing the availability of component and system level protective actions. This indication does not perform a safety function.

d. All circuits are electrically independent of the plant safety systems to prevent the possibility of adverse effects.

e. Each indicator is provided with dual lamps and can be periodically tested.

The individual out-of-service condition that initiates a system level out-of-service alarm is listed below.

a. Pump breaker control power undervoltage

b. Pump breaker not connected

c. Pump breaker locked out

d. Loss of power to relay logic

e. Loss of power to control valve or valve motor overload

f. System logic in test

g. Trip unit in calibration or failure

h. Loss of power to trip unit or trip unit out of file

i. Manual out of service

j. Loss of system support HVAC

k. Valves operated from the control room that are not automatically positioned by the initiation signal

l. Transfer switch out of position

For the specific alarms that are associated with a system, refer to the functional control diagram for that system as listed in Chapter 7 figures and to the schematics E-648 as listed in Table 1.7-1.

Systems monitored as discussed above are as follows:

a.	RPS	Drawings C71-1010-F-002, C71-1010-F-003, C71-1010-F-004, and C71-1010-F-005
b.	CS System	Figure 7.3-9
c.	PCRVICS	Figure 7.3-8
d.	HPCI System	Figure 7.3-7
e.	RHR System	Drawings E11-1030-F-001, E11-1030-F-002, and E11-1030-F-003
f.	ESW System	Table 1.7-1
g.	Standby ac Power System	Table 1.7-1
h.	RCIC	Drawings E51-1030-F-004, E51-1030-F-005, E51-1030-F-006, E51-1030-F-007, E51-1030-F-008, and E51-1030-F-009
i.	RHR-SCM	Drawings E11-1030-F-001, E11-1030-F-002, and E11-1030-F-003
j.	REIS	Drawings B21-1030-F-002, B21-1030-F-002, B21-1030-F-003, B21-1030-F-004, B21-1030-F-005 and M-76FD
k.	SGTS	Drawing M-76FD
l.	RERS	Drawing M-76FD
m.	Control Enclosure HVAC Systems	Drawing M-78FD
n.	NMS	Figure 7.6-1

o. SLCS Table 1.7-1

p. CGCS Table 1.7-1

Regulatory Guide 1.47 compliance for Items (k), (l), and (m) above is through the use of a trouble alarm in the control room that will direct the operator to a local control panel in the control enclosure for more information. For Items (n) through (p), alarms are provided in the control room that provide the cause of the out-of-service condition. No status lights are provided.

The following three systems do not have system level out-of-service alarms in the control room: NMS, SLCS, and CGCS. The following conditions which can make these systems out of service are specifically annunciated in the control room:

a. NMS (Drawing E-620)

SRM	Downscale
SRM	Upscale/Inoperable
SRM	Retracted When Not Permitted
IRM	Upscale/Inoperable
IRM	Downscale
IRM	Upscale
RBM	Downscale/Trouble
APRM/RBM	Flow Reference Off-Normal
RBM	Upscale/Inoperable
APRM	Downscale
APRM	Upscale
LPRM	Downscale
LPRM	Upscale
APRM	Upscale Trip/Inoperable
OPRM/APRM	Trouble
OPRM	Upscale Trip
OPRM	Trips Enabled

b. SLCS (Drawing E-620)

SLCS	Pump A/B/C Overload/Loss of Power
SLCS	Tank High/Low Level
SLCS	Tank High/Low Temperature
SLCS	Squib Valve Loss of Continuity
SLCS	Isolation Valves Not Fully Open

c. CGCS (Drawing E-622)

Drywell H_2 Recombiner System Trouble 1A
Drywell H_2 Recombiner System Trouble 1B
The following alarms are provided on the recombiner control panels which are located in the control room behind the main control boards:

Return Gas Temperature High
Reaction Chamber Shell Temperature High

Blower Inlet Gas Pressure High
Reaction Chamber Gas Temperature High
Blower Inlet Temperature High
Blower Inlet Gas Flow Low
Reaction Chamber Gas Temperature Low
Heater Wall Temperature High

The above alarms for these four systems represent all conditions which can prevent the system from performing its safety function. The requirements of Regulatory Guide 1.47 for these systems are therefore satisfied. Any other conditions can be annunciated by manually causing one of the above annunciators to light.

Details of the administrative procedures that control access as a means for bypassing are contained in Section 7.2.2.1.1.1.8.

7.1.2.5.12 Regulatory Guide 1.53 (June 1973) - Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems

LGS is in conformance with this guide which provides that protection systems meet section 4.2 of IEEE 279 (1971), in that any single failure within the protection systems will not prevent proper protective action at the system level when required. Conformance is achieved by specifying, designing, and constructing the ESFs to meet the single failure criterion, section 4.2 of IEEE 279 (1971), "Criteria for Protection Systems for Nuclear Power Generating Stations," and IEEE 379 (1972), "IEEE Trial Use Guide for the Application of the Single Failure Criterion to Nuclear Power Generating Station Protection Systems." See Sections 7.2, 7.3, 7.4, and 7.6 for a discussion of conformance for each system.

7.1.2.5.13 Regulatory Guide 1.56 (July 1978) - Maintenance of Water Purity in Boiling Water Reactors

The RWCU instrumentation is in conformance with Regulatory Guide 1.56. Further discussion is provided in Sections 7.7.2.8.2.3 and 5.4.8. Conformance of the deep bed condensate demineralizer system is discussed in Section 10.4.6.

7.1.2.5.14 Regulatory Guide 1.62 (October 1973) - Manual Initiation of Protective Actions

LGS is in conformance with this guide which provides that manual initiation of each protective action at the system level be provided, that such initiation accomplish all actions performed by automatic initiation, and that protective action at the system level goes to completion once manually initiated. In addition, manual initiation is by switches readily accessible in the control room, and a minimum of equipment should be used in common with automatically initiated protective action.

Means are provided for manual initiation of the PCRVICS, the ECCS, and for RPS scram at the system level through the use of armed push buttons, as described below:

ACTION INITIATED	NUMBER OF SWITCHES
PCRVICS	Four
ADS	Four: two in Division 1 and two in Division 3
HPCI	One in Division 2

RHR A/CS A*	One in Division 1
RHR B/CS B*	One in Division 2
RHR C/CS C*	One in Division 3
RHR D/CS D*	One in Division 4
RPS	Four

The note "*" indicates that pumps A and C are for one CS injection system, and the B and D pumps are for the other system.

The operation of these switches initiates all actions performed by the automatic initiation circuitry.

For a detailed discussion on Regulatory Guide 1.62 compliance, refer to the following UFSAR Sections:

PCRVICS	Section 7.3.2.2.2.1.7
ADS	Section 7.3.2.1.2.1.9
HPCI	Section 7.3.2.1.2.1.9
RHR/CS	Section 7.3.2.1.2.1.9
RPS	Section 7.3.2.1.2.1.9

7.1.2.5.15 Regulatory Guide 1.63 (July 1978) - Electric Penetration Assemblies in Containment Structures for Light-Water-Cooled Nuclear Power Plants

Conformance to this guide is discussed in Section 8.1.6.1.

7.1.2.5.16 Regulatory Guide 1.68 (August 1978) - Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors

Conformance to this guide is discussed in Section 14.2.

7.1.2.5.17 Regulatory Guide 1.70 (November 1978) - Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants

Chapter 7 conforms to the format of Regulatory Guide 1.70.

7.1.2.5.18 Regulatory Guide 1.73 (January 1974) - Qualification Tests of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants

Conformance to this guide is discussed in Sections 8.1.6.1 and 3.11.2.2.

7.1.2.5.19 Regulatory Guide 1.75 (September 1978) - Physical Independence of Electric Systems

Conformance is discussed in Section 8.1.6.1.14.

7.1.2.5.20 Regulatory Guide 1.80 (June 1974) - Preoperational Testing of Instrument Air Systems

Conformance to this guide is discussed in Section 14.2.

7.1.2.5.21 Regulatory Guide 1.89 (November 1974) - Qualification of Class 1E Equipment for Nuclear Power Plants

Discussion of degree of conformance to Regulatory Guide 1.89 is given in Section 3.11.2 for NSSS equipment and in Section 8.1.6.1 for non-NSSS equipment.

7.1.2.5.22 Regulatory Guide 1.96 (May 1975) - Design of Main Steam Isolation Valve Leakage Control Systems for Boiling Water Reactor Nuclear Power Plants

In 1994, LGS received approval to remove the MSIV-LCS and replace it with the MSIV Leakage Alternate Drain Pathway discussed in Section 6.7.

7.1.2.5.23 Regulatory Guide 1.97 (December 1980) - Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident

See Section 7.5 for a discussion of the degree of conformance.

7.1.2.5.24 Regulatory Guide 1.100 (August 1977) - Seismic Qualification of Electric Equipment for Nuclear Power Plants

The degree of conformance to this guide is discussed in Section 3.10.

7.1.2.5.25 Regulatory Guide 1.105 (November 1976) - Instrument Setpoints

Although this guide does not apply to LGS per its implementation section except for the RRCS, the following is an assessment of the design supplied.

The nominal trip setpoint and allowable value for Limiting Safety System Settings are contained in the Technical Specifications. These parameters are determined based on the appropriate combination of engineering judgment, historical practice, and allowances for instrument performance (7.1.2.4). The setpoints are within the operating capability of the associated instruments. The established setpoints provide sufficient margin to satisfy both safety requirements, and plant availability objectives.

Related setpoint methodology concerns have been addressed by Reference 7.1-1. In a May 15, 1984 submittal, LGS endorsed the work scope and schedule proposed by Reference 7.1-1, which was accepted by the NRC staff in Reference 7.1-2. The licensee agreed to show compliance with the methodology within 6 months of NRC approval of the methodology. The methodology was submitted by GE on November 19, 1986. This methodology has been accepted by the NRC by virtue of issuance of an SSER for the Power Re-Rate for LGS.

7.1.2.5.26 Regulatory Guide 1.118 (June 1978) - Periodic Testing of Electric Power and Protection Systems

This guide, which endorses/modifies IEEE 338 (1977), is not applicable to LGS per its implementation section except for the RRCS. Discussion of IEEE 338 is presented on a system-by-system basis in the analysis portion of Section 7.2, 7.3, 7.4, and 7.6 with the following clarification of the regulatory guide requirements:

Position C.2 - Insofar as is practical and safe, response time testing will be performed from sensor inputs (at the sensor input connection for process instruments) to and including the actuated device.

Sensor response time testing for pressure sensors for the RPS will be performed in accordance with Regulatory Guide 1.118 (June, 1978). Response of the sensor output and the final actuation device will be measured. Response time testing for the differential pressure (level) sensors is not required based on the analysis performed in NEDO-32291-A. Response time testing of the trip unit and relay logic are required. Neutron detectors are exempt from response time testing; response time will be measured from the input of the first electronic component in the channel. Except for the MSIVs, individual sensor response times and logic system response times are not required for isolation systems because the signal delay (sensor response) is concurrent with the 13 second diesel startup. (Refer to LGS Technical Specification Bases 3/4.3.2 "Isolation Actuation Instrumentation" and 3/4.3.3 "ECCS Actuation Instrumentation.")

Position C.6b - Trip of an associated protective channel or actuation of an associated Class 1E load group is required on removal of fuses or opening of a breaker only for the purpose of deactivating instrumentation and control circuits.

Evaluation of the systems to be surveillance tested has determined that the actions required will include opening of circuit breakers. This action is required in a limited number of cases. The circuit breakers will be opened during monthly testing but will also bring up an out-of-service alarm that will not clear with the breaker open.

A review of safety-related control circuits that may be affected by racking-out their individual circuit breakers reveals that disabling of one component does not render redundant components inoperable. All modes of test, operation, and failure were considered; specifically, a study was conducted to identify safety systems with crossover interlocks. The effects of disabling of these components and their associated interlocks were then analyzed. The review identified that several crossover interlocks exist in the ESW and RHRSW systems and in several of the NSSS fail-safe logic circuits. However, the analysis did not disclose any cases where disabling the component or the associated interlocks would adversely affect the redundant safety circuit or components.

Response to Information Notice 84-37 – Lifting of leads will be required to perform a limited number of the surveillance tests. Each of these tests, however, will follow the guidance provided by Information Notice 84-37, dated May 10, 1984.

The procedure for these tests will include instructions requiring the reconnecting of the lifted leads following the completion of the surveillance. This procedural step will be documented by a sign-off sheet to be initialed by the tester when the lifted leads have been reconnected. An independent or double verification will be performed and documented in the procedure to verify that the lifted leads have been returned to service. If permitted by existing plant design, functional tests designed to verify the restoration of proper system configuration will be performed.

The lifting of leads will be limited to surveillance tests that fall into one of the four categories below:

a. Test that involve thermocouples

b. Test that require the introduction of test equipment into the instrument channel being tested

c. Tests on extensive systems that would otherwise become unnecessarily large and complex

d. Tests on systems or components for which the plant design permits no other reasonable alternative.

7.1.2.5.27 Regulatory Guide 1.139 (May 1978) - Guidance for Residual Heat Removal

Conformance to this guide is discussed in Section 5.4.

7.1.2.6 Conformance to 10CFR50, Appendix A, General Design Criteria

The statements which follow on the degree of conformance to various GDC are intended to demonstrate an overall safety system level of compliance. The applicability of the conformance statements to each system is found in Table 7.1-3. Each individual system analysis discussion defines any difference in the degree of conformance to a particular GDC.

7.1.2.6.1 GDC 1 - Quality Standards and Records

All systems required for safety are designed and built in accordance with an established quality assurance program.

7.1.2.6.2 GDC 2 - Design Bases for Protection Against Natural Phenomena

All systems required for safety are designed to withstand the effects of natural phenomena without loss of capability to perform their safety functions.

7.1.2.6.3 GDC 3 - Fire Protection

All systems and components required for safety are designed and located to minimize the probability and effect of fires and explosions. Materials that are heat-resistant and noncombustible have been chosen wherever practicable.

7.1.2.6.4 GDC 4 - Environmental and Dynamic Effects Design Bases

Systems and components required for safety are designed to accommodate the effects of and be compatible with the environmental conditions associated with normal operations maintenance testing and postulated accidents, including LOCAs. These systems and components are appropriately protected against dynamic events such as missiles and pipe whipping.

7.1.2.6.5 GDC 5 - Sharing of Structures, Systems, and Components

Systems and components required for safety are not shared with any other nuclear power unit, except for the RHRSW, the ESW, the SGTS and the control structure ventilation systems, which are common systems.

7.1.2.6.6 GDC 10 - Reactor Design

The reactor core and associated coolant, control, and protection systems are designed with appropriate margins to ensure that specified acceptable fuel design limits will not be exceeded

during any condition of normal operation, including the effects of anticipated operational occurrences.

7.1.2.6.7 GDC 12 - Suppression of Reactor Power Oscillations

The instrumentation and control systems are designed to readily detect and initiate action to suppress reactor power oscillations.

7.1.2.6.8 GDC 13 - Instrumentation and Control

Instrumentation is provided to monitor variables and systems over their anticipated ranges for normal operation, anticipated operational occurrences, and accident conditions and to control these variables and systems to ensure adequate safety.

7.1.2.6.9 GDC 15 - Reactor Coolant System Design

The RCS instrumentation and control systems are designed to ensure that the design conditions of the RCPBs are not exceeded.

7.1.2.6.10 GDC 19 - Control Room

A control room is provided where actions can be taken to operate the nuclear power unit under normal and abnormal conditions. A remote shutdown capability is also provided.

7.1.2.6.11 GDC 20 - Protection System Functions

The protection systems are designed to sense accident conditions and automatically initiate the operation of appropriate systems important to safety to ensure that specified fuel design limits are not exceeded.

7.1.2.6.12 GDC 21 - Protection System Reliability and Testability

The conformance discussion of this GDC is presented on a system-by-system basis in the analysis portions of Sections 7.2, 7.3, 7.4, and 7.6.

7.1.2.6.13 GDC 22 - Protection System Independence

The protection systems are designed with independence through redundancy or functional diversity to prevent loss of the protection function.

7.1.2.6.14 GDC 23 - Protection System Failure Modes

The protection systems are designed to be fail-safe during anticipated operational occurrences including postulated adverse environments.

7.1.2.6.15 GDC 24 - Separation of Protection and Control Systems

The protection systems are separated from control systems to the extent that failure of any single control system component or channel, or failure or removal from service of any single protection

system component or channel which is common to both, leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system.

7.1.2.6.16 GDC 25 - Protection System Requirements for Reactivity Control Malfunctions

The protection system is designed so that fuel design limits are not exceeded even with any single malfunction of the reactivity control system.

7.1.2.6.17 GDC 26 - Reactivity Control System Redundancy and Capability

The conformance discussion of this GDC is presented on a system-by-system basis in the analysis portions of Sections 7.4, 7.6, and 7.7.

7.1.2.6.18 GDC 27 - Combined Reactivity Control Systems Capability

The conformance discussion of this GDC is presented on a system-by-system basis in the analysis portions of Sections 7.4, and 7.7.

7.1.2.6.19 GDC 28 - Reactivity Limits

The conformance discussion of this GDC is presented on a system-by-system basis in the analysis portions of Sections 7.6 and 7.7.

7.1.2.6.20 GDC 29 - Protection Against Anticipated Operational Occurrences

The protection and reactivity control systems are designed to ensure an extremely high probability of accomplishing their safety function in the event of an anticipated operational occurrence.

7.1.2.6.21 GDC 30 - Quality of Reactor Coolant Pressure Boundary

The conformance discussion of this GDC is presented in the analysis portions of Sections 7.3, 7.4, and 7.6.

7.1.2.6.22 GDC 33 - Reactor Coolant Makeup

Reactor coolant makeup is provided to ensure that specified acceptable fuel design limits are not exceeded because of reactor coolant losses in the RCPB.

7.1.2.6.23 GDC 34 - Residual Heat Removal

A system is provided to remove reactor residual heat to ensure that the specified acceptable fuel design limits are not exceeded even assuming a single failure.

7.1.2.6.24 GDC 35 - Emergency Core Cooling

An ECCS is provided to ensure cooling of the reactor following any loss of reactor coolant at undesirable rates even assuming a single failure.

7.1.2.6.25 GDC 37 - Testing of Emergency Core Cooling System

The ECCS is designed to permit appropriate periodic pressure and functional testing including the controls which bring the system into operation.

7.1.2.6.26 GDC 38 - Containment Heat Removal

A system is provided to ensure heat removal from the reactor containment following any LOCA even assuming a single failure.

7.1.2.6.27 GDC 40 - Testing of Containment Heat Removal System

The containment heat removal system is designed to permit appropriate periodic and functional testing including the controls which bring the system into operation.

7.1.2.6.28 GDC 56 - Primary Containment Isolation

Each line that connects directly into the containment atmosphere and penetrates the primary reactor containment is provided with isolation valves that comply with the requirements of this criterion.

7.1.2.6.29 GDC 57 - Closed System Isolation Valves

See GDC 56.

7.1.2.6.30 GDC 60 - Control of Releases of Radioactive Materials to the Environment

The nuclear power unit is designed to control the release of radioactive material and from gaseous, liquid, and solid effluents to within prescribed limits, through monitoring the release points and processing the effluent.

7.1.2.6.31 GDC 61 - Fuel Storage and Handling and Radioactivity Control

The conformance discussion of this GDC is presented in the analysis portion of Section 7.7.

7.1.2.6.32 GDC 63 - Monitoring Fuel and Waste Storage

The conformance discussion of this GDC is presented in the analysis portion of Section 7.7.

7.1.2.6.33 GDC 64 - Monitoring Radioactivity Releases

The conformance discussion of this GDC is presented in the analysis portion of Section 7.6.

7.1.2.7 Conformance to Industry Codes and Standards

The statements which follow on the degree of conformance to various industry standards are intended to demonstrate an overall safety system level of compliance. The applicability of the conformance statements to each system is found in Table 7.1-3. Each individual system analysis discussion will define any difference in the degree of conformance to a particular industry standard.

Reference 7.1-3 discusses the conformance of the sensors to industry standards and regulatory guides.

Conformance other than that discussed in NEDO-21617-A is discussed in Section 7.1.2.5 and 7.1.2.6 and also on a system-by-system basis in Sections 7.2, 7.3, and 7.4.

7.1.2.7.1 IEEE 279 (1971) - Criteria for Protection Systems for Nuclear Power Generating Stations

This discussion is presented on a system-by-system basis in the analysis portions of Sections 7.2, 7.3, 7.4, and 7.6.

7.1.2.7.2 IEEE 308 (1971 and 1974) - Criteria for Class 1E Electrical Systems for Nuclear Power Generating Stations

Conformance to IEEE 308 as described in Section 8.3 is applicable to safety-related instrumentation and control equipment.

7.1.2.7.3 IEEE 317 (1972) - Electric Penetration Assemblies in Containment Structures for Nuclear Power Generating Stations

Penetration assemblies meet the requirements of IEEE 317 (1972) and GDC 50 of 10CFR50, Appendix A.

All containment electrical penetration assemblies used for Class 1E and non-Class 1E circuits are designed to withstand, without loss of containment integrity, the maximum postulated overcurrent versus time conditions, assuming a single failure of the circuit primary overcurrent protection apparatus.

7.1.2.7.4 IEEE 323 (1971) - IEEE Trial Use Standard: General Guide for Qualifying Class 1 Electric Equipment for Nuclear Power Generating Stations

Written procedures and responsibilities are developed for the design and qualification of Class 1E electric equipment. This includes preparation of specifications, qualification procedures, and documentation. Whenever possible qualification testing or analysis is accomplished before release of the engineering design for production. Standards manuals are maintained containing specifications, practices, and procedures for implementing qualification requirements. The environmental qualification of this equipment is being evaluated to the criteria of NUREG-0588 Category II. An Environmental Qualification Report will be provided to present the results of this evaluation.

See Sections 3.11.2 and 8.1.6.1 for a conformance discussion of IEEE 323 and Regulatory Guide 1.89 for NSSS and non-NSSS equipment, respectively.

7.1.2.7.5 IEEE 336 (1971) - Installation, Inspection, and Testing Requirements for Instrumentation and Electric Equipment During the Construction of Nuclear Power Generating Stations

See Section 8.1.6.1 for a conformance discussion of Regulatory Guide 1.30 which endorses/modifies IEEE 336 (1971).

7.1.2.7.6 IEEE 338 (1971, 1975, and 1977) - Criteria for the Periodic Testing of Nuclear Power Generating Station Protection Systems

This discussion is presented on a system-by-system basis in the analysis portion of Sections 7.2, 7.3, 7.4, and 7.6.

See Section 7.1.2.5.26 for a conformance discussion of Regulatory Guide 1.118, which endorses/modifies this standard.

7.1.2.7.7 IEEE 344 (1971 or 1975) - Guide for Seismic Qualification of Class 1 Electric Equipment for Nuclear Power Generating Stations

All safety-related instrumentation and control equipment is classified as seismic Category I and designed to withstand the effects of an SSE, and function before, during and after such a seismic event. Equipment required to function after an SSE is also qualified for such service. Qualification and documentation procedures used for seismic Category I equipment and systems meet the provisions of IEEE 344 as identified in Section 3.10.

7.1.2.7.8 IEEE 379 (1972 or 1977) - Guide for the Application of the Single Failure Criterion to Nuclear Power Generating Station Protection Systems

The extent to which the single failure criteria of IEEE 379 are satisfied is specifically covered for each system in the analysis of IEEE 279, paragraph 4.2.

7.1.2.7.9 IEEE 382 (1972) - Trial Use Guide for Type Test of Class 1 Electric Valve Operators for Nuclear Power Generating Stations

The extent of conformance to this standard is given in Sections 3.11.2 and 8.1.6.1.13.

7.1.2.7.10 IEEE 383 (1974) - Standard for Type Test of Class 1E Electric Cables, Field Splices, and Connections for Nuclear Power Generating Stations

The extent of conformance to this standard is given in Section 7.7.2.21.2.2.1.

7.1.2.7.11 IEEE 384 (1974 or 1977) - Criteria for Separation of Class 1E Equipment and Circuits

The safety-related systems described in Sections 7.2, 7.3, 7.4, and 7.6 meet the independence and separation criteria for redundant systems in accordance with IEEE 279, paragraph 4.6 (Section 7.1.2.5.1).

The electrical power supply, instrumentation, and control wiring for redundant portions of safety-related systems have physical separation to preserve redundancy and ensure that no single credible event prevents operation of the associated function. Credible events include, but are not limited to, the effects of short circuits, pipe rupture, pipe whip, high pressure jets, missiles, fire, earthquake, and falling objects, and are considered in the basic plant design.

The independence of tubing, piping, and control devices for safety-related controls and instrumentation is achieved by physical space or barriers between separation groups of the same protective function. In locations where a specific hazard exists (missile, jet, etc.) that could produce damage to safety-related controls and instrumentation, the physical separation or structural protection provided is adequate to ensure that no multiple failures can result from a single common event.

The criteria and bases for the independence of electrical cable, including routing, marking, and cable derating, are discussed in Section 8.1. Fire detection and protection in the areas where wiring is installed are discussed in Section 9.5.1.

Regulatory Guide 1.75, which endorses/modifies this standard, is discussed in Section 7.1.2.5.19.

7.1.2.8 Conformance to Branch Technical Positions

7.1.2.8.1 BTP ICSB 3

The HPLPSI conform to BTP ICSB 3 as discussed in Section 7.6.1.2.

7.1.2.8.2 BTP ICSB 21

Conformance to BTP ICSB 21 is discussed below, by position:

B1. Individual indicator lights are arranged together on a control room panel to indicate what function of the system is out-of-service, bypassed, or otherwise inoperable. All bypass and inoperability indicators both at a system level and component level are grouped only with items that will prevent a system from operating if needed.

B2. LGS has only one control room. When a protective function of a shared system is bypassed, it is annunciated on the annunciator panel for the shared system, and status indication for the system is provided on the control panel for the shared system.

B3. As a result of design, preoperational testing, and startup testing, no erroneous bypass indication is anticipated. Capability for cancelling bypass indications is not provided.

B4. These indication provisions serve to supplement administrative controls and to aid the operator in assessing the availability of component and system level protective actions. This indication does not perform a safety function.

B5. All circuits are electrically independent of the plant safety systems to prevent the possibility of adverse effects.

B6. The out-of-service annunciators can be tested by depressing the annunciator test switches on the control room bench boards. Each status indicating light can be tested by depressing the light assembly.

The bypass and inoperable status indicators are further discussed in Section 7.1.2.5.11.

7.1.2.8.3 BTP ICSB 22

The conformance to the provisions of D.4 of Regulatory Guide 1.22 for actuated equipment not tested during power operation is discussed in Section 7.3.2.1.2.3.1.10 for the ADS valves and Sections 7.4.2.2.2.3.1.9 and 7.4.2.2.2.3.1.10 for the SLCS explosive valves.

7.1.2.8.4 BTP ICSB 26

Anticipating or backup trips for the system comply with the requirements of IEEE 279 (1971) as discussed in Section 7.2.2.1.2.3.1.

7.1.2.9 Technical Design Bases

The technical design bases appear as follows:

RPS	Section 7.2.1
ESFs	Section 7.3.1
Systems required for safe shutdown	Section 7.4.1
Other systems required for safety	Section 7.6.1

7.1.2.10 Safety System Settings

The Limiting Safety System Settings are listed in the Technical Specifications discussions for each safety system. The settings are determined based on operating experience and conservative analyses. The settings are set to preclude inadvertent initiation of the safety action, while ensuring that a sufficient margin is maintained to satisfy safety requirements. The appropriate combination of engineering judgment, historical practice, and allowances for instruments performance are considered in the setpoint determination (Section 7.1.2.4). The margin between the limiting safety system settings and the actual safety limits includes consideration of the design basis transients in the process being measured, expected for the time the specific functions are required.

7.1.2.11 Operating Experience Assessment

Review of operating experiences and assessment of their applicability to LGS is conducted as discussed in Section 13.4.5. The actions taken by the licensee for LGS for some specifically requested NRC Bulletins, Circulars and Information Notices is provided in Table 7.1-7. Specific actions taken for some of these is provided below.

7.1.2.11.1 Bulletin 80-06, Engineered Safety Feature Reset Controls

Bulletin 80-6 requires that safety-related equipment remain in its emergency mode on reset of an ESF actuation signal.

To determine whether or not all safety-related equipment remains in its emergency mode on isolation signal reset, schematic drawings for all LGS systems serving safety-related functions were reviewed. The review showed that a number of valves were subject to reverting to their normal mode on isolation signal reset. All continuous-duty loads were found to remain in their emergency mode on isolation signal reset.

In general, control schemes of safety-related valves found not to remain in their emergency mode on reset of an isolation signal were revised to provide a control switch interlock with the isolation signal reset circuit (Figure 7.1-5). To reset an isolation signal, every valve subject to reverting to normal mode on reset of the isolation signal must have its control switch placed in the closed position. A normally open contact of each of the valve control switches is wired in series with the

isolation signal reset contact. On manual placement of all of the subject control switches in the closed position, the permissive series of control switch contacts will all be closed, thus allowing the isolation signal reset contact to complete the reset circuit.

On the bases of the design review, the following systems and valve control schemes were modified as described above:

System	Valve No.	
CAC System	HV57-117	SV57-133
	HV57-118	SV57-183
	HV57-104	SV57-191
	HV57-114	SV57-181
	HV57-123	SV57-132
	HV57-124	SV57-134
	HV57-121	SV57-150
	HV57-131	SV57-141
	SV57-184	SV57-142
	SV57-185	SV57-143
	SV57-186	SV57-144
	SV57-190	SV57-145
	SV57-195	SV57-159
PCIG System	HV59-129A	SV59-131
	HV59-102	SV59-135
	HV59-129B	
NSSSS	HV41-1F084	HV51-1F079A
	HV41-1F085	HV51-1F079B
	HV43-1F019	HV51-1F080A
	HV43-1F020	HV51-1F080B

In addition to the foregoing valves, drywell purge exhaust fan inlet isolation valves HV76-030 and HV76-031 were found to revert to their normal mode on isolation signal reset. Thus, if the valves were in their open purge mode on receipt of an isolation signal, the valves would revert to the open purge mode isolation signal reset. To ensure that these valves remain in their closed emergency mode on isolation signal reset, the valve control schemes were modified to the configuration shown on Figure 7.1-6. The auxiliary relay (95-2) is picked up by the normally closed isolation signal contacts and by the placement of the valve control switch in the "CLOSE" position. Once picked up, the auxiliary seals itself in with a contact around the valve control switch "CLOSE" contact. The valves are placed in the "OPEN" purge position through a contact from the auxiliary relay and the placement of the valve control switch in the "OPEN" position. On receipt of an isolation signal, the normally closed isolation signal contacts open, thus dropping out the auxiliary relay, which in turn opens the auxiliary relay seal-in circuit and de-energizes the valve "OPEN" circuit, thus closing the valve. Resetting the isolation signal will not re-energize the auxiliary relay because the valve control switch is in the "OPEN" position. Thus, the valve "OPEN" circuit will remain de-energized and the valves will remain closed.

The liquid radwaste collection isolation valves, HV61-110, HV61-111, HV61-130 and HV61-131 were found to revert to normal mode on isolation signal reset. To ensure that these valves

remained in their emergency mode, seal-in relays were added in their control circuit. Because these valves are a part of the drywell sump tank level control system and the primary containment leakage detection system, these valves have been excluded from the system logic reset and are provided with individual reset circuits.

The following are exceptions to Bulletin 80-06 guidance:

a. RCIC

All actuated equipment remains in its abnormal condition, except for the RCIC system inboard and outboard steam line isolation valves, E51-F007 and E51-F008.

b. HPCI

All actuated equipment remains in its abnormal condition, except for the HPCI system inboard and outboard steam line isolation valves, E41-F002 and E41-F003.

The reset control for the HPCI/RCIC isolation logics do not strictly meet the intent of Bulletin 80-06. If the isolation logic is reset with the valve control switches in the open position, the isolation valves will open, but we believe the design is acceptable. There are two completely independent isolation logics for the HPCI and RCIC. Each of these logics consists of two logic channels, one for the inboard valves and one for the outboard valves. Each of these logic channels is sealed in until a reset switch in that logic is depressed. Therefore activation of the reset switch only affects one logic channel and will only cause the inboard or outboard valves to open on the system being reset. The line will remain isolated, i.e., in its safe mode, until both the isolation logics for each system are reset. In addition, the logic reset has no effect if the initiation signal is still present. Administrative Procedures will instruct the operator to place the control switches in the closed position before resetting the isolation logic. In addition to this procedural caution, a caution tag will be added to the control board next to the reset switch. This tag will instruct the operator to place the control switches for the associated valves in the closed position before resetting the logic.

Even if the HPCI of RCIC isolation valves were inadvertently reopened before the pipe break condition was corrected, due to both isolation logics being reset after the isolation parameters have cleared, the pipe break condition would be detected again and the isolation valves would reclose. The offsite radiological doses due to the released steam would be a small fraction of the 10CFR50.67 limits.

The results of this review will be verified as part of the system preoperational testing.

7.1.2.11.2 Information Notice 79-22, Qualification of Control Systems

Information Notice 79-22 discusses the effects of a HELB on nonsafety-related control systems to determine whether any adverse effects initiated by a HELB could result in an event more severe than the transient and accident events analyzed in Chapter 15.

In response, a comprehensive, systematic study has been conducted to determine the consequences of postulated HELBs and their effects on adjacent, nonsafety-related, control systems components. In most cases, the effects of the postulated HELB (control systems failures) events are less severe than the Unacceptable Results for Incidents of Moderate Frequency -

Anticipated Operational Transients presented in Chapter 15. In all cases, the effects of the postulated events are bounded by the Unacceptable Results for Limiting Faults - Design Basis (Postulated) Accidents presented in Chapter 15. It is concluded that safe reactor shutdown is assured for all events postulated therein, and the consequences of these postulated events do not result in any significant risk to the health and safety of the public.

Details of the LGS Unit 1 analysis were submitted on May 4, 1984. The report was later updated to confirm its applicability to Unit 2 and submitted on February 17, 1989.

7.1.2.11.3 Bulletin 79-27, Loss of Non-Class 1E Instrumentation and Control Power Systems Bus During Operation

Bulletin 79-27 discussed a failure of a bus supplying power to control systems and vital instrumentation resulting in a malfunction of the control systems and a simultaneous loss to the operator of information required for a safe shutdown. In response, an analysis has been conducted to demonstrate that the control systems used to achieve a hot shutdown are designed to perform their intended function with a loss of any single power source. Subsequent cooldown to cold shutdown conditions will be accomplished using diverse means. One method utilizes the shutdown cooling mode of the RHR system. An alternate method utilizes the ADS to depressurize, core spray for make up, and RHR in the suppression pool cooling mode.

An analysis has also been conducted to demonstrate that for a loss of power to an instrument there is another instrument available, fed from an independent bus, that monitors the same parameter or a diverse parameter that will provide sufficient information to achieve cold shutdown.

From these reviews we conclude that there exists sufficient diversity and redundancy of the plant's power supplies and that the capability to place the plant in a cold shutdown condition would not be compromised by a loss of Class 1E or non-Class 1E instrument and/or control system power supply and that for all instrumentation and controls needed for safe shutdown a loss of power is annunciated directly or indirectly in the control room.

Details of the LGS Unit 1 analysis were submitted on December 14, 1983 and supplementation on June 5, 1984. The report was later updated to confirm its applicability to Unit 2 and submitted on February 17, 1989.

7.1.3 PROTECTION SYSTEM INSERVICE TESTABILITY

Testability provisions for each system are discussed in Sections 7.2, 7.3, 7.4, and 7.6.

---

(1) LGS and SSES designs are very similar; however, there are differences common to all systems that refer to this note. The differences are that LGS uses transmitter/trip unit system for testability, four divisions of separation, and uninterruptible power supplies for the RPS.

(2) The RPS logics are the same, however, LGS uses a single relay contact for trip functions.

(3) The PCRVICS logics are the same, however, LGS utilizes more sensors for the leak detection system.

(4) The RMCS for LGS and SSES are designed to perform the same. The differences that exists are due to SSES's use of the advanced control room. The advanced control room layout full core display is on the console rather than a wall panel. The differences in the control rooms change the panel location of RMCS modules. These changes don't change the module functions.

Table 7.1-2 (Cont'd)

(5) Instrumentations used for SSES and LGS are of similar design, they both use testability and four division separation. The setpoints, instrument numbering, quantity of instruments, and division assignments are different for LGS. LGS uses excess flow checks and orificing on instrument lines connected to the reactor vessel. Nonessential vessel instrumentation is functionally identical to SSES, except LGS has added gauge pressure transmitters for measurement of shutdown and upset range water level during refueling.

(6) LGS uses more detectors.

(7) The leak detection system for LGS uses 94 sensors as compared to 51 for SSES. This increases the redundant instruments available. The power for sensors not supplied by RPS bus are powered from four instrument ac buses. LGS uses meters rather than a recorder for the spare thermocouple in each location.

(8) RCIC is identical except as indicated in note (1).

(9) LGS and Shoreham shutdown systems are designed to provide all of the same control functions. The differences are due to divisional separation and device numbering related to this. LGS has four divisions of separation making divisional assignment of valves different.

(10) The safety-related display instruments for LGS and SSES are designed to provide the same types of indications to the operator. LGS provides more redundant indication and utilizes four divisions of separation. SSES has the advanced control room making differences in location of the display to the operator.

(11) Deleted

(12) PBAPS uses 4 diesel generators and batteries shared between 2 units. LGS has 8 diesel generators and batteries which are not shared between units.

(13) The LGS recirculation system does not have a bypass valve at the discharge block valve; the SSES system does. The SSES recirculation pumps are provided with decontamination connections; these connections are not required for LGS.

(14) The rod worth minimizers are functionally identical. The differences are in plant interfaces. Millstone Unit 1 is a BWR, 660 MWe, 145 control rods. Each LGS Unit is a BWR, 1055 MWe, 185 control rods.

(15) Deleted

(16) The neutron monitoring system is identical to SSES's except for the TIP system, which uses a gamma-measuring probe instead of a thermal neutron-measuring probe.

(17) Deleted

Note: Historical Information - Comparative plant data provided to support original plant licensing.

Neutron monitoring channel				
APRM	1	2	3	4
IRM	A & E	B & F	C & G	D & H
RPS trip logic	A1	B1	A2	B2
APRM flow reference	A	B	C	D

(1) Penetrations across top of table for 4 penetration grouping carry cables for neutron monitoring channels shown, and each channel serves RPS trip logic directly below it.

(2) Horizontal zoning represents LPRM cable distribution to APRMs from various penetrations, e.g., penetration B carries cables for LPRMs going to APRM channel 2 (Figure 7.1-1).

(3) Designations for penetrations and wireways are arbitrary and may be deviated from provided that an equivalent separation is maintained.

(4) Routing of SRM channels has been chosen for convenience and not for safeguard separation reasons.

NRC BULLETINS, CIRCULARS, AND INFORMATION NOTICES

Bulletin #	Description	LGS Response
78-01	Flammable contact arm retainers in GE relays	GE performed an inspection to verify that all CR120A relays have proper fire resistant retainers.
78-05	Malfunction of CR105 relay auxiliary contacts	It was confirmed by review that no auxiliary contacts from these relays are used in safety related circuits.
79-09	Failures of GE type AK-2 circuit breakers	None of these type breakers are used in safety related circuits.
79-12	Short period scrams at BWR	Station staff to prepare procedure and review with operators during training. This Bulletin applied to operating plants. No modifications required.
79-24	Frozen instrument lines	A review of the ECCS minimum flow lines was made as well as the criteria for application and design of heat tracing and freeze protection on instrument, process and sample lines. No modifications were made as existing design was deemed adequate.
79-27	Loss of Instrument ac	Study complete and submitted to NRC. No modifications needed.
79-28	Failure of Namco limit switches	No switches of this type were found. Some Namco switches are being replaced with qualified models due to environmental qualification concerns.
80-06	Engineered safety feature control reset	Study completed. Modifications to circuitry completed. Detailed discussion provided in Section 7.1.2.11.1.
80-09	Failure of ITT actuators	Vendor reviews and testing determined that several actuators required spring replacements. Corrective actions have been completed.

Table 7.1-7 (Cont'd)

Bulletin #	Description	LGS Response
80-14	Degradation of Scram Discharge Volume Capability	Diverse means of measuring SDV capacity have been added to the LGS design.
80-16	Misapplication of Rosemount transmitters	Transmitters to be replaced have been identified. Unit 1 replacements completed. Unit 2 was completed prior to fuel load.
80-17	Failure of control rods to insert	Modification made as part of ATWS fix.
80-23	Failure of Valcor solenoid valves	Review indicated that no Valcor valves of the type described are used in safety related applications.
Circular #	**Description**	**LGS Response**
79-07	Recirculation pump speed increase	Maintenance procedures to include recommended actions.
79-24	Calibration of pipe detection equipment	Problem not applicable as design is different at LGS than Duane Arnold.
80-08	RPS Response time	Start up test program will verify adequate response time on as-built system.
81-01	Honeywell push button switches	Review shows that no switches of this type are used in any safety related systems.
81-03	Inoperable seismic monitoring equipment	Maintenance procedure to include lessons learned.
81-06	Foxboro transmitter defects	Review indicated that this type transmitter is not used in any safety related systems.
81-11	Inadequate decay heat removal	Preliminary review of calculations showed flow rates to be adequate. Shutdown procedures will address this concern.

Table 7.1-7 (Cont'd)

Circular #	Description	LGS Response
81-13	MOV torque switch bypass circuit	MOV rework program on all safety related MOVs includes rewiring and checking connections internal to the operator.
81-14	MSIV Failures	Reviewed operating experience at PBAPS and other plants. Causes of failures were identified. Based on analyses no modifications to LGS valve or air supply design are required.

Notice #	Description	LGS Response
79-13	Water Level Instrumentation	Review indicated LGS will not experience problem due to different design.
79-22	Environmental Effects on non-Class 1E control systems	Study indicated no potential problems. Analysis and rationale provided in Section 7.1.2.11.2.
79-32	Separation of HPCI and ADS cables	Review of LGS design shows this problem does not exist.
80-11	ASCO valve problems	Review showed that ASCO valves are not used in the conditions described.
80-13	SBM Switch defects	All SBM switches have been inspected. Defective switches have been replaced.
80-30	Control air-CRD interactions	Review shows that LGS design precludes this problem
80-31	Defective K600 circuit breakers	These breakers are used at LGS. Each breaker is inspected and tested to procedures before installation and acceptance. Any corrective work if needed is completed before final acceptance.
80-34	SDV water level instrumentation failure	Problem not applicable to LGS due to different design.

LGS UFSAR

Table 7.1-7 (Cont'd)

Notice #	Description	LGS Response
80-39	Valcor solenoid valve malfunction	This type valve is not used in safety systems at LGS.
80-45	Failure of backup scram capability	Not applicable to LGS RPS Design.
81-01	HFA relay failures	All Class 1E HFA relays have been replaced. All non-Class 1E relay coils are being replaced.
81-06	Failure of ITE K600 circuit breakers	Inspections completed to find and fix loose connections.
81-11	ARI design	This concern will be addressed by GE in the LGS ATWS modifications.
81-16	CRD system possible malfunctions	Operator training and plant procedures to be used to avoid problem.
81-25	P-transmitter valve misalignment	Plant procedures to be used to avoid problem.

(1) Radiation monitoring display system

(2) Meteorological monitoring display and reporting subsystem

(3) These systems are used for monitoring and display only, not for control of any system. Microprocessors (which incorporate ROMs) are used in the RRCS. The RRCS does not perform any reactor control functions. It does provide signals to trip the recirculation system, to run back the feedwater system, to initiate SLCS, and to initiate ARI to mitigate an ATWS event. No plant control is implemented by microprocessors, multiplexers, or computers.

7.2 REACTOR TRIP SYSTEM (REACTOR PROTECTION SYSTEM) - INSTRUMENTATION AND CONTROLS

7.2.1 DESCRIPTION

7.2.1.1 System Description

7.2.1.1.1 RPS Identification

The RPS includes sensors, relays, bypass circuitry, and switches that cause rapid insertion of control rods (scram) to shut down the reactor. The RPS also includes outputs to the process computer system and annunciators, which are not part of the RPS. Trip signals are received from the NMS; other portions of this system are treated in Sections 7.5, 7.6, and 7.7.

A completely separate and diverse system, the RRCS, is provided to mitigate the potential consequences of an ATWS event (Section 7.6.1.8).

7.2.1.1.2 RPS Classification

The RPS is classified as Safety Class 2, seismic Category I, Quality Group B, and electric Class 1E.

7.2.1.1.3 RPS Power Sources

Power to each of the two RPS trip systems is supplied by separate buses powered by independent static inverter sets. Each static inverter set is designed to provide uninterruptible ac power to the loads. Each static inverter set is supplied by two electrical sources, one from the plant auxiliary electrical source (alternate) and the other from the class 1E 250 V dc system (preferred). The inverter output and the plant auxiliary electrical source are connected to a static transfer switch within the inverter set and ahead of the loads. The switch will normally connect the load to the preferred source. Upon failure or undervoltage of the preferred source, the switch will automatically transfer the load to the alternate source. Additionally, if an overload occurs while the load is supplied from the inverter, the switch will automatically transfer the load to the ac source. If, while being fed from the alternate supply the inverter recovers, and the static transfer switch is in auto, the transfer switch will automatically transfer the load to the inverter. Alternatively, if the static transfer switch is in manual, the load transfer requires manual action. Refer to Section 7.6.1.4.5 for independent powering of APRMs.

The static inverter sets are not part of the RPS and are not Class 1E devices. Two Class 1E circuit breakers are located between each static transfer switch and its respective RPS distribution panel (Drawing E-32) to isolate the RPS from the inverter and the bypass ac source if there is an overvoltage, undervoltage, or underfrequency condition. The trip points of the overvoltage, undervoltage, and frequency relays are set to ensure that the power supplied to the RPS is within the limits to which the RPS equipment has been designed and qualified.

A bypass disconnect test switch is installed in parallel with the two class IE circuit breakers. The test switch allows for testing of the breakers without loss of power to the RPS distribution panels. During the test, when the breakers are bypassed, the AC source is monitored for overvoltage, undervoltage, or underfrequency conditions as determined by the trip points. When not in test, the disconnect test switch is locked open.

Dc power is supplied to the backup scram valve solenoids from the Class 1E station batteries.

The power source used to drive the control rods during scram is pressurized water contained in the scram accumulator furnished as part of each HCU, as described in Section 4.6.1.

7.2.1.1.4 RPS Equipment Design

7.2.1.1.4.1 General

Trip systems are designated A and B. Trip system A is comprised of instrument channels A, C, E, and G; trip logics A1 and A2; and the scram contactors A, E, C and G. Trip system B comprises of instrument channels B, D, F and H; trip logics B1 and B2; and the scram contactors B, D, F and H. During normal operation, all sensor and trip contacts essential to safety and corresponding trip logic channel contacts are closed, and the scram contactors are energized. Trip channel bypass contacts are normally open.

Table 7.2-1 lists the instruments that provide signals for the system. Figure 7.2-2 summarizes the RPS signals that cause a scram.

The functional arrangement of channels that constitute trip system A is shown in Figure 7.2-5. When a channel sensor contact opens, its sensor relay de-energizes, opening its contacts and thereby de-energizing its associated scram contactors. Trip system B is similar to that shown on Figure 7.2-5 for trip system A. Scram contactors and scram contactor logics for trip systems A and B are shown in Figure 7.2-4. When a scram contactor is de-energized, its contacts associated with the pilot solenoids open and those associated with the backup scram valves close. As seen on Figure 7.2-4, tripping A1 or A2 or both A1 and A2 trip logics will open the circuits associated with the trip system A pilot solenoids and close corresponding contacts in both trip system A and B backup scram valve circuits. When both trip systems A and B have tripped, all pilot solenoids are de-energized and both backup scram valves are energized, either of which will cause a reactor scram.

There is one scram pilot valve and two scram valves for each control rod, arranged as shown in Drawing C71-1010-F-002. Each scram pilot valve is solenoid-operated with two normally energized pilot solenoids. The scram pilot valve control the air supply to the scram valves for each control rod. With either pilot solenoid energized, air pressure holds the scram valves closed. The scram valves control the supply and discharge paths for CRD water. As shown in Figure 7.2-4, one of the pilot solenoids for each control rod is controlled by trip system A logic A1 and A2, and the other solenoid is controlled by trip system B logic B1 and B2.

When trip system A, logic A1 or A2, and trip system B, logic B1 or B2, are tripped, air is vented from the scram valves, allowing CRD water to act on the CRD piston. Thus, all control rods are scrammed. The water displaced by the movement of each rod piston is exhausted into a SDV.

To restore the RPS to normal operation following any single trip of the trip logic or a scram, the trip logic must be reset manually. Reset is possible only if the conditions that caused the trip have been cleared. Reset after a scram is permissible only after a 10 second delay. The trip systems are reset by a three-position switch in the control room. Figure 7.2-5 shows the functional arrangement of reset contacts for trip system A.

There are two dc solenoid-operated backup scram valves that provide a second means of controlling the air supply to the scram valves for all control rods. When the solenoid for either backup scram valve is energized, the backup scram valve vents the air supply for the scram

valves. This action initiates insertion of any withdrawn control rods regardless of the action of the scram pilot valves. The backup scram valve solenoids are energized (initiate scram) when trip logic A1 or A2 and trip logic B1 or B2 are tripped.

7.2.1.1.4.2 RPS Initiating Circuits

The RPS scram functions, shown in Figure 7.2-2, are discussed in the following paragraphs.

a. Neutron Monitoring System

NMS instrumentation is described in Section 7.6.1.4. Figure 7.2-6 clarifies the relationship between NMS channels and the trip system logics. The NMS channels are considered to be part of the NMS; however, the NMS logics are considered to be part of the RPS. Each NMS logic receives signals from one IRM channel and one APRM voter channel. The position of the reactor mode switch determines which input signals affect the output signal from the logic.

The NMS logics are arranged so that failure of any one logic cannot prevent the initiation of a high neutron flux scram. As shown in Drawings C51-1020-F-009, C51-1020-F-010, C51-1020-F-011, C51-1020-F-012, C51-1020-F-013, C51-1020-F-014, C51-1020-F-015, and C51-1020-F-016, there are eight NMS logics associated with the RPS. Each trip system logic receives inputs from two NMS logics.

For the initial fuel load, and during shutdown margin demonstration testing performed as a special test, trip contacts from each SRM are combined with IRM trips to produce a noncoincident reactor NMS trip via removal of the RPS "shorting links".

Note that during the routine shutdown margin demonstra-tion testing performed during the first startup following refueling operations, the RPS "shorting links" remain installed and the SRMS do not contribute to the SCRAM function.

1. IRM System Logic

The IRMs monitor neutron flux between the upper portion of the SRM range to the lower portion of the APRM range. The IRM detectors can be positioned in the core by remote control. The detectors are inserted into the core for a reactor startup and are withdrawn after the reactor reaches a predetermined power level within the power range.

The IRM is able to generate a trip signal that can be used to prevent fuel damage resulting from abnormal operational transients that occur while operating in the intermediate power range. The IRM is divided into two groups of IRM channels arranged in the core as shown in Drawings C51-1010-F-002, C51-1010-F-003, and C51-1010-F-0023. Four IRM channels are associated with one of the two trip systems of the RPS. Two IRM channels and their trip auxiliaries from each group are installed in one bay of a cabinet; the remaining two channels are installed in a separate bay of the cabinet. Full-length side covers separate the cabinet bays. The arrangement of IRM channels allows one IRM channel in each group to be bypassed without compromising intermediate range neutron monitoring.

Each IRM channel includes four trip circuits as standard equipment. One trip circuit is used as an instrument trouble trip. It operates on four conditions: when the high voltage drops below a preset level; when one of the modules is not plugged in; when the negative 20 V dc supply is lost: or when the operate-calibrate switch is not in the operate position. Each of the other trip circuits can be specified to trip when preset downscale or upscale levels are reached.

The trip functions actuated by the IRM trips are indicated in Table 7.6-2. The reactor mode switch determines whether IRM trips are effective in initiating a rod block or a reactor scram (Figure 7.2-6). Section 7.7.1.2.3.2.3.3 describes the IRM rod block trips. With the reactor mode switch in refuel or startup, an IRM upscale or inoperative trip signal actuates an NMS trip of the RPS. Only one of the IRM channels must trip to initiate an NMS trip of the associated trip system of the RPS.

2. APRM System Logic

The APRM channels receive input signals from the LPRM detectors and provide a continuous indication of average reactor power from a few percent to greater than rated reactor power.

The APRM subsystem has sufficient redundant channels to meet industry and regulatory safety criteria. Even with the permitted APRM bypasses, the subsystem is capable of generating a scram trip signal before the average neutron flux or the magnitude of any thermal-hydraulic instability caused power oscillations increases to the point that fuel damage is probable.

The digital electronics for each APRM channel, via APRM interface hardware, provides trip signals directly to the Reactor Manual Control System (RMCS) and Redundant Reactivity Control System (RRCS) and via the APRM 2-out-of-4 voter channels to the Reactor Protection System (RPS). An APRM upscale trip or inoperative in any two unbypassed APRM channels can initiate an RPS trip in both RPS trip systems. Similarly, an OPRM upscale trip from any two unbypassed APRM channels can initiate an RPS trip in both RPS trip systems if the reactor mode switch is in the RUN position, and the plant is operating within the OPRM trip enabled region of the power-flow map. Any single APRM upscale trip or inoperative or OPRM upscale trip will not initiate an NMS trip in the RPS. Table 7.6-4 itemizes the APRM system trip functions. Any one unbypassed APRM can initiate a rod block, depending upon the position of the reactor mode switch. Section 7.7.1.2.3.2.3.3 describes in detail the APRM rod block interlock functions. The APRM Simulated Thermal Power - Upscale rod block and the APRM Simulated Thermal Power - Upscale scram trip setpoints vary as a function of reactor recirculation loop flow. The OPRM upscale trip output to the RPS is automatically bypassed when the reactor is operating below the lower power limit or above the upper flow limit of the OPRM trip enabled region.

Manually moving the reactor mode switch out of the RUN position to any other position causes the APRM rod block and APRM neutron flux scram

setpoints to be lowered. The manual positioning of the reactor mode switch is governed by the standard reactor startup (shutdown) procedure. The operator can bypass the trips from any one APRM channel, but only one APRM channel may be bypassed at any time. No APRM voter channels may be bypassed.

A simplified circuit arrangement is shown in Figure 7.6-7.

NMS scram operating bypasses are described in Section 7.2.1.1.4.4.6. Diversity of trip initiation for unusual excursions in reactor power is provided by the NMS trip signals and reactor vessel high pressure trip signals. An increase in reactor power initiates protective action from the NMS discussed in the above paragraphs. The increase in power causes reactor pressure to increase because of a higher rate of steam generation with no change in turbine control valve position resulting in a trip from reactor vessel high pressure. These variables are independent of one another and provide diverse initiation of protective action for this condition.

b. Reactor Pressure (RPS Initiating Circuits)

Reactor pressure is measured at four physically separated locations. A pipe from each location is routed through the drywell and terminates in the reactor enclosure. One locally mounted pressure sensor monitors the pressure in each pipe. Cables from these sensors are routed to the RPS logic cabinets. Each sensor provides a high pressure signal to one channel as shown in Figure 7.2-3. The physical separation and the signal arrangement ensure that no single physical event can prevent a scram caused by nuclear system high pressure.

The environmental conditions for the RPS are described in Section 3.11. The piping arrangement of the reactor pressure sensors is shown in Drawing M-41.

The discussion of diversity for reactor vessel high pressure is provided in Section 7.2.1.1.4.6.

c. Reactor Vessel Water Level (RPS Initiating Circuits)

Reactor vessel low water level signals are initiated from level sensors that sense the difference between the pressure that is due to a constant reference column of water and the pressure that is due to the actual water level in the vessel. The level sensors (A, B, C and D) have separate RPV reference leg taps; however, sensors A and B share the same variable leg tap and common piping to the outside of the primary containment where the piping is split for these and other sensors as shown in Drawing M-42. Sensors C and D are of a similar configuration with their tap and piping physically separated from that used by sensors A and B. A break (or blockage) in either of the common piping runs will result in a reactor scram because the one-out-of-two-twice logic is arranged with sensors A and C in trip logic A and sensors B and D in trip logic B. The physical separation of redundant sensors and the signal arrangement ensure that no single physical event can prevent a scram that is due to reactor vessel low water level.

Diversity of trip initiation for breaks in the RCPB is provided by reactor vessel low water level trip signals and high drywell pressure trip signals. If a break in the primary system boundary occurs, a volume of primary coolant is released to the drywell in the form of steam. This release causes reactor vessel water level to decrease and drywell pressure to increase, resulting in protective action initiation. These variables are independent of one another and provide diverse initiation of protective action for this condition.

The locations of the reactor vessel low water level sensors are shown in Drawings C71-1010-F-002, C71-1010-F-003, C71-1010-F-004, and C71-1010-F-005, and the environmental conditions for the RPS are described in Section 3.11. The piping arrangement of the reactor vessel low water level sensors is shown in Drawing M-42.

d. Turbine Stop Valve (RPS Initiating Circuits)

Turbine stop valve closure inputs to the RPS come from valve stem position switches mounted on the four turbine stop valves. Each of the double-pole, single-throw switches opens before the valve is more than 7% closed to provide the earliest positive indication of closure (Technical Specification - Setpoint <= 5%, Allowable Value <= 7%). Either of the two channels associated with one stop valve, can signal valve closure, as shown in Figure 7.2-7. The logic is arranged so that closure of three or more valves initiates a scram.

Turbine stop valve closure trip channel operating bypasses are described in Section 7.2.1.1.4.4.1.

Diversity of trip initiation for increases in reactor vessel pressure that are due to termination of steam flow by turbine stop valve or control valve closure is provided by reactor vessel high pressure and high power trip signals. A closure of the turbine stop valves or control valves at steady-state conditions would result in an increase in reactor vessel pressure. If a scram were not initiated from these closures, a scram would occur from high reactor vessel pressure or power. Reactor vessel high pressure and power are independent variables for this condition and provide diverse initiation of protective action.

The locations of the turbine stop valve closure position switches are shown in the instrument location drawing provided in Drawing E-1112. The environmental conditions for the RPS are described in Section 3.11.

e. Turbine Control Valve (RPS Initiating Circuits)

Turbine control valve fast closure inputs to the RPS are from oil line pressure sensors on each of four fast-acting control valve hydraulic mechanisms. These hydraulic mechanisms are part of the turbine control, and they are used to effect fast closure of the turbine control valves. These pressure switches provide signals to the RPS. If hydraulic oil line pressure is lost, a turbine control valve fast closure scram is initiated.

Turbine control valve fast closure trip channel operating bypasses are described in Section 7.2.1.1.4.4.1.

The discussion of diversity for turbine control valve fast closure is the same as that for turbine stop valve closure provided in Sections 7.2.1.1.4.2.d and 7.2.1.1.4.6.

The locations of the turbine control valve fast closure pressure switches are shown in the instrument location drawings provided in Drawing M-677. The environmental conditions for the RPS are described in Section 3.11. The piping arrangement of the turbine control valve fast closure pressure switch is shown in Drawing M-01.

f. Main Steam Isolation Valves (RPS Initiating Circuits)

Position switches mounted on the eight MSIVs signal MSIV closure to the RPS. Each of the double-pole, single- throw switches is arranged to open before the valve is more than 12% closed to provide the earliest positive indication of closure (Technical Specification - Setpoint <= 8%, Allowable Value <= 12%). Either of the two channels associated with one isolation valve can signal valve closure. To facilitate the description of the logic arrangement, the position-sensing channels for each valve are identified and assigned to RPS logics as follows:

Valve Identification	Position-Sensing Channels	Feeds Trip Logic
Main steam line A, inboard valve	F022A	A1, B1
Main steam line A, outboard valve	F028A	A1, B1
Main steam line B, inboard valve	F022B	A1, B2
Main steam line B, outboard valve	F028B	A1, B2
Main steam line C, inboard valve	F022C	A2, B1
Main steam line C, outboard valve	F028C	A2, B1
Main steam line D, inboard valve	F022D	A2, B2
Main steam line D, outboard valve	F028D	A2, B2

Thus, each logic receives signals from the valves associated with two steam lines (Figure 7.2-8). The arrangement of signals within each logic requires closing of at least one valve in each of the two steam lines associated with that logic to cause a trip of that logic. For example, closure of the inboard valve of steam line A and the outboard valve of steam line C causes a trip of logic B1. This in turn causes trip system B to trip.

No scram occurs, because no trips occur in trip system A. In no case does closure of two valves or isolation of two steam lines cause a scram that is due to valve closure. Closure of at least one valve in three or more steam lines causes a scram. The wiring for the position-sensing channels from one position switch is physically separated in the same way that wiring to duplicate sensors on a common process tap is separated. The wiring for position-sensing channels feeding the different trip logics of one trip system is also separated.

MSIV closure trip channel operating bypasses are described in Section 7.2.1.1.4.4.2.

Diversity of trip initiation that is due to main steam isolation is provided by reactor vessel high pressure and power trip signals. A closure of the MSIVs at steady-state conditions would cause an increase in reactor vessel pressure and power. If a scram were not initiated from MSIV closure, a scram would occur from high reactor vessel pressure or high power. These variables are independent and provide diverse initiation of protective action for this condition.

The locations of the MSIV closure position switch are shown in the instrument location drawing in Figures 7.2-12 and 7.2-13. The environmental conditions for the RPS are described in Section 3.11.

g. Scram Discharge Volume (RPS Initiating Circuits)

Four nonindicating float switches (one for each channel) provide SDV high water level inputs to the four RPS channels. In addition, a trip unit, with a level transmitter, in each channel provides diversity with the float-type level switch in that channel. This arrangement provides diversity, as well as redundancy, to ensure that no single event can prevent a scram caused by SDV high water level. With the predetermined scram setting, a scram is initiated when sufficient capacity still remains in the tank to accommodate a scram.

SDV water level trip channel operating bypasses are described in Section 7.2.1.1.4.4.3.

The SDV function is to receive water that is discharged from the CRD during a scram. If at the completion of the scram the level of water in the SDV is greater than the trip setting, the RPS cannot be reset until the discharge volume has been drained or the discharge volume level switch is in the bypass position and the reactor mode switch is in the shutdown or refuel mode. In addition, the SDV water level scram setting has been selected so that the CRD water discharged because of a scram can fit in the volume, along with prior leakage that would have initiated the scram.

The locations of the SDV water level sensors are shown in the instrument location drawing in Drawings E-1164 and E-1165. The environmental conditions for the RPS are described in Section 3.11. The piping arrangement of the SDV level sensors is shown in Drawings C11-1030-F-008,C11-1030-F-009,C11-1030-F-010,C11-1030-F-011,C11-1030-F-012,C11-1030-F-013, and C11-1030-F-014.

h. Drywell Pressure (RPS Initiating Circuits)

Drywell pressure is monitored by four pressure sensors mounted on instrument racks outside the drywell in the secondary containment. Pipes that terminate in the secondary containment connect the sensors with the drywell interior. The sensors are physically separated and electrically connected to the RPS so that no single event prevents a scram caused by drywell high pressure. Cables are routed from the sensors to the RPS logic cabinets. Each sensor provides an input to one channel (Figure 7.2-3).

The discussion of diversity for high drywell pressure is provided in Sections 7.2.1.1.4.2 and 7.2.1.1.4.6.

The drywell pressure sensors are located on instrument racks outside the drywell. Instrument location drawings listed in Table 1.7-3 show the rack locations. The environmental conditions of the RPS are described in Section 3.11.

i. Deleted

j. Manual Scram (RPS Initiating Circuits)

A scram can be initiated manually. There are four scram buttons, one for each trip logic (A1, A2, B1, and B2). To initiate a manual scram, at least one button in each trip system must be depressed. The manual scram logic is the same as the automatic scram logic. The manual scram buttons are arranged in two groups of two switches. One group contains the A1 and B1 switches. The A2 and B2 switches are in the other group. The switches in each group are located close enough to permit one hand motion to initiate a scram. By operating the manual scram button for one trip logic at a time and then resetting that logic, each actuator logic can be tested for manual scram capability. The reactor operator can also scram the reactor by placing the mode switch in its shutdown position.

k. Mode Switch in Shutdown (RPS Initiating Circuits)

A scram is initiated whenever the mode switch is placed in the shutdown position. The mode switch has four electrically separated banks of gear-driven contacts. Each bank provides inputs into a separate RPS trip logic. The mode switch is located on the reactor control console in the control room. The environmental conditions for the control room are described in Section 3.11. The discussion of mode switch in shutdown operating bypass is discussed in Section 7.2.1.1.4.4.4.

The discussion of mode switch interlocks is given in Sections 7.2.1.1.4.5 and 7.2.1.1.6.2.1.

The mode switch in shutdown does not require diversity as discussed in Section 7.2.1.1.4.4.4.

7.2.1.1.4.3 RPS Logic

The basic one-out-of-two-twice logic arrangement of the RPS is illustrated in Drawings C71-1010-F-002, C71-1010-F-003, C71-1010-F-004, and C71-1010-F-005. The system is arranged as two separately powered trip systems. Each trip system has two redundant logics, as shown in Figures

7.2-4 and 7.2-5. Each logic receives input signals from at least one channel for each monitored variable. Each variable is monitored by at least four channels.

Channel and logic relays are fast response, high reliability relays. Power relays for interrupting the scram pilot valve solenoids have high current carrying capabilities and are highly reliable. All RPS relays are selected so that the continuous load will not exceed 50% of the continuous-duty rating.

The time response for the RPS sensor and sensor trip to actuators de-energized is provided in Chapter 16. The time requirements for control rod movement are discussed in Section 4.6.3.

Each trip logic provides inputs into each of the actuator logics of one trip system, as shown in Figures 7.2-4 and 7.2-5. Thus, either of the two logics associated with one trip system can produce a trip system trip. The arrangement is a one-out-of-two-twice logic. To produce a scram, the actuator logics of both trip systems must be tripped.

Diversity of variables is provided for the RPS but not in the logic. One-out-of-two-twice logic is used, but the logic channels are identical.

The RPS reset switch is used to momentarily bypass the seal-in contacts of the final actuators of the RPS. The reset is effected in conjunction with auxiliary relays. If a single channel is tripped, the reset is accomplished immediately upon operation of the reset switch. On the other hand, if a reactor scram condition is present, manual reset is prohibited for a 10 second period to permit the control rods to achieve their fully inserted position.

7.2.1.1.4.4 RPS Scram Operating Bypasses

A number of manual and automatic scram bypasses are provided to accommodate the varying protection requirements that depend on reactor conditions. These are automatically removed when the permissives conditions are not present. In addition, individual channels can be bypassed under administrative control for test and maintenance.

All manual bypass switches are in the control room, under the direct control of the control room operator.

7.2.1.1.4.4.1 Turbine Stop Valve and Turbine Control Valve Fast Closure

Turbine stop valve closure and turbine control valve fast closure trip bypass is effected by four pressure sensors associated with the turbine first stage.

Two physically separate and redundant pressure taps located in the turbine steam supply lines upstream of the high pressure turbine first stage are each piped to two non-redundant pressure sensors that sense first stage pressure. Redundancy has been achieved by connecting one pressure transmitter output to each of the four divisional trip logics so that at least two divisions must be bypassed, by action of the turbine first-stage pressure scram bypass trip units, to prevent a scram from turbine stop valve closure or turbine control valve fast closure.

The turbine stop valve closure scram and turbine control valve fast closure scram are automatically bypassed if the turbine first-stage pressure is less than a predetermined value. Closure of these turbine valves below a low initial power level does not threaten the integrity of any radioactive material release barrier. Any one channel in a bypass state produces a control room annunciation. The sensors are arranged so that no single failure can prevent a turbine stop valve closure scram

or turbine control valve fast closure scram. In addition, this bypass is automatically removed when the turbine first-stage pressure exceeds the setpoint corresponding to 29.5% of rated power.

7.2.1.1.4.4.2 MSIV Closure (RPS Scram Bypass)

At plant shutdown and during initial plant startup, a bypass is required for the MSIV closure scram trip to properly reset the RPS. This bypass is in effect when the reactor mode switch is in the SHUTDOWN, REFUEL, or STARTUP position. The bypass allows plant operation when the MSIVs are closed during low power operation. The operating bypass is removed when the mode switch is placed in the run position.

The discussion of diversity for MSIV closure is provided in Section 7.2.1.1.4.2.f.

7.2.1.1.4.4.3 Scram Discharge Volume Level (RPS Scram Bypass)

The SDV high water level trip bypass is controlled by the manual operation of two key-locked switches, a bypass switch, and the mode switch. The mode switch must be in the shutdown or refuel position to allow manual bypass of this trip. This bypass allows the operator to reset the RPS scram relays so that the SDV may be drained. Resetting the trip actuators opens the SDV vent and drain valves. An annunciator in the control room indicates the bypass condition.

The discussion of diversity of the SDV level trip is provided in Section 7.2.1.1.4.2.g.

7.2.1.1.4.4.4 Mode Switch in Shutdown (RPS Scram Bypass)

The scram initiated by placing the mode switch in shutdown is automatically bypassed after a short time delay. The bypass allows the CRD hydraulic system valve lineup to be restored to normal. An annunciator in the control room indicates the bypassed condition.

Diversity of variables is not provided for this function because the placing of the mode switch in shutdown is part of the normal method for shutting down the reactor and requires only operator action for initiation. The mode switch in shutdown is not a safety function and does not require diversity.

7.2.1.1.4.4.5 Maintenance, Calibration, or Test RPS Scram Bypasses

Each reactor scram sensor can be tested and calibrated. When an instrument is valved out for test or calibration, the administratively controlled system out-of-service annunciation is manually actuated.

Individual channels for drywell high pressure, reactor vessel high pressure, reactor vessel low water level, CRD SDV high water level, and main steam line high radiation are tripped when any one sensor is physically removed for maintenance. The bypass of the turbine stop valve closure and turbine control valve fast closure trip remains in the unbypassed state when the one turbine first-stage pressure sensors are physically removed for maintenance.

7.2.1.1.4.4.6 NMS (RPS Scram Bypass)

Bypasses for the NMS channels are described below.

The neutron monitoring scram logic trip outputs for IRM and APRM can be bypassed, during any mode of operation by hand operated selector switches located on the reactor control bench board in the control room. The bypasses for APRM channels 1, 2, 3, and 4 are controlled by one fiber-optic selector switch. None of the four APRM 2-out-of-4 voter channels can be bypassed. The bypasses for IRM channels A, C, E, and G are controlled by one selector switch and the bypasses for IRM channels B, D, F, and H are controlled by a second selector switch.

The APRM and IRM bypass switches can bypass only one NMS channel at a time. Each APRM and IRM bypass is indicated by a light in the control room.

Bypassing one APRM channel with the APRM selector switch does not inhibit the NMS from providing protective action when required. Bypassing one IRM channel with each IRM selector switch does not inhibit the NMS from providing protective action when required. Bypass indication is discussed in Section 7.2.2.1.2.1.7.

The operating bypasses of the NMS are controlled by the reactor mode switch located on the control room reactor control bench board. When the reactor mode switch is in the RUN mode, the IRM trips are bypassed; protection is provided by the APRM trips. When the reactor mode switch is not in the RUN mode, the IRM trips are active. As reactor power is increased and the APRM system reaches its operating range, by procedure the IRM detectors are withdrawn from the reactor core. When reactor power is decreased to the IRM operating range, by procedure the IRM detectors are inserted into the reactor core.

Plant administration procedures manuals specify the administrative controls used during maintenance, test, and calibration.

7.2.1.1.4.5 RPS Interlocks

The SDV high water level trip bypass signal interlocks with the RMCS to initiate a rod block. The interlock is isolated by relay contacts so that no failure in the control system can prevent a scram.

Reactor vessel low water level, reactor vessel pressure, main steam line radiation, turbine stop valve closure, and drywell high pressure signals are shared with the PCRVICS. The sensors operate relays in the RPS whose contacts interlock with the PCRVICS.

A discussion of the NMS interlocks to rod block functions is provided in Section 7.6.1.4.

Each APRM and IRM bypass is indicated by a light in the control room. The reactor mode switch has interlocks to systems other than the RPS. These interlocks are discussed in Section 7.6.1.4.

7.2.1.1.4.6 RPS Redundancy and Diversity

Redundant portions of the RPS have physically separated sensor taps, sensing lines, sensors, sensor racks, cable routing, and logic. By the use of redundant sensors for each RPS variable and separate redundant logic and wiring, the RPS system has been protected from the credible single failures. For additional information on redundancy of RPS subsystems, see Section 7.2.1.1.4.2.

Redundancy of the fail-safe RPS power supply is not required. There are two uninterruptible power supplies for continuity of service only.

Diversity is provided by monitoring diverse sets of independent reactor vessel variables. MSIV closure, turbine stop valve closure, and turbine control valve fast closure are anticipatory of a reactor vessel high pressure and power scram trip. Therefore reactor high pressure and power are diverse scram inputs to main steam line closure. Drywell high pressure and reactor low water level are diverse scram variables for a steam or water line break inside the containment. Diversity of variables for main steam line breaks outside the drywell, which initiate main steam line isolation and in turn reactor trip initiation, is covered in Section 7.3.1.1.2.8.1.

Additional discussion of diversity of RPS variables is provided in Section 7.2.1.1.4.2.

7.2.1.1.4.7 RPS Actuated Devices

The trip system logic opens when a trip signal is received and de-energizes the scram pilot valve solenoids. There are two pilot solenoids per control rod. Both solenoids must de-energize to bleed the instrument air from, and open, the inlet and outlet scram valves to allow drive water to scram a control rod. One solenoid receives its signal from trip system A, and the other receives it from trip system B. The control rods are arranged in four groups. Within each trip system, each group of control rods has its own scram contactor logic as shown in Figure 7.2-4. The failure of one control rod group to scram does not prevent a complete shutdown. The instrument air system provides support to the RPS by keeping the air operated scram valve closed until a scram is required.

The individual control rods and their controls, the scram valves, and the pilot solenoids are not part of the RPS; however, the RPS does interface with these devices by controlling the pilot solenoids. The pilot solenoids for the scram pilot valves are part of the HCU (C11-D001) of the associated control rod in the CRD system. The backup scram valves (C11-F110A & B), classified as nonessential, are also not part of the RPS, but are part of the CRD system. The valves are supplied with 125 V dc safeguard power from separate supplies. For further information on the scram valves and control rods, see Section 4.6.1.2.4.3.

The pilot solenoid valves are supplied from the RPS uninterruptible power sources.

In addition to the two scram valves for each CRD, there are two backup scram valves that are used to vent the common header for all control rods. Both backup scram valves are energized to initiate venting and are individually supplied with 125 V dc power from the Class 1E plant batteries. In any auxiliary use of the plant instrument air system, a failure of the air system causes a safe direction actuation of the safety device.

7.2.1.1.4.8 RPS Separation

Four independent sensor channels monitor the various process variables listed in Section 7.2.1.1.4.2. The redundant sensor devices are separated so that no single failure can prevent a scram. All RPS wiring outside the control system cabinets is run in totally enclosed metallic raceways or in embedded PVC conduits. Physically separated cabinets or cabinet bays are provided for the four trip logics. The rack number for RPS sensors is shown in Drawing M-01 and M-42. The locations for local RPS racks and panels are shown on the instrument location drawings listed in Table 1.7-3. Cable routing from sensor to panel is shown in raceway plans listed in Section 1.7. The criteria for separation of sensing lines and sensors are discussed in Section 7.1.2.2.

The mode switch, SDV high water level trip bypass switch, scram reset switch, and manual scram switches are all mounted on one control console. Each device is mounted in a metal enclosure

and has a sufficient number of barrier devices when required to maintain adequate separation between redundant portions of the RPS. Within the panel, conduit is provided from the metal enclosures to the point where adequate physical separation can be maintained without barriers.

The outputs from the logic cabinets to the pilot solenoids are run in four separate raceway systems to match the four scram groups shown in Drawings C71-1010-F-002 and C71-1010-F-003. The groups are selected so that the failure of one group to scram does not prevent a reactor shutdown.

RPS inputs to annunciators and the computer are arranged so that no malfunction of the annunciating or computing equipment can functionally disable the RPS. Direct signals from RPS sensors are not used as inputs to annunciating or data logging equipment. Isolation is provided between the primary signal and the information output.

7.2.1.1.4.9 RPS Testability

The RPS has components that are not activated or tested during normal operation with an integrated testing procedure. These components are tested using manual test methods which allow for independent checking of individual system components. This testing includes verification of each channel trip, including scram contactors, by using the associated installed sensors and circuits to verify proper operation. The frequency of these tests and parameters to be verified are identified in the Technical Specifications.

The RPS can be tested during reactor operation by an overlapping series of tests.

a. The manual scram test is as follows: By depressing the manual scram button for one trip channel, appropriate scram contactors are de-energized, opening contacts in the scram contactor logics. After the first trip channel is reset, the second trip channel is tripped manually and so forth for the four manual scram buttons. The total test verifies the ability to de-energize the scram pilot valve solenoids without scram by using the manual scram push button switches. In addition to control room and computer printout indications, scram group indicator lights verify that the scram contractor contacts have opened and interrupted power in these pilot solenoids.

b. Calibration of the NMS is by simulated inputs from calibration signal generators. Calibration and test controls for the NMS are located in the auxiliary equipment room. Their physical location places them under control of the operating shift management. Section 7.6.1.4 describes the calibration procedure of the NMS.

c. The single rod scram test verifies the capability of each rod to scram. It is accomplished by operating two toggle switches on the hydraulic control unit for the particular CRD. Timing traces can be made for each rod scrammed. Before the test, a physics review must be conducted to ensure that the rod pattern during scram testing does not create a rod of excessive reactivity worth.

d. MSIV position switches, turbine control valve fast closure sensors, and turbine stop valve position switches can be checked for operability.

e. The process computer verifies the correct operation of many sensors during plant startup and shutdown. The verification provided by the process computer is not considered in the selection of test and calibration frequencies and is not required for plant safety.

f. The overall RPS response time from sensor trip to channel relay de-energization and scram contactor de-energization is verified by test.

g. The fourth test involves one of two methods for applying test signals to each RPS channel in turn and observing that a logic trip results. This test also verifies the independence of the channel circuitry. The test signals can be applied to the process-type sensing instruments (pressure and differential pressure) through calibration taps, or a calibration input may be applied to each instrument trip unit by use of a built-in calibrator. Calibration and test controls for pressure sensors and differential pressure sensors are located in the turbine enclosure and secondary containment. Calibration controls for the trip units are located in the auxiliary equipment room. To gain access to the setting controls for each sensor, a cover plate or sealing device must be removed. The control room operator is responsible for granting access to the setting controls. Only properly qualified plant personnel are granted access for testing or calibration adjustments.

   In addition to the above test, the operability of the pressure and level sensors may be verified by cross-checking instrument readouts in the auxiliary equipment room at any time during operations.

The CRD SDV level sensors are tested by valving the sensor out of service and injecting and varying a test source to the level sensor.

7.2.1.1.5 RPS Environmental Considerations

Electrical modules for the RPS are located in the drywell, control structure, secondary containment, and turbine enclosure. The environmental conditions for these are discussed in Section 3.11.

7.2.1.1.6 RPS Operational Considerations

7.2.1.1.6.1 Reactor Operator Information

7.2.1.1.6.1.1 Indicators

Scram group indicators extinguish when trip logic opens.

Recorders in the control room also provide information regarding reactor vessel water level, reactor vessel pressure, drywell pressure, and reactor power level.

7.2.1.1.6.1.2 Annunciators (RPS Operator Information)

Each manual and/or automatic RPS input is annunciated in the control room by isolated relay contacts. Trip logic trips also actuate the annunciator system.

When an RPS sensor channel trips, a corresponding red annunciator window on the reactor control panel in the control room indicates the out-of-limit variable. Each trip logic also initiates a corresponding red annunciator window that indicates the trip logic that has tripped. An RPS channel trip also actuates an annunciator system horn, which can be silenced by the operator. The annunciator window lights latch-in until reset manually. Reset is not possible until the condition that

caused the trip has been cleared. The location of alarm windows permits the operator to quickly identify the cause of RPS trips and to evaluate the threat to the fuel or RCPB.

7.2.1.1.6.1.3 Computer Alarms (RPS Operator Information)

A computer printout identifies each tripped channel. All RPS trip events are recorded by the NSSS process computer system. This permits subsequent analysis of an operational transient that occurs too rapidly for operator comprehension of events as they occur. The first 80 events are recorded in chronological sequence; events occurring within 4 milliseconds of one another are treated as having occurred simultaneously. The use of the computer is not required for plant safety. The printout of trips is particularly useful in routinely verifying the correct operation of pressure, level, and valve position switches as trip points are passed during startup, shutdown, and maintenance operations.

7.2.1.1.6.2 RPS Reactor Operator Controls

7.2.1.1.6.2.1 Mode Switch

A conveniently located, multiposition mode switch is provided to select the necessary scram functions for various plant conditions. The mode switch selects the appropriate sensors for scram functions and provides appropriate bypasses. The switch also interlocks such functions as control rod blocks and refueling equipment restrictions, which are not considered here as part of the RPS. The switch is designed to provide separation between the four trip channels. The mode switch positions and their related scram functions are as follows:

a. Shutdown

   Initiates a reactor scram; bypasses main steam line isolation scram.

b. Refuel

   Selects the IRM trips for low neutron flux level operation (disables the OPRM upscale trip but does not disable the APRM upscale and inoperative trips); bypasses main steam line isolation scram.

c. Startup

   Selects the IRM trips for low neutron flux level operation (disables the OPRM upscale trip but does not disable the APRM upscale and operative trips); bypasses main steam line isolation scram.

d. Run

   Selects the APRM trips, including the OPRM upscale trip, for power range operation.

7.2.1.1.6.3 Setpoints (RPS Operational Considerations)

Instrument ranges are chosen to cover the range of expected conditions for the variable being monitored. Additionally, the range is chosen to provide the necessary accuracy for any required setpoints and to meet the overall accuracy requirements of the channel.

a. NMS Trip

To protect the fuel against high heat generation rates, neutron flux is monitored and used to initiate a reactor scram. The NMS setpoints and their bases are discussed in Section 7.6.1.4.

b. Reactor Vessel High Pressure

Excessively high pressure within the reactor vessel threatens to rupture the RCPB. A reactor vessel pressure increase during reactor operation compresses the steam voids and results in a positive reactivity insertion; this causes increased core heat generation that could lead to fuel failure and system overpressurization. A scram counteracts a pressure increase by quickly reducing core fission heat generation. The reactor vessel high pressure scram setting selected is slightly above the reactor vessel maximum normal operation pressure, to permit normal operation without a spurious scram and yet provide a wide margin to the maximum allowable reactor vessel pressure. The location of the pressure measurement, as compared to the location of the highest nuclear system pressure during transients, was also considered in the selection of the high pressure scram setting. The reactor vessel high pressure scram works in conjunction with the pressure relief system to prevent reactor vessel pressure from exceeding the maximum allowable pressure. The reactor vessel high pressure scram setting also protects the core from exceeding thermal-hydraulic limits resulting from pressure increases during events that occur when the reactor operates below rated power and flow.

c. Reactor Vessel Low Water Level (RPS Setpoints)

Low water level in the reactor vessel indicates that the reactor is in danger of being inadequately cooled. Decreasing water level while the reactor operates at power decreases the reactor coolant inlet subcooling. The effect is the same as raising feedwater temperature. If the water level decreases further, fuel damage could result as steam forms around fuel rods. A reactor scram protects the fuel by reducing the fission heat generation within the core. The reactor vessel low water level scram setting was selected to prevent fuel damage following abnormal operational transients caused by single equipment malfunctions or single operator errors that result in a decreasing reactor vessel water level. The scram setting is far enough below normal operational levels to prevent spurious scrams. The setting is high enough above the top of the active fuel to ensure that enough water is available to account for evaporation, loss, and displacement of coolant following the most severe abnormal operational transient involving a level decrease.

d. Turbine Stop Valve Closure (RPS Setpoints)

Closure of the turbine stop valve with the reactor operating at power can result in a significant addition of positive reactivity to the core as the reactor vessel pressure rise causes steam voids to collapse. The turbine stop valve closure scram initiates a scram earlier than either the NMS or reactor vessel high pressure. It is required to provide a satisfactory margin below core thermal-hydraulic limits for this category of abnormal operational transients. By inserting

negative reactivity with control rods, the scram counteracts the addition of positive reactivity caused by increasing pressure. Although the reactor vessel high pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the turbine stop valve closure scram provides additional margin to the reactor vessel pressure limit. The turbine stop valve closure scram setting provides the earliest positive indication of valve closure.

e. Turbine Control Valve Fast Closure (RPS Setpoints)

With the reactor and turbine-generator at power, fast closure of the turbine control valves can result in a significant addition of positive reactivity to the core as nuclear system pressure rises. The turbine control valve fast closure scram initiates a scram earlier than either the NMS or reactor vessel high pressure. It is required to provide a satisfactory margin to core thermal-hydraulic limits for this category of abnormal operational transients. By inserting negative reactivity with control rods, the scram counteracts the addition of positive reactivity resulting from increasing pressure. Although the reactor vessel high pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the turbine control valve fast closure scram provides additional margin to the nuclear system pressure limit. The turbine control valve fast closure scram setting is selected to provide timely indication of control valve fast closure.

f. Main Steam Line Isolation (RPS Setpoints)

MSIV closure can result in a significant addition of positive reactivity to the core as nuclear system pressure rises. The main steam line isolation trip initiates a scram earlier than either the NMS or reactor vessel high pressure. By inserting negative reactivity with control rods, the scram counteracts the addition of positive reactivity resulting from increasing pressure. Although the reactor vessel high pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the main steam line isolation scram provides additional margin to the nuclear system pressure limit. The main steam line isolation scram setting is selected to give the earliest positive indication of isolation valve closure. The logic allows functional testing of main steam line isolation trip channels by partially closing an MSIV.

g. SDV High Water Level (RPS Setpoints)

Water displaced by the CRD pistons during a scram goes to the SDV. If the SDV fills with water so that insufficient capacity remains for the water displaced during a scram, control rod movement would be hindered during a scram. To prevent this situation, the reactor is scrammed when the water level in the discharge volume is high enough to verify that the volume is filling up, yet low enough to ensure that the remaining capacity in the volume can accommodate a scram.

h. Drywell High Pressure (RPS Setpoints)

High pressure inside the drywell may indicate a break in the RCPB. It is prudent to scram the reactor in such a situation to minimize the possibility of fuel damage and

to reduce energy transfer from the core to the coolant. The drywell high pressure scram setting is selected to be as low as possible without inducing spurious scrams.

i. Left blank intentionally.

j. Manual Scram (RPS Setpoints)

Push buttons are located in the control room to enable the operator to shut down the reactor by initiating a scram.

k. Mode Switch in Shutdown (RPS Setpoints)

When the mode switch is in shutdown, the reactor is to be shut down with all control rods inserted. This scram is not considered a protective function, because it is not required to protect the fuel or reactor vessel process barrier, and it bears no relationship to minimizing the release of radioactive material from any barrier. The scram signal is removed after a short delay, permitting a scram reset that restores the normal valve lineup in the CRD hydraulic system.

l. Turbine First-Stage Pressure (RPS Setpoints)

The turbine stop valve closure scram and turbine control valve fast closure scram are automatically bypassed if the turbine first-stage pressure is less than a predetermined value. This setpoint is chosen so that closure of these valves below the setpoint does not threaten the integrity of any radioactive material release barrier.

7.2.1.1.7 RPS Containment Electrical Penetration Assignment

See Section 6.2.6.

7.2.1.1.8 RPS Control Room Area

The control room area is divided into three floors, the auxiliary equipment room, the control room, and the cable spreading room. Each floor is divided into a Unit 1 and Unit 2 section. The RPS control board is located in the control room. The bench board for reactor control contains the reactor mode switch, bypass switches, scram solenoid valve status indicating lights, and manual scram switches. The RPS vertical boards are located in the auxiliary equipment room. The RPS vertical boards contain the trip units, trip channel and logic relays, test switches, trip indicating lights, and terminal boards. The vertical boards are installed on PGCC floor sections and are connected to individual termination cabinets by under-floor cable ducts. A general description of the cable spreading in the PGCC floor sections is contained in NEDO-10466A, "Power Generation Control Complex", and a further description is contained in Section 8.1.6.1.14.b.6.

There is no RPS equipment except for cables located in the cable spreading room. In the cable spreading room the RPS cables are routed in identified, totally enclosed metallic raceways. The arrangement of the equipment is shown in Drawings M-602 and M-603.

7.2.1.1.9 Test Methods that Enhance RPS Reliability

Surveillance testing is performed periodically on the RPS during operation and shutdown. This testing includes sensor calibration, response time testing, trip channel actuation, and trip time

measurement with simulated inputs to individual trip units and sensors. The sensors that are transmitters can be checked by comparison of the readings on other channels of the same variable.

7.2.1.1.10 Interlock Circuits to Inhibit Rod Motion as Well as Vary the Protection Function

Section 7.7.1.2.3.2.3.3 describes interlock circuits to inhibit rod motion that are derived from neutron flux and recirculation flow measurements. Electrical isolation is provided between the RBM interlock circuits and the APRM protective action circuits.

There are no interlock circuits that inhibit rod motion as well as vary the protective functions.

7.2.1.1.11 RPS Support Cooling Systems

Operation of the control enclosure chilled water system and associated unit coolers is required to ensure operation of the RPS components within their design requirements. The control enclosure chilled water system is described in Section 7.3.1.1.13.

7.2.1.2 RPS Design Bases

Design basis information requested by IEEE 279 (1971) is discussed in the following paragraphs. These IEEE 279 design bases aspects are considered separately from those more broad and detailed design bases for this system cited in Section 7.1.

7.2.1.2.1 Conditions

The generating station conditions that require reactor trip system protective action are as follows:

a. Generator load rejection above the turbine steam bypass capability

b. Turbine trip above the turbine steam bypass capability

c. MSIV closure during operation in the run mode

d. Turbine pressure regulator failure (valve open) resulting in MSIV closure that is due to dropping line pressure

e. Excess reactor coolant inventory resulting in turbine trip that is due to high reactor water level

f. Loss of feedwater flow

g. Recirculation flow control failure with increasing flow

h. Control rod-drop accident

i. LOCA

j. Main steam line break

k. Feedwater system piping break

7.2.1.2.2 Variables

The generating station variables that require monitoring in order to provide protective actions, are identified in Table 7.2-2.

7.2.1.2.3 Sensors

A minimum number of LPRMs per APRM are required to provide adequate protective action. This is the only variable that has spatial dependence as discussed in IEEE 279, paragraph 3.3. A discussion of these requirements is in Section 7.6.

7.2.1.2.4 Operational Limits

Operational limits for each safety-related variable trip setting are selected with sufficient margin so that a spurious scram is avoided. It is then verified by analysis that the calculated radioactive material releases are kept within acceptable bounds. Design basis operational limits are listed in Chapter 16. Technical Specifications are based on operating experience and constrained by the safety design basis and the safety analyses.

7.2.1.2.5 Margin Between Operational Limits

The margin between operational limits and the levels requiring protective action for the RPS are listed in Chapter 16, Technical Specifications. The margin includes the allowance for instrument accuracy, calibration error, sensor response times, and sensor and setpoint drift.

7.2.1.2.6 Levels Requiring Protective Action

Levels requiring protective action are provided in Chapter 16, Technical Specifications.

7.2.1.2.7 Ranges of Energy Supply and Environmental Conditions

The RPS 120 V ac power is provided by two static inverter sets that are each fed by two electrical sources, one from the plant auxiliary source and the other from the station batteries. The plant auxiliary source is a 480/120 V transformer, which is supplied through a transfer switch either from a non-Class 1E 440 V MCC or from a non-Class 1E 440 V MCC energized by a non-Class 1E UPS. Voltage regulation of the RPS power source is ±2% under steady-state conditions.

Environmental conditions for the RPS components inside and outside the containment are discussed in Section 3.11.

7.2.1.2.8 Unusual Events

Unusual events are defined as malfunctions, accidents, and other events that could cause damage to safety systems. The following accidents and events are considered: floods; storms; tornadoes; earthquakes; fire; LOCA; pipe break outside containment; feedwater line break; and missiles. Each of these events is discussed below for the RPS.

a. Floods

The structures containing RPS components are designed to meet the PMF at the site location as described in Section 3.4. This ensures that the structures remain

water-tight under PMF, including wind-generated wave action and wave run-up. Therefore, none of the RPS functions is affected by flooding.

b. Storms and Tornados (RPS Design Bases Unusual Events)

The structures containing RPS components are designed to withstand all credible meteorological events and tornados as described in Section 3.3.2. Superficial damage may occur to miscellaneous station property during a postulated tornado, but this will not impair the RPS capabilities.

c. Earthquakes (RPS Design Bases Unusual Events)

The structures containing RPS components, except the turbine enclosure, are seismically qualified as described in Sections 3.7 and 3.8. These structures containing RPS components remain functional during and following a SSE. The only RPS components located in the nonseismically qualified turbine enclosure are the sensors and associated cables for turbine stop valve closure, turbine control valve fast closure, turbine stop valve closure, and control valve fast closure bypass. Since reactor pressure and power trips are diverse to these turbine scram variables, locating these sensors in the turbine enclosure does not compromise the ability of the RPS to provide protective action when required.

d. Fires (RPS Design Bases Unusual Events)

To protect the RPS from a fire, the RPS trip logics are divided into four separate sections within two separate RPS panels. The sections within a panel are separated by fire barriers. If a fire were to occur within one of the sections or in the area of one of the panels, the RPS functions would not be prevented by the fire. The use of separation and fire barriers ensures that, even though some portion of the system may be affected, the RPS continues to provide the required protective action.

A nonsafety-related fire detection system using both thermal (rate of temperature rise) and ionization smoke detectors is provided in the PGCC floor sections, termination cabinets, and the space between the slab and the elevated floor in the periphery of the auxiliary equipment room. The entire space, with the exception of the termination cabinets, is protected by a Halon 1301 total flooding fire suppression system. The system is automatically initiated by heat detectors within the protected space. Detection of fire by smoke detectors and automatic initiation of the Halon suppression system are annunciated in the control room.

The control room is provided with ionization smoke detectors. Manual fire fighting capability provided for the control room consists of portable halon fire extinguishers within the control room and carbon dioxide hose stations outside of the control room. Additionally, fire hose stations with hose lines equipped with combination nozzles are installed outside the control room.

These fire protection systems are fully discussed in Section 9.5.1.

e. LOCA (RPS Design Bases Unusual Events)

The following RPS components are located inside the drywell and would be subjected to the effects of a design basis LOCA:

1. NMS cabling from the detectors to the control room

2. MSIV inboard position switches

3. Reactor vessel pressure and reactor vessel water level instrument taps and sensing lines that terminate outside the drywell

4. Drywell pressure instrument taps

These items and all RPS Class 1E components are environmentally qualified to remain functional during and following a LOCA as discussed in Section 3.11.

f. Pipe Break Outside Secondary Containment (RPS Design Bases Unusual Events)

This condition would not affect the reliability of the RPS.

g. Feedwater Break (RPS Design Bases Unusual Events)

This condition would not affect the reliability of the RPS.

h. Missiles (RPS Design Bases Unusual Events)

See Section 3.5.

7.2.1.2.9 Performance Requirements

The minimum performance requirements are referenced in Chapter 16.

A logic combination (one-out-of-two-twice) of instrument channels and their trips, actuated by abnormal or accident conditions, initiates a scram and produces independent logic seal-ins within each of the four logic divisions. The trip conditions are annunciated and recorded on the process computer. The trip seal-in maintains a scram signal condition at the CRD system terminals until the instrument channels have returned within their normal operating range and the seal-in is manually reset by operator action. Thus, once a trip signal is present long enough to initiate a scram, the protective action goes to completion.

7.2.1.3 RPS Final System Drawings

The final RPS drawings are processed at two different levels relative to this UFSAR.

a. System IED and channel logic diagrams are provided in this section.

b. Detailed circuit diagrams, electrical elementary diagrams, and cabinet and panel layout drawings are listed in Section 1.7. This documentation is complementary to discussions and drawings included in this UFSAR.

There are no functional or architectural design basis differences or changes to this system between the approved preliminary PSAR design and the FSAR final design, except for the following changes:

1. 600 psi permissive in MSIV closure trip was deleted.

2. 15% APRM trip was added.

3. Trip units/transmitters were added.

4. Logics A3 and B3 were deleted.

A direct comparison of the PSAR and FSAR verifies these observations.

7.2.2 ANALYSIS

7.2.2.1 Reactor Protection System - Instrumentation and Controls

7.2.2.1.1 RPS General Functional Requirements Conformance

Presented below are analyses to demonstrate how the various general functional requirements and the specific regulatory requirements listed under the RPS design bases (Section 7.1.2.1) are satisfied.

7.2.2.1.1.1 RPS Conformance to Design Bases Requirements

7.2.2.1.1.1.1 Design Basis (Section 7.1.2.1.1.1.a)

The RPS is designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier. Chapter 15 identifies and evaluates events that jeopardize the fuel barrier. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are detected and identified, are presented in that chapter.

The design basis from Section 7.1.2.1.1 requires that the precision and reliability of the initiation of reactor scrams be sufficient to prevent or limit fuel damage.

Table 7.2-1 lists the sensors selected to initiate reactor scrams and delineates the needed accuracy, range, and time response for each sensor. This information, along with the information in the Technical Specifications establishes the precision of the RPS variable sensors.

The reliability of the RPS is ensured by design through the selection of reliable components, configuration of components in redundant logic, the use of components based on previous design, and periodic testing.

The selection of scram trip settings has been developed through analytical modeling, experience, historical use of initial setpoints, and adoption of new variables and setpoints as experience was gained. The initial setpoint selection method provided for settings that were sufficiently above the normal operating levels (to preclude the possibilities of spurious scrams or difficulties in operation) but low enough to protect the fuel. As additional information became available or systems were changed, additional scram variables were provided using the above method for initial setpoint selection. The selected scram settings are analyzed to verify that they are conservative and that

the fuel and fuel barriers are adequately protected. In all cases, previous operating experience and the analytical models have been taken into consideration, so that the specific scram trip point selected is a conservative value that prevents damage to the fuel.

7.2.2.1.1.1.2 RPS Design Basis (Section 7.1.2.1.1.1.b)

The scram initiated by the RCPB high pressure, in conjunction with the pressure relief system, is sufficient to prevent damage to the RCPB as a result of internal pressure. The MSIV closure scram provides a greater margin to the RCPB pressure safety limit than the high pressure scram does. For turbine-generator trips, the stop valve closure scram and turbine control valve fast closure scram provide a greater margin to the nuclear system pressure safety limit than the high pressure scram does. Chapter 15 identifies and evaluates accidents and abnormal operational events that result in nuclear system pressure increases. In no case does pressure exceed the RCPB safety limits.

7.2.2.1.1.1.3 RPS Design Basis (Section 7.1.2.1.1.1.d)

The scram initiated by the reactor vessel low water level satisfactorily limits the radiological consequences of gross failure of the RCPB. Chapter 15 evaluates gross failures of the RCPB; in no case does the release of radioactive material to the environment result in exposures that exceed the guide values of applicable published regulations.

7.2.2.1.1.1.4 RPS Design Basis (Section 7.1.2.1.1.1.d)

Scrams are initiated by variables that are designed to indirectly monitor fuel temperature and protect the RCPB. The NMS monitors fuel temperature indirectly using incore detectors. The incore detectors monitor the reactor power level by detecting the neutron level in the core. Reactor power level is directly proportional to neutron level and the heat generated in the fuel. Although the NMS does not monitor fuel temperature directly, by establishing a correlation between fuel temperature and reactor power level, scram setpoints can be determined for protective action, which prevents fuel damage.

The RCPB is protected by monitoring parameters that indicate reactor pressure directly or anticipate reactor pressure increases. Reactor pressure is monitored directly by pressure sensors that are connected directly to the RPV through sensing lines and pressure taps. In addition, reactor pressure transients are anticipated by monitoring the closure of valves that shut off the flow of steam from the RPV and cause rapid pressure increases. The variables monitored to anticipate pressure transients are MSIV position, turbine stop valve closure, and turbine control valve fast closure. If any of these valves were to close, pressure would rise very rapidly. Therefore, the pressure rise is anticipated, and a trip is initiated to minimize the pressure transient.

Chapter 15 identifies and evaluates the conditions that threaten fuel and RCPB integrity. In no case does the core exceed a safety limit.

7.2.2.1.1.1.5 RPS Design Basis (Section 7.1.2.1.1.1.e)

The scrams initiated by the NMS, drywell pressure, reactor vessel pressure, reactor vessel water level, turbine stop valve closure, and the turbine control valve fast closure prevent fuel damage. The scram setpoints and response time requirements for these variables are referenced in Chapter 16 and have been designed to cover the expected range of magnitude and rates of change during abnormal operational transients without fuel damage. Chapter 15 identifies and evaluates

the conditions that threaten fuel integrity. With the selected variables and scram setpoints, adequate core margins are maintained relative to thermal-hydraulic safety limits.

7.2.2.1.1.1.6 RPS Design Basis (Section 7.1.2.1.1.1.f)

Neutron flux is the only essential variable with spatial dependence that provides inputs to the RPS. Neutron flux is monitored both as an indication of average reactor power (APRM upscale trips) and as indication of thermal-hydraulic instability caused power oscillations (OPRM upscale trip).

Two transient analyses are used to determine the minimum number and physical location of required LPRMs for each APRM for average power monitoring.

a. The first analysis is performed with operating conditions of 100% reactor power and 100% recirculation flow using a continuous rod withdrawal of the maximum worth control rod. In the analysis, LPRM detectors are mathematically removed from the APRM channels. This process is continued until the minimum number and locations of detectors needed to provide protective action are determined for this condition.

b. The second analysis is performed with operating conditions of 100% reactor power and 100% recirculation flow using a reduction of recirculation flow at a fixed design rate. Again, LPRM detectors are mathematically removed from the APRM channels. This process is continued until the minimum number and locations of detectors needed to provide protective action are determined for this condition.

The results of the two analyses are evaluated and compared to establish the actual minimum number and location of LPRMs needed for each APRM channel.

The OPRM upscale function monitors LPRMs combined into cells of 4 LPRMs each (see Figure 7.2-17). If more than 2 of the 4 LPRMs in an OPRM cell are bypassed the cell is determined to be inoperable and removed from the logic. The minimum required number of operable OPRM cells per APRM channel is determined by performing an analysis that mathematically removes LPRMs (and OPRM cells when the number of remaining LPRMs in a cell falls below the required minimum) and calculates the hot-bundle MCPR change that will result prior to an OPRM trip due to a power oscillation. That calculated value is compared to the hot-bundle MCPR change calculated with no LPRMs bypassed. The minimum required number of operable OPRM cells is that number that assures that the hot-bundle MCPR change that results prior to an OPRM upscale trip is equal to or less than the corresponding value calculated with no LPRMs bypassed (References 7.6-1 through 7.6-4).

Analyses like those discussed above for APRMs have also been conducted for the IRMs. These analyses have established the actual minimum number and location of IRM sensors and channels (Reference 7.2-1).

7.2.2.1.1.1.7 RPS Design Basis (Sections 7.1.2.1.1.1.g.1 through 7.1.2.1.1.1.g.8)

Sensors, channels, and logics of the RPS are not used directly for automatic control of process systems. Therefore, failure in the controls and instrumentation of process systems cannot induce failure of any portion of the protection system.

The RPS system is a normally energized system. Failure of either RPS power supply results in the de-energization of one of the two pilot solenoids associated with each control rod. Alternate power is available to the RPS buses. A complete loss of electrical power to both power supplies results in a scram. Loss of one or both power supplies does not prevent a reactor scram.

The RPS is designed so that trip variables need only exceed their trip setpoints for a sufficient length of time to de-energize the scram relay contactors and open the seal-in contacts of the associated trip logic. Once this is accomplished, the scram will go to completion, regardless of the state of the variable that initiated the protective action.

When the initiating condition has cleared and a sufficient (10 second) time delay has occurred, the scram logic may be reset only by actuation of the scram reset switches in the control room by the operator.

Reactor protection cabling is routed in separate, totally-enclosed metallic raceways or in embedded PVC conduits for all wiring between sensors, racks, panels, and scram solenoids.

Physical separation and electrical isolation among redundant portions of the RPS are provided by separated process instrumentation, separated racks, separated portions of panels, and separated cabling, as described in Section 7.2.1.1.4.8. This separation ensures that environmental factors, electrical transients, and physical events do not impair the ability of the RPS to respond correctly when required.

The RPS has four divisions housed in two panels in the auxiliary equipment room and one panel in the control room. Each panel has metallic fireproof barriers between divisions. Where equipment from more than one division is in a panel, divisional separation is provided by fire barriers or a physical distance of 6 inches or more where practicable. Where wiring from more than one redundant division is present at a single component, divisional separation is provided by fire barriers on the component, in addition to routing the wiring from the component in separate conduits or by routing wiring in such a way as to prevent any failure within the component from affecting redundant divisions. Separate racks are provided for the reactor protection sensor instrumentation in redundant divisions and they are either installed in different locations or separated by metal barriers.

The ability of the RPS to withstand an SSE is discussed in Section 7.2.2.1.2.1.4.

The ability of the RPS to function properly with a single failure is discussed in Section 7.2.2.1.2.3.1.2.

The ability of the RPS to function properly while any one sensor or channel is bypassed or is undergoing testing or maintenance is discussed in Section 7.2.2.1.2.3.1.11.

The RPS logic circuit is designed so that an automatic scram is initiated when at least one sensor in each trip system for any monitored variable exceeds the scram setpoint.

7.2.2.1.1.1.8 RPS Design Basis (Section 7.1.2.1.1.1.h)

Access to trip settings, component calibration controls, test points, and other terminal points is under the control of plant operations supervisory personnel.

Access control is provided by the use of administration control procedures. These require that approved procedures be used to perform calibration and testing; permission must be obtained before performance of all calibration and testing. It is also required that operations personnel, within the control room, monitor and control access to panels and cabinets within the control room.

Manual bypass of instrumentation and control equipment components is under the control of the control room operator. If the ability to trip some essential part of the system is bypassed during a mode of operation that requires operability of that part of the system, this fact is continuously annunciated in the control room, as described in Section 7.2.2.1.2.1.7.

7.2.2.1.1.1.9 Other RPS Design Basis Requirements

The RPS is a one-out-of-two-twice logic system. Theoretically, its reliability is slightly higher than a two-out-of-three system and slightly lower than a one-out-of-two system. However, because the differences are slight, they can be neglected. The dual trip system is advantageous because it can be tested thoroughly during reactor operation without causing a scram. This capability for a thorough testing program significantly increases reliability.

The environment in which the instruments and equipment of the RPS must operate is discussed in Section 3.11.

The control room maximum environment is predicated on supplying the control room with 100% outside air with no refrigeration. The minimum environment is predicated on a mixture of outside and recirculated air concurrent with minimum equipment heat loss. The RPS components that must function in the environment resulting from a RCPB break inside the drywell are the condensing chambers and the inboard MSIV position switches. Special precautions are taken to ensure their operability after the accident.

The condensing chambers have been qualified by analysis to the applicable ASME Codes. The chamber itself is strictly a mechanical assembly with no moving parts and no active functions. There is no environmental requirement on the condensing chambers, other than that each maintain its integrity under the most severe environmental condition. The results of the seismic qualification of the condensing chambers are documented in the LGS SQRT Program.

The environmental qualification of the existing MSIV limit switches has been evaluated as part of the LGS environmental qualification program. As a result of the licensee's evaluation, the originally supplied limit switches have been replaced with prequalified limit switches. The selection criteria for the replacement switches include qualification levels appropriate for a RCPB break inside the drywell.

Other essential components of the control and electrical equipment are either similar to those that have successfully undergone qualification testing in connection with other projects, or additional qualification testing under simulated environmental conditions has been conducted.

To ensure that the RPS remains functional, the number of operable channels for the essential monitored variables is maintained at or above the minimums referenced in Chapter 16. The minimums apply to any untripped trip system; a tripped trip system may have any number of inoperative channels. Because reactor protection requirements vary with the mode in which the reactor operates, the tables show different functional requirements for the run and startup modes. These are the only modes in which more than one control rod can be withdrawn from the fully inserted position.

In case of a LOCA, reactor shutdown occurs immediately following the accident as process variables exceed their specified setpoint. Operator verification that shutdown has occurred may be made by observing one or more of the following indications:

a. Control rod status lamps indicating each rod fully inserted

b. Control rod scram pilot valve status lamps indicating open valves

c. Neutron monitoring power range channels and recorders downscale

d. Annunciators for RPS variables and trip logic in the tripped state

e. Process computer logging of trips and control rod position log

Following generator load rejection, a number of events occur in the following chronological order:

a. The pressure in the hydraulic oil lines to the control valve fast closure solenoid drops, and the pressure sensors provide a trip signal to RPS. Simultaneously the turbine control logic initiates fast opening of the turbine bypass valves which minimizes the pressure from the transient.

b. The RPS scrams the reactor upon receipt of the turbine control valve fast closure signal, provided that at the time of load rejection the unit load is equal to or greater than 29.5% of rated power output.

   The reactor scram is averted, if at the time of load rejection, the unit load is within the capacity of the turbine bypass system.

c. The APRM Simulated Thermal - Upscale trip setting is automatically reduced from 117% to 97% Simulated Thermal Power, as recirculation flow is run back from 100% to 50% of the rated flow.

The trip settings discussed in Section 7.2.1.1.6.3 are not changed to accommodate abnormal operating conditions. Actions required during abnormal conditions are discussed in Chapter 16. Transients requiring activation of the RPS are discussed in Chapter 15. The discussions there designate which systems and instrumentation are required to mitigate the consequences of these transients.

Operability of the anticipatory signals from the turbine control valve fast closure or turbine stop valve closure following an SSE is not a system design basis. There is no reason to expect concurrent failures of these trips without the SSE. However, if the gross failure of these trips should occur, the reactor would scram on high neutron flux or high reactor pressure. The results of this event would not be more severe than the one caused by closure of all the MSIVs without the MSIV position switch trip. That event is discussed in Section 5.2.2.2.2.4 as the relief valve sized transient.

7.2.2.1.2 RPS Specific Regulatory Requirements Conformance

7.2.2.1.2.1 RPS Conformance to Regulatory Guides

Conformance of the transmitter/trip unit system used in the RPS is discussed in Licensing Topical Report NEDO-21617-A, "Analog Transmitter/Trip Unit System for Engineered Safeguard Sensor Inputs." Conformance of the other features with the regulatory guides is discussed in the following sections.

7.2.2.1.2.1.1 RPS - Regulatory Guide 1.6 (1971) - Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems (Safety Guide 6)

Conformance is discussed in Section 7.1.2.5.1.

7.2.2.1.2.1.2 RPS - Regulatory Guide 1.11 (1971) - Instrument Lines Penetrating Primary Reactor Containment (Safety Guide 11)

Conformance to Regulatory Guide 1.11 is discussed in Section 6.2.4.3.

7.2.2.1.2.1.3 RPS - Regulatory Guide 1.22 (1972) - Periodic Testing of Protection System Actuation Functions (Safety Guide 22)

The system is designed so that it may be tested during plant operation from sensor device to final actuator device. The test must be performed in overlapping portions so that an actual reactor scram does not occur as a result of the testing.

7.2.2.1.2.1.4 RPS - Regulatory Guide 1.29 (1978) - Seismic Design Classification

All electrical and mechanical devices and circuitry between process instrumentation and protection actuators and monitoring of systems important to safety are classified as seismic Category I.

7.2.2.1.2.1.5 RPS - Regulatory Guide 1.30 (1972) - Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment (Safety Guide 30)

See Section 8.1.6.1.5 and Chapter 17.

7.2.2.1.2.1.6 RPS - Regulatory Guide 1.32 (1977) - Criteria for Safety-Related Electric Power Systems for Nuclear Power Plants

Although not a design basis, an assessment of the LGS design shows that it meets the guidelines of Regulatory Guide 1.32 (1977) and conforms to IEEE 308 (1971).

7.2.2.1.2.1.7 RPS - Regulatory Guide 1.47 (1973) - Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems

a. Regulatory Positions C.1, C.2, and C.3

Automatic indication is provided in the control room to inform the operator that a system is out-of-service. Indicator lights indicate which part of a system is not operable. System out-of-service annunciators energize whenever one or more of the following conditions occur:

1. Trip units are being tested or a gross failure of a transmitter is detected.

2. Trip units are out of their card file, or there is a loss of power to the transmitters, or trip units.

These are the only conditions expected to occur more than once a year that would cause inoperability of the RPS. In addition, there is a switch in the control room that the operator can use to manually bring up the system out-of-service annunciator.

Instruments that form part of a one-out-of-two-twice logic system can be removed from service for calibration. Removal of the instrument from service is indicated in the control room by manual actuation of the system out-of-service annunciator by the system out-of-service switch.

b. Regulatory Position C.4

All the annunciators can be tested by depressing the annunciator test switches on the control room bench boards.

The following discussion expands the explanation of conformance to Regulatory Guide 1.47 to reflect the importance of providing accurate information for the operator and reducing the possibility for the indicating equipment to adversely affect its monitored safety system.

1. Individual indicator lights are arranged together on the control room console to indicate what function of the system is out-of-service, bypassed, or otherwise inoperable. All bypass and inoperability indicators both at a system level and component level are grouped only with items that prevent a system from operating if needed.

2. A manual switch is provided for manual actuation to cover out-of-service conditions that could not be automatically annunciated.

3. These indication provisions serve to supplement administrative controls and to aid the operator in assessing the availability of component and system level protective actions. This indication does not perform a safety function.

4. All system out-of-service annunciator circuits are electrically independent of the plant safety systems to prevent the possibility of adverse effects.

5. Each indicator light is provided with dual lamps. These are tested periodically, along with the other devices in the circuit.

7.2.2.1.2.1.8 RPS - Regulatory Guide 1.53 (1973) - Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems

Compliance with Regulatory Guide 1.53 is obtained by specifying, designing, and constructing the RPS to meet the single failure criterion, section 4.2 of IEEE 279 (1971), "Criteria for Protection Systems for Nuclear Power Generating Stations," and IEEE 379 (1972), "IEEE Trial Use Guide for the Application of the Single Failure Criterion to Nuclear Power Generating Station Protection Systems." Redundant instrument tubing, sensors, wiring, logic, and actuators are separated to ensure that a single failure in any portion of the RPS does not prevent protective action.

Facilities for testing are provided so that the equipment can be operated in various test modes to confirm that it operates properly when required. Testing incorporates all elements of the system under one test mode or another, including sensors, logic, actuators, and actuated equipment. The testing is planned to be performed at intervals so that there is an extremely low probability of failure in the periods between tests. During testing, there are always enough channels and systems available for operation to provide proper protection action.

7.2.2.1.2.1.9 RPS - Regulatory Guide 1.62 (1973) - Manual Initiation of Protective Actions

Means are provided for manual initiation of reactor manual scram at the system level through the use of four, armed push button switches, one for each trip logic. Operation of these switches accomplishes the initiation of all actions performed by the automatic initiation circuitry. These switches are located on the control room bench board and are easily accessible to the operator so that action can be taken expeditiously.

The amount of equipment common to the initiation of both manual scram and automatic scram is kept to a minimum through the implementation of manual scram as close to the final devices (scram contactor) as practicable. No single failure in the manual, automatic, or common portions of the protection system prevents initiation of reactor scram by manual or automatic means.

The "minimum of equipment" objective is accomplished for the initiation of manual scram through its implementation "as close as practicable to" the final actuating devices (scram contactor) of the protection system.

Manual initiation of reactor scram, once initiated, goes to completion as required by IEEE 279 (1971), section 4.16.

7.2.2.1.2.1.10 RPS - Regulatory Guide 1.63 (1978) - Electric Penetration Assemblies in Containment Structures for Light-Water-Cooled Nuclear Power Plants

Conformance to Regulatory Guide 1.63 is discussed in Section 8.1.6.1.12.

7.2.2.1.2.1.11 RPS - Regulatory Guide 1.68 (1978) - Preoperational and Initial Startup Test Programs for Water-Cooled Power Reactors

Conformance to Regulatory Guide 1.68 is discussed in Section 14.2.

7.2.2.1.2.1.12 RPS - Regulatory Guide 1.75 (1978) - Physical Independence of Electric Systems

Conformance is discussed in Section 8.1.6.14.

7.2.2.1.2.1.13 RPS - Regulatory Guide 1.89 (1974) - Qualification of Class 1E Equipment for Nuclear Power Plants

Conformance is discussed in Sections 3.11 and 8.1.6.1.16.

7.2.2.1.2.1.14 RPS - Regulatory Guide 1.97 (1980) - Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident

Conformance to this guide is discussed in Section 7.5.2.5.1.1.2.

7.2.2.1.2.1.15 RPS - Regulatory Guide 1.100 (1977) - Seismic Qualification of Electric Equipment for Nuclear Power Plants

General compliance for Regulatory Guide 1.100 is found in Section 3.10.2.

7.2.2.1.2.1.16 RPS - Regulatory Guide 1.105 (November 1976) - Instrument Setpoints

RPS conformance to this guide is discussed in Section 7.1.2.5.25.

7.2.2.1.2.1.17 RPS - Regulatory Guide 1.118 (June 1978) - Periodic Testing of Electric Power and Protection Systems

RPS conformance to this guide is discussed in Section 7.1.2.5.26.

Position C.5 for APRM:

With respect to conformance to position C.5, the inherent time response of the incore sensors used for APRM (fission detectors operated in the ionization chamber mode) is many orders of magnitude faster than the APRM channel response time requirements and the signal conditioning electronics. The sensors cannot be tested without disconnecting and reconnecting to special test equipment.

7.2.2.1.2.2 RPS Conformance to 10CFR50, Appendix A, General Design Criteria

7.2.2.1.2.2.1 RPS - GDC 1 - Quality Standards and Records

The QA program for the system ensures sound engineering in all phases of design and construction through conformity to regulatory requirements and design bases described in the license application. The QA program is discussed in Chapter 17.

Documents are maintained that demonstrate that all the requirements of the QA program are being satisfied. These records are maintained during the life of the operating licenses.

7.2.2.1.2.2.2 RPS - GDC 2 - Design Bases for Protection Against Natural Phenomena

Wind and tornado loadings are discussed in Section 3.3, flood design is described in Section 3.4, and seismic qualification of instrumentation and electrical equipment is discussed in Section 3.10.

7.2.2.1.2.2.3 RPS - GDC 3 - Fire Protection

The fire protection system and its design basis are discussed in Section 9.5.1. Fire protection for cable systems is described in Sections 8.3.1.1.7 and 8.3.1.1.8.

7.2.2.1.2.2.4 RPS - GDC 4 - Environmental and Dynamic Effects Design Bases

The system is designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including LOCAs.

The system is appropriately protected against dynamic effects including the effects of missiles, pipe whipping, and discharging fluids that may result from equipment failures. Missile protection is discussed in Section 3.5, pipe whip in Section 3.6, and environmental qualification of equipment in Section 3.11.

7.2.2.1.2.2.5 RPS - GDC 10 - Reactor Design

The RPS is designed to monitor certain reactor parameters, to sense abnormalities, and to scram the reactor, thereby preventing fuel design limits from being exceeded when trip points are exceeded. Scram trip setpoints are selected based on operating experience and by the safety design basis. There is no case in which the scram trip setpoints allow the core to exceed the thermal-hydraulic safety limits. Power for the RPS is supplied by two independent uninterruptible ac power supplies.

The system is designed to ensure that the specified fuel and RCPB design limits are not exceeded during conditions of normal or abnormal operation.

7.2.2.1.2.2.6 RPS - GDC 12 - Suppression of Reactor Power Oscillations

The system design provides protection from excessive fuel cladding temperatures and protects the RCPB from excessive pressures that threaten the integrity of the system. An OPRM Upscale Function BWROG Long Term Stability Solution Option III is incorporated into each APRM channel to detect power oscillations in the operating ranges where thermal-hydraulic instability has been determined to be credible. Upon detection of power oscillations, the OPRM Upscale Function generates a trip signal to RPS which results in an automatic scram to suppress the oscillation before the MCPR Safety Limit is reached. High reliability of the reactor protection system is achieved through the combination of redundant sensors, logic, trip channel actuators, and physical separation of these redundant portions of the RPS.

7.2.2.1.2.2.7 RPS - GDC 13 - Instrumentation and Control

Instrumentation is provided to monitor the variables identified in Table 7.2-1 over their anticipated ranges for normal operation, anticipated operational occurrences, and accident conditions. If these variables exceed a predetermined setpoint, the RPS automatically takes action to ensure the integrity of the reactor core and the RCPB.

7.2.2.1.2.2.8 RPS - GDC 15 - Reactor Coolant System Design

The RPS acts to provide sufficient margin to ensure that the design conditions of the RCPB are not exceeded during any condition of normal operation, including anticipated operational occurrences. If the monitored variables exceed their predetermined settings, the RPS automatically responds to maintain the variables and systems within allowable design limits.

7.2.2.1.2.2.9 RPS - GDC 19 - Control Room

Controls and instrumentation for the RPS are provided in the control room to allow the operator to safely shut down the plant. The reactor can also be shut down in an orderly manner from outside the control room as described in Section 7.4.1.4.

7.2.2.1.2.2.10 RPS - GDC 20 - Protection System Functions

The RPS constantly monitors the appropriate plant variables to maintain the fuel barrier and primary coolant pressure boundary and initiates a scram automatically when the variables exceed the established setpoints.

7.2.2.1.2.2.11 RPS - GDC 21 - Protection System Reliability and Testability

The system is designed with four redundant, independent, and separated channels. No single failure can prevent a scram. Removal from service of any component or channel does not result in loss of the required minimum redundancy. The system can be tested during plant operation to ensure its reliability.

7.2.2.1.2.2.12 RPS - GDC 22 - Protection System Independence

The redundant portions of the RPS are separated so that no single failure or credible natural disaster can prevent a scram. Even though the turbine scram inputs originate from the nonseismic turbine enclosure, reactor pressure and power are diverse to these turbine scram variables to ensure protective action during and following a seismic event. Diversity is used to the extent practicable in the monitoring of other variables as described in Section 7.2.1.1.4.6 to prevent loss of the protective function.

7.2.2.1.2.2.13 RPS - GDC 23 - Protection System Failure Modes

The RPS is fail-safe. A loss of electrical power, a loss of air supply, or postulated adverse environments do not prevent a scram.

7.2.2.1.2.2.14 RPS - GDC 24 - Separation of Protection and Control Systems

The RPS has no control function and no components common to any control systems. There are interlocks to control systems through isolation devices. Failure of any single control system component or channel leaves the integrity of the RPS system intact, without compromising any reliability, redundancy, or independence requirements of the RPS.

7.2.2.1.2.2.15 RPS - GDC 25 - Protection System Requirements for Reactivity Control Malfunctions

The system provides protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier. Any monitored variable that exceeds the scram setpoint initiates an automatic scram and does not prevent the remaining variables from being monitored. Fuel design limits are not exceeded for any single malfunction of the reactivity control system.

7.2.2.1.2.2.16 RPS - GDC 29 - Protection Against Anticipated Operational Occurrences

The RPS is highly reliable so that it causes a scram if there are anticipated operational occurrences where any of the RPS trip setpoints are exceeded.

7.2.2.1.2.3 RPS Conformance to Industry Codes and Standards

Conformance of the transmitter/trip unit system, used in the RPS, is discussed in Licensing Topical Report NEDO-21617-A, "Analog Transmitter/Trip Unit System for Engineered Safeguard Sensor Inputs." Conformance of the other features with the industry standards is discussed in the following sections.

7.2.2.1.2.3.1 RPS - IEEE 279 (1971) - Criteria for Protection Systems for Nuclear Power Generating Stations

7.2.2.1.2.3.1.1 RPS - IEEE 279 (1971), Paragraph 4.1 - General Functional Requirement

The following RPS trip variables provide automatic initiation of protective action in compliance with this requirement:

a. SDV high water level trip

b. MSIV closure trip

c. Turbine stop valve closure trip

d. Turbine control valve fast closure trip

e. Reactor vessel low water level trip

f. Left blank intentionally.

g. Neutron monitoring (APRM) system trip (including OPRM trip)

h. Neutron monitoring (IRM) system trip

i. Drywell high pressure trip

j. Reactor vessel high pressure trip

The reactor system mode switch selects appropriate operating bypasses for various RPS variables in the shutdown, refuel, startup, and run modes of operation. Other manual controls, such as the SDV high water level bypass, the manual scram push button switches, and the three-position RPS reset switch are arranged to ensure that the process variables providing automatic initiation of protective action continue to remain in compliance with this requirement.

The three-position RPS reset switch is under the administrative control of the reactor operator. Since the reset switch does not connect redundant circuits in parallel with the trip logic, failure of the reset switch cannot prevent initiation of protective action.

Manual reset by the operator bypasses the seal-in contact to permit a trip system to be reset to its normally energized state when all process sensor trip channels are within their normal (untripped) range of operation.

The trip system logic, scram contactors, and scram contactor logic are designed to comply with this requirement through automatic removal of electric power to the CRD scram solenoids when one or more RPS variables exceed the specified trip setpoint.

7.2.2.1.2.3.1.2 RPS - IEEE 279 (1971), Paragraph 4.2 - Single Failure Criterion

The following RPS trip variables are individually implemented with four physically separated, redundant channels in compliance with this requirement:

a. MSIV closure trip

b. Turbine stop valve closure trip

c. Turbine control valve fast closure trip

d. Reactor vessel low water level trip

e. Drywell high pressure trip

f. Reactor vessel high pressure trip

g. SDV high water level trip

The APRM and IRM trips comply with the single failure criterion through the use of physical panel barriers and electrical isolation provisions to provide independence among the two redundant APRM 2-out-of-4 voter channels and four redundant IRM channels in either trip system A or B. Four redundant APRM channels provide inputs to both trip system A and trip system B.

Redundant sensors, wiring, logic, and actuators are physically separated to prevent a single failure from preventing the protective action. Wiring between redundant portions of the RPS and between RPS and non-Class 1E circuitry is configured to eliminate a possible single failure.

Wiring to each group of scram solenoids is routed in individual raceways separated from wiring to the other groups of scram solenoids.

Wiring from each sensor to the relay cabinets is run in a separate, totally enclosed metallic raceway or embedded PVC conduit to maintain electrical isolation and physical separation among redundant sensor trip channels.

RPS manual controls also comply with the single failure criterion. Four manual scram push buttons are arranged into two groups on one control room panel. The switch contact blocks are physically separated by metal barriers.

The reactor mode switch consists of a single manual actuator connected to four separated switch banks. Each bank is housed within a fire-retardant cover. Contacts from each bank are wired in conduit to a metallic terminal box with separation barriers.

Although the SDV high water level trip bypass is controlled by only one switch, the design of the bypass circuit complies with the single failure criteria. This bypass requires manual operation of a bypass switch and the mode switch to establish four bypass channels; the design of the bypass function complies with this design requirement. For the bypass switch, a single operator connects to two physically and electrically separated blocks of switch contacts within the switch body that separates redundant trip channels. Wiring from the contacts is routed in conduit to separate metallic terminal boxes. One set of switch contacts in conjunction with separated mode switch contacts is used to energize each trip channel bypass relay when the bypass condition is desired. There is no single failure of this bypass function that could establish a spurious bypass condition of more than one channel. Hence, this function complies with the single failure criterion.

The main steam line valve closure trip operating bypass is implemented with separated mode switch contacts.

The turbine stop valve closure trip and control valve fast closure trip operating bypass complies with the single failure criterion. Nonredundant pairs of pressure sensors are mounted at each of two, physically separated pressure taps located in the turbine steam supply lines upstream of the high pressure turbine first stage. Wiring from the metallic raceway or embedded PVC conduit

sensors is routed in a TEMR or to the RPS cabinets in the auxiliary equipment room. A single bypass is associated with a single trip channel for stop valve closure and for control valve fast closure. The worst case single failure could result in the bypass of the turbine stop valve closure and turbine control valve fast closure for the A and B trip logics or the C and D trip logics. The logic is arranged so that this failure does not interfere with the normal protective action of the RPS.

The three-position RPS reset switch and associated logic comply with this design requirement. The reset switch is constructed with a single operator and two physically and electrically separated contact blocks. The wires from the contact blocks go through conduit to metallic terminal boxes.

Since the opening of the process sensor trip channel contact is the initiating event for reactor scram, failure of the reset switch does not prevent de-energization of the trip actuators during the time interval that the process actually exceeds the trip setpoint.

Those portions of the RPS downstream of the trip channels also comply with this design requirement. Any postulated single failure of a given trip logic does not affect the remaining three trip logics. Similarly, any single failure of a scram contactor does not affect the remaining scram contactors, and any single failure of one trip logic does not affect the other trip logics. The cabling associated with one control rod group is routed in conduit that is physically separated from similar cabling associated with the other control rod groups. Cabling from the scram contactor logic to the scram solenoid groups is routed in individual, totally-enclosed, metallic raceway or in PVC conduits when embedded in concrete to comply with this design requirement. Because both the "A" or "B" solenoid valves must de-energize to scram, the wiring of these two solenoids for one control rod group is routed together within a single raceway, separate from all other wiring.

7.2.2.1.2.3.1.3 RPS - IEEE 279 (1971), Paragraph 4.3 - Quality of Components and Modules

All RPS trip variables are implemented with components and modules used on previous GE BWR plants and that exhibit high quality and high reliability characteristics.

The selected RPS manual switches are also of high quality and reliability.

The four pressure sensors selected for the turbine stop valve closure and control valve fast closure operating bypass are of high quality and reliability.

The RPS trip system logic consists of series-connected relay contacts from the trip channel output relays. The relays are of high quality and reliability.

The RPS scram contactor logic consists of interconnecting trip logics to form a trip system by means of scram contactor contacts. The scram contactors are of high quality and reliability.

7.2.2.1.2.3.1.4 RPS - IEEE 279 (1971), Paragraph 4.4 - Equipment Qualification

Qualification tests of RPS equipment are conducted to confirm their adequacy. Details of this testing are contained in Section 3.10 and 3.11. In addition, the vendor is required to certify that the sensors associated with each of the RPS trip variables, manual switches, and trip logic components perform in accordance with the requirements listed on the purchase specification as well as in the intended application. This certification, in conjunction with the qualification tests and existing field experience with these components in this application, serves to qualify these components.

Qualification tests of the panels are conducted to confirm their adequacy. Details of this testing are contained in Sections 3.10 and 7.1.2.7.4.

7.2.2.1.2.3.1.5 RPS - IEEE 279 (1971), Paragraph 4.5 - Channel Integrity

All the components of the RPS trip variables are specified to operate under normal and abnormal conditions of environment, energy supply, and accidents, except as follows:

a. Turbine stop valve closure trip (not guaranteed to operate under an SSE design basis event)

b. Turbine control valve fast closure trip (not guaranteed to operate under an SSE design basis event)

c. Turbine stop valve bypass circuit (not guaranteed to operate under an SSE design basis event)

The RPS trip systems, trip logics, and scram contactors are designed to be operable under normal and abnormal conditions of environment, energy supply, malfunctions, and accidents.

The cables for the turbine stop valves and fast closure valves are run in protective conduit from the sensor to the seismic Category I qualified auxiliary equipment room. Each channel is run in its own conduit which provides the required separation. Starting at the sensor is a flexible metallic conduit section which is connected to a rigid steel conduit section leading to the flooring. The cables are routed in PVC conduit embedded in the floor from the turbine enclosure to the auxiliary equipment room, which contains the reactor trip system.

Table 7.3-6 shows these and other sensors and circuits located in nonseismically qualified structures. Drawings showing the cable routing are E-1112, E-1121, E-1124, E-1125, and E-1183. The applicable sensors shown on E-1112 are ZS01-104A through D and PS01-102A through D.

The routing of the four cables, each in its own separate run, to the trip sensors in the turbine enclosure for the turbine stop valve and turbine valve fast closure trips is such that the only credible failures that will challenge the system are: 1) a SSE, 2) a turbine missile, and 3) a HELB. The expected failure mode caused by these events would be loss of the sensors due to opening or loss of continuity, which would result in a reactor trip.

If the trip sensors failed closed or shorted due to the fault, the reactor pressure and reactor power trips, which are diverse, will still function to prevent damage to the reactor. Shorting of a single sensor would not prevent protective action by the other sensors. Each of the inputs is isolated from the remainder of the RPS logic by the use of interposing relays. If a sensor circuit opened, the signal would be a trip from that input.

7.2.2.1.2.3.1.6 RPS - IEEE 279 (1971), Paragraph 4.6 - Channel Independence

The four redundant trip channels for the following RPS trip variables are physically separated from one another to meet this design requirement:

a. SDV high water level trip

b. Turbine stop valve closure trip

c. Turbine control valve fast closure trip

d. Reactor vessel low water level trip

e. Left blank intentionally.

f. Drywell high pressure trip

g. Reactor vessel high pressure trip.

The individual switch boxes for the turbine variables are physically separated.

The MSIV closure trip is derived from 8 individual channels. Two channels associated with each trip logic are separated as shown in Figure 7-2.8.

The 8 IRM and 4 APRM channels and 4 APRM 2-out-of-4 voter channels are electrically isolated and physically separated from one another so as to comply with this design requirement.

The redundant scram push buttons are physically separated and electrically isolated to comply with this design requirement.

The mode switch banks are physically separated and electrically isolated to comply with this design requirement.

The circuitry for the RPS operating bypasses complies with this design requirement. Sufficient physical separation and electrical isolation of redundant circuits exists to ensure that the operating bypass channels are satisfactorily independent.

The four RPS reset channels to the trip logics are physically separated and electrically isolated. Similarly, the four RPS trip logics and scram contactors are physically separated. The wiring to each rod group scram schedules A and B is routed in TEMRs with module wiring. The details of the physical independence provided between redundant channels are in Section 7.1.2.2.3.2.1.

7.2.2.1.2.3.1.7 RPS - IEEE 279 (1971), Paragraph 4.7 - Control and Protection System Interaction

The RPS is electrically isolated from the plant control systems in compliance with this design requirement.

Each trip channel output relay uses one contact within the RPS trip logic. One additional contact on each relay is wired to a common annunciator in the control room, and another contact on each relay is wired to the process computer cabinets to provide a written log of the channel trips. There is no single failure that prevents proper functioning of any protective function when it is required.

The MSIV and turbine stop valve limit switch contacts for RPS use are routed through TEMRs separated from the other limit switches used for indicator lights in the control room. After the cabling emerges from the limit switch junction box associated with each MSIV or turbine stop valve, it is routed in Class 1E raceway to the RPS panels in the auxiliary equipment room.

Turbine control valve fast closure pressure sensor outputs for RPS use are routed separately relative to other outputs used for indicator lights and turbine control purposes. After the cabling

emerges from the junction boxes, it is routed in Class 1E raceway to the logic cabinets in the auxiliary equipment room.

Within the IRM modules (i.e., before their output trip unit driving the RPS), analog outputs are derived for use with control room meters, recorders, and the process computer. Electrical isolation is incorporated into the design at this interface to prevent any single failure from influencing the protective output from the trip unit. The trip unit outputs are physically separated and electrically isolated from other plant equipment in their routing to the RPS panels.

Within the APRM equipment (i.e., before their output trip driving the RPS), analog outputs are derived for use with control room meters and recorders. Electrical isolation is incorporated into the design at this interface to prevent any single failure from influencing the protective trip output. The trip outputs are physically separated and electrically isolated from other plant equipment in their routing to the RPS panel.

The manual scram push buttons have no control interaction.

The reactor system mode switch is used for protective functions and restrictive interlocks on control rod withdrawal and refueling equipment movement. Additional contacts of the mode switch are used to disable certain computer inputs when the alarms would represent incorrect information for the operator. No control functions are associated with the mode switch. Hence, the switch complies with this design requirement. The system interlocks to control systems only through isolation devices so that no failure or combination of failures in the control system has any effect on the RPS.

The RPS SDV high water level trip operating bypass complies with this design requirement. For each trip channel, one contact is used in the bypass logic. One contact of each relay is also wired to a common annunciator in the control room. One contact from A1 and one contact from B1 trip systems are wired to the control rod block circuitry to prevent rod withdrawal whenever the trip channel bypass is in effect. The system interlocks for control rod block are through isolation devices so that no failure or combination of failures in the control system has any effect on the RPS.

The MSIV closure trip bypass has no interaction with any control system in the plant. Two contacts of each relay are used to initiate a control room annunciator for this bypass function.

Turbine stop valve and control valve trip bypasses have no interaction with any control system in the plant. One output relay contact is used in the RPS trip logic, one output relay contact is used in the Recirc Pump Trip circuitry, and one additional contact from each relay is used to initiate a control room annunciator for this bypass function.

Switch contacts of the three-position reset switch are used only to control auxiliary relays. Contacts from the relays are used only in the scram contactor coil circuits. Consequently, this RPS function has no interaction with any other system in the plant.

The four RPS trip logics are totally separate from all other plant systems. The RPS trip logics use the power contacts of the scram contactors to provide the scram contactor logic and the seal-in contact of the trip logics, and use auxiliary contacts for control room annunciation, the process computer inputs, and initiation of the backup scram valves. Because of the design of this output

and separation of the cabling, there is no interaction with control systems of the plant. The scram solenoids are physically separate and electrically isolated from the other portions of the CRD HCU.

In summary, the transmission of signals from the RPS to control systems is through isolation devices that are part of the RPS. No credible failure at the output of these isolation devices can prevent the RPS from meeting its minimum performance requirements. No single random failures can cause a control system action that results in a condition requiring action by the RPS that can also disable a portion of the RPS designed to protect against that condition.

An SSE is the only single credible event that can cause a control system action resulting in a condition requiring protective action and that can concurrently prevent operation of a portion of the RPS. In an SSE, the turbine stop valve closure trip and the turbine control valve fast closure trip may be disabled. The reactor vessel high pressure and high power trips provide diverse protection for this event.

7.2.2.1.2.3.1.8 RPS - IEEE 279 (1971), Paragraph 4.8 - Derivation of System Inputs

The following RPS trip variables are direct measures of a reactor overpressure condition, a reactor overpower condition, a gross fuel damage condition, or abnormal conditions within the RCPB:

a. Reactor vessel low water level trip

b. Left blank intentionally.

c. Neutron monitoring (APRM) system trip

    1. Neutron flux trip

    2. Simulated thermal power trip

    3. OPRM upscale trip

d. Neutron monitoring (IRM) system trip

e. Drywell high pressure trip

f. Reactor vessel high pressure trip

The measurement of SDV water level is an appropriate variable for this protective function. The desired variable is "available volume" to accommodate a reactor scram. However, the measurement of consumed volume is sufficient to infer the amount of remaining available volume, because the total volume is a fixed, predetermined value established by the design.

The measurement of MSIV position and turbine stop valve position is an appropriate variable for the RPS. The desired variable is "loss of the reactor heat sink"; however, isolation or stop valve closure is the logical variable from which to infer that the steam path has been blocked between the reactor and the heat sink.

Because of the normal throttling action of the turbine control valves with changes in the plant power level, measurement of control valve position is not an appropriate variable from which to infer the desired variable, which is "rapid loss of the reactor heat sink." Consequently, a measurement of valve closure rate is necessary.

Protection system design practice has discouraged the use of rate sensing devices for protective purposes. In this instance, it was determined that detection of hydraulic actuator operation would be a more positive means of determining fast closure of the control valves.

Loss of hydraulic pressure in the EHC oil lines, which initiates fast closure of the control valves, is monitored. These measurements indicate that fast closure of the control valves is imminent.

This measurement is adequate and a proper variable for the protective function, taking into consideration the reliability of the chosen sensors relative to other available sensors and the difficulty in making direct measurements of control valve fast closure rate.

Since the mode switch is used to bypass certain RPS trips depending on the operating state of the reactor, the selection of particular contacts to perform this logic operation is an appropriate means for obtaining the desired function.

The turbine stop valve closure trip and control valve fast closure trip operating bypass permits continued reactor operation at low power levels when the turbine stop or control valves are closed. The selection of turbine first-stage pressure is an appropriate variable for this bypass function. In the power range of reactor operation, turbine first-stage pressure is essentially linear with increasing reactor power. Consequently, this variable provides the desired measurement of power level.

7.2.2.1.2.3.1.9 RPS - IEEE 279 (1971), Paragraph 4.9 - Capability for Sensor Checks

During reactor operation, the analog outputs of each of the four redundant transmitters for the following RPS trip variables may be directly cross-compared to meet this requirement:

a. Reactor vessel low water level trip

b. Drywell high pressure trip

c. Reactor vessel high pressure trip

During reactor operation, one transmitter of each of these variables may also be valved out of service at a time to perform calibration. During this test, operation of the sensor and the RPS trip unit and relay may be confirmed. At the conclusion of the test, administrative control must be used to ensure that the sensor has been properly returned to service.

In addition, the trip unit associated with these variables may be tested by injecting an electronic calibration signal into the trip unit input.

During reactor operation, the sensors associated with the SDV high water level trip may be valved out of service to perform a functional test. During the test, one RPS trip logic is tripped and produces both control room annunciation and computer logging of the trip. At the conclusion of the test, administrative control is used to ensure that the sensors have been returned to service.

The MSIV position switches are tested during valve movements that cause the limit switches to operate at the setpoint value of the valve position.

The eight MSIV isolation channels are combined into the four RPS logics as follows:

a. A1 (tripped) = inboard or outboard valve partially closed in main steam line A, and inboard or outboard valve partially closed in main steam line B

b. A2 (tripped) = inboard or outboard valve partially closed in main steam line C, and inboard or outboard valve partially closed in main steam line D

c. B1 (tripped) = inboard or outboard valve partially closed in main steam line A, and inboard or outboard valve partially closed in main steam line C

d. B2 (tripped) = inboard or outboard valve partially closed in main steam line B, and inboard or outboard valve partially closed in main steam line D

For any test of a single valve closure, two of the eight instrument channels are placed in a tripped condition, but none of the channel logics is tripped, and no RPS annunciation or NSSS computer logging occurs. This arrangement permits single valve testing without corresponding tripping of the RPS. At full power operation the main steam line closure logic test switch for one main steam line may be opened, and the other MSIV may be closed to produce a channel trip with annunciation and computer output.

At reduced power levels, two valves may be tested in sequence to produce RPS trips, annunciation of the trips, and computer printout of the trip channel identification. For example, closure of one valve in main steam line A and another valve in main steam line B produces an A1 logic trip and does not produce trips in A2, B1, or B2 channel logic circuits. These observations are another important test result that confirms proper RPS operation.

In sequence, each possible combination of single valve closure and switch operation is performed to confirm proper operation of all eight instrument channels.

The turbine stop valve position switches are also tested during valve movements that cause the limit switches to operate at the setpoint value.

The eight turbine stop valve isolation channels are combined into the four RPS logics as follows:

a. A1 (tripped) = turbine stop valve 3 partially closed, and turbine stop valve 4 partially closed

b. A2 (tripped) = turbine stop valve 1 partially closed, and turbine stop valve 2 partially closed

c. B1 (tripped) = turbine stop valve 1 partially closed, and turbine stop valve 3 partially closed

d. B2 (tripped) = turbine stop valve 2 partially closed, and turbine stop valve 4 partially closed

For any test of a single stop valve closure, two of the eight instrument channels are placed in a tripped condition, but none of the RPS trip logics is tripped, and no RPS annunciation or NSSS computer logging occurs. This arrangement permits single valve testing without corresponding tripping of the RPS, and the observation that no RPS trips result is a valid and necessary test

result. At full power, the stop valve logic test switch can be activated and the other stop valve in the same logic can be closed, causing a logic trip with annunciation and computer logging.

At reduced power levels, but greater than 29.5% of rated power, two valves may be tested in sequence to produce RPS trips, annunciation of the trips, and computer printout of the trip channel identification. These observations are another important test result that confirms proper RPS operation.

In sequence, each possible combination of single valve closure and test switch operation is performed to confirm proper operation of all eight instrument channels.

The turbine control valve fast closure EHC oil pressure sensors may be tested during the routine turbine system tests. During any control valve fast closure test, one RPS trip logic is tripped and produces both control room annunciation and computer logging of the trip.

The four RPS instrument logics are arranged as follows, assuming initial operation above 29.5% of rated power:

a. A1 (tripped) = pressure switch A loss of oil pressure

b. A2 (tripped) = pressure switch B loss of oil pressure

c. B1 (tripped) = pressure switch C loss of oil pressure

d. B2 (tripped) = pressure switch D loss of oil pressure

During reactor operation in the run mode, the IRM detectors are stored below the reactor core in a low flux region. Movement of the detectors into the core permits the operator to observe the instrument response from the different IRM channels and confirms that the instrumentation is operable.

Each APRM instrument channel may also be calibrated with a simulated signal introduced into the amplifier input, and each IRM instrument channel may be calibrated by introducing an external signal source into the amplifier input.

During these tests, proper instrument response may be confirmed by observation of instrument lights in the control room and trip annunciators.

Proper operation of the mode switch may be verified by the operator during plant operation by performing certain sensor tests to confirm proper RPS operation. Movement of the mode switch from one position to another is not required for these tests, since the connection of appropriate sensors to the RPS logic as well as the bypass of inappropriate sensors may be confirmed from the sensor tests.

7.2.2.1.2.3.1.10 RPS - IEEE 279 (1971), Paragraph 4.10 - Capability for Testing and Calibration

The following RPS trip variable sensors may be tested by cross-comparison of channels. They also have provisions for sensor test and calibration during reactor operation in compliance with this design requirement. See Section 7.1.3.

a. Reactor vessel low water level trip

b. Neutron monitoring (APRM) system trip (including OPRM trip)

c. Neutron monitoring (IRM) system trip

d. Drywell high pressure trip

e. Reactor vessel high pressure trip.

A test of individual SDV water level switches can be performed during full power operation by valving out the sensor and injecting water into a test tap. At plant shutdown, the level switches may be calibrated by introducing a fixed volume of water into the discharge volume and observing that all level switches operate at the specified capacity.

During plant operation the operator can set the turbine stop valve or main steam line closure logic test switch in a test position and actuate the other valve, which results in a logic trip, with annunciation and computer logging. The operator can confirm that the MSIV and turbine stop valve limit switches operate during valve motion, from fully open to fully closed and vice-versa, by comparing the time that the RPS channel trip occurs with the time that the valve position indicator lights in the control room signal that the valve is fully open and fully closed. This test does not confirm the exact setpoint but does provide the operator with an indication that the limit switch operates between the limiting positions of the valve. During reactor shutdown, calibration of the MSIV and turbine stop valve limit switch setpoint is possible by physical observation of the valve stem.

During reactor operation, the operability of the individual EHC oil line pressure sensors associated with turbine control valve fast closure is confirmed during each test of the turbine control valve closure. Calibration of the sensor may be accomplished by valving one sensor out-of-service at a time and introducing a test pressure input during shutdown.

The APRMs are calibrated to reactor power by using a reactor heat balance and the TIP system to establish the relative local flux profile. LPRM gain settings are determined from the local flux profiles measured by the TIP system once the total reactor heat balance has been determined.

The gain adjustment factors for the LPRMs are produced as a result of the process computer nuclear calculations involving the reactor heat balance and the TIP flux distributions. These adjustments, when incorporated into the LPRMs, permit the nuclear calculations to be completed for the next operating interval and establish the APRM calibration relative to reactor power.

During reactor operation, one manual scram push button may be depressed to test the proper operation of the switch and trip logic relay. Once the RPS has been reset, the other switches may be depressed to test their operation one at a time. For each such operation, a control room annunciation is initiated and the process computer logs the trip.

Operation of the reactor mode switch from one position to another may be employed to confirm certain aspects of the RPS trip channels during periodic test and calibration at shutdown only. During tests of the trip channels, proper operation of the mode switch contacts may be easily verified by noting that certain sensors are connected into the RPS logic and that other sensors are bypassed in the RPS logic in an appropriate manner dependent on the position of the mode switch.

In the startup and run modes of plant operation, tests confirm that SDV high water level trip channels cannot be bypassed as a result of the operating bypass switches. In the shutdown and refuel modes of plant operation, tests may be used to bypass all four scram discharge volume trip channels. Because of the discrete on-off nature of the bypass function, calibration is not meaningful.

Administrative control must be exercised to valve one turbine first-stage pressure sensor out-of-service for the periodic test. During this test, a variable pressure source may be introduced to operate the sensor at the setpoint value. When the condition for bypass has been achieved on an individual sensor under test, the control room annunciator for this bypass function is initiated. If the RPS trip channel associated with this sensor has been in its tripped state, the process computer logs the return-to-normal state for the RPS trip logic. When the plant is operating above the switch setpoint, testing of the turbine stop valve and control valve fast closure trip channels confirms that the bypass function is not in effect.

Operation of the three-position RPS reset switch following a trip of one RPS trip system confirms that the switch is performing its intended function. Operation of the reset switch following trip of both RPS trip systems confirms that all portions of the switch and relay logic are functioning properly, since half of the scram contactors are returned to a normal state for each actuation of the switch.

The manual scram switches permit each trip logic, scram contactor, and scram contactor logic to be tested on a periodic basis. Testing of each process sensor of the protection system affords an opportunity to verify proper operation of these components. Calibration of the time response of the trip channel relays and trip logics may be accomplished by the connection of external test equipment.

7.2.2.1.2.3.1.11 RPS - IEEE 279 (1971), Paragraph 4.11 - Channel Bypass or Removal from Operation

The following RPS trip variables have no provision for sensor removal from service because of the use of valve position limit switches as the channel sensor:

a. MSIV closure trip

b. Turbine stop valve closure trip

During periodic testing of any one of the following trip channels, a sensor may be valved out of service and returned to service under administrative control procedures. Since only one sensor is valved out-of-service at any given time during the test interval, protective capability for the following RPS trip variables is maintained through the remaining redundant instrument channels:

a. SDV high water level trip

b. Turbine control valve fast closure trip

c. Reactor vessel low water level trip

d. Drywell high pressure trip

e. Reactor vessel high pressure trip

A sufficient number of IRM channels are provided to permit any one IRM channel in a given trip system to be manually bypassed and still ensure that the remaining operable IRM channels comply with the IEEE 279 single failure design requirements.

One IRM manual bypass switch is provided for each RPS trip system. The mechanical characteristics of this switch permit only one of the four IRM channels of that trip system to be bypassed at any time. To accommodate a single failure of this bypass switch, electrical interlocks are incorporated into the bypass logic to prevent the bypassing of more than one IRM in that trip system at any time. Consequently, with any IRM bypassed in a given trip system, three IRM channels remain in operation to satisfy the protection system requirements.

One manual APRM bypass switch is provided for all four APRM channels. This is a mechanical/optical switch which allows only one APRM channel to be bypassed at any time. This interlock is accomplished independently in each of the APRM 2-out-of-4 voter channels. With any one APRM channel bypassed, the three remaining operating channels provide the necessary protection of the reactor.

None of the APRM 2-out-of-4 voter channels may be bypassed.

7.2.2.1.2.3.1.12 RPS - IEEE 279 (1971), Paragraph 4.12 - Operating Bypasses

The following RPS trip variables have no provision for an operating bypass:

a. Reactor vessel low water level trip

b. Left blank intentionally.

c. Neutron monitoring (APRM) system trip

d. Drywell high pressure trip

e. Reactor vessel high pressure trip

An operating bypass of the SDV high water level trip is provided in the control room for the operator to use to bypass the trip outputs in the shutdown and refuel modes of operation. Control of this bypass is achieved through administrative means, and its only purpose is to permit reset of the RPS following reactor scram. The bypass is manually initiated and must be manually removed to commence withdrawal of control rods after a reactor shutdown.

An operating bypass is provided for the MSIV closure trip. The bypass requires that the reactor system mode switch, which is under the administrative control of the operator, be placed in the shutdown, refuel, or startup positions. The only purpose of this bypass is to permit the RPS to be placed in its normal energized state for operation at low power levels with the MSIVs closed or not fully open.

The operating bypasses of the NMS are controlled by the reactor mode switch located on the control room reactor control bench board. When the reactor mode switch is in the RUN mode, the IRM trips are bypassed; protection is provided by the APRM and OPRM trips. When the reactor mode switch is not in the RUN mode, the IRM and APRM flux trips are active, but the OPRM trip is bypassed. As reactor power is increased and the APRM system reaches

its operating range, by procedure the IRM detectors are withdrawn from the reactor core. When reactor power is decreased to the IRM operating range, by procedure the IRM detectors are inserted into the reactor core.

For each of these operating bypasses, four independent bypass channels are provided through the mode switch to ensure that all of the protection system criteria are satisfied.

An operating bypass of the turbine stop valve and control valve fast closure trip is provided whenever the turbine is operating at a low initial power level. The purpose of the bypass is to permit the RPS to be placed in its normal energized state for operation at low power levels with the turbine stop valves not fully open.

During normal plant operation above the switch setpoint, the bypass is automatically removed. Under these conditions, removal of the bypass for periodic testing is permitted, since it has no effect on plant safety. Under plant conditions below the switch setpoint, one bypass channel may be removed from service at a time without initiating protective action or affecting plant safety. This removal from service is accomplished under administrative control of plant personnel.

7.2.2.1.2.3.1.13 RPS - IEEE 279 (1971), Paragraph 4.13 - Indication of Bypasses

The mode switch produces operating bypasses that need not be annunciated, because they are numbered by manual reactor operating sequence.

The control room operator must exercise administrative control over the valving out-of-service of one RPS trip variable sensor at a time. The out-of-service condition is manually alarmed as described in Section 7.2.2.1.2.1.7. Once a sensor is removed from service and a simulated test signal is introduced in excess of the setpoint, a control room annunciator indicates the tripped condition, and the process computer provides a typed record of the channel identification. The trip unit in calibration also causes actuation of the system out-of-service annunciator.

When any IRM or APRM instrument channel output to the RPS is bypassed, this fact is indicated by lights for each channel located on the control room panels.

Operating bypasses are annunciated in the control room. The SDV high water level trip operating bypass, the MSIV closure trip operating bypass, and the turbine stop valve closure and control valve fast closure trips operating bypass are individually annunciated to the operator.

When the conditions for any single bypass channel are satisfied, the control room operator is notified by an annunciator for the particular set of bypass conditions. Bypassing is not allowed in the trip logic or scram contactor logic.

7.2.2.1.2.3.1.14 RPS - IEEE 279 (1971), Paragraph 4.14 - Access to Means for Bypassing

All instrumentation valves associated with the periodic testing of individual RPS trip variable sensors are under administrative control.

During periodic testing, administrative control procedures must be followed to remove one main steam line high radiation monitor from service and subsequently return it to service.

Manual bypassing of any IRM or APRM channel is accomplished with control room selector switches under the administrative control of the operator.

Manual controls for the SDV high water level trip operating bypass and the MSIV closure trip operating bypass are located in the control room and are under the direct administrative control of the operator. Manual key-lock switches are used to control these operating bypasses.

The mode switch is a key-lock switch under the administrative control of plant personnel. Since other controls must be operated or other sensors must be in an appropriate state to complete the operating bypass logic, the mode switch itself satisfies this requirement.

Under normal operating conditions, all four channels of the turbine stop valve closure trip and control valve fast closure trip operating bypass are in operation and are automatically removed from service as reactor power is increased above the switch setpoint and are automatically reinstated as reactor power is reduced below this same setpoint. During periodic testing of each bypass channel, one sensor is removed from service under administrative control.

7.2.2.1.2.3.1.15 RPS - IEEE 279 (1971), Paragraph 4.15 - Multiple Setpoints

The design requirement is not applicable to the following RPS trip variables, because the setpoint values are fixed and do not vary with other reactor or plant parameters:

a. SDV high water level trip

b. MSIV closure trip

c. Turbine stop valve closure trip

d. Turbine control valve fast closure trip

e. Reactor vessel low water level trip

f. Left blank intentionally.

g. Neutron monitoring neutron flux and OPRM trips

h. Drywell high pressure trip

i. Reactor vessel high pressure trip

The trip setpoint of each IRM channel is established at a fixed percentage of full-scale for each range of IRM operation. The IRM is a linear, half decade per range instrument. Therefore, as the operator switches an IRM from one range to the next, the trip setpoint tracks the operator's selection. In the startup mode the APRM Neutron Flux - Upscale trip setpoint is reduced to 15% of Rated Thermal Power.

In the run mode, the APRM Simulated Thermal Power - Upscale trip varies automatically with recirculation flow. For further discussion, see Section 7.6.1.4.

Each of these multiple setpoint provisions is a portion of the RPS and complies with the design requirements of IEEE 279.

Operation of the mode switch from one position to another bypasses various RPS trip channels in accordance with the reactor conditions implied by the given position of the mode switch. This action does not influence the established setpoint of any given RPS trip channel, but merely connects one set of channels as another set is disconnected. Consequently, the mode switch meets this design requirement.

7.2.2.1.2.3.1.16 RPS - IEEE 279 (1971), Paragraph 4.16 - Completion of Protective Action Once It Is Initiated

It is only necessary that the instrument channel remain in a tripped condition for a sufficient length of time to de-energize the scram contactors and open their seal-in contacts.

Once the manual scram push buttons are depressed, it is only necessary to maintain them in that condition until the scram contactors have de-energized and opened their seal-in contacts.

The function of the mode switch is to provide appropriate RPS trip channels for the RPS trip logic on a steady-state basis for each of four given reactor operating states: shutdown, refuel, startup, and run. Protective action, in terms of the needed transient response, is derived from the other portions of the trip channels independent of the mode switch. Hence, the mode switch does not influence the completion of protective action in any manner.

The turbine operating bypass is put into effect only when the turbine first-stage pressure is at or below a preset level. For plant operation above this setpoint, the trip channels initiate protective action once the scram contactors have de-energized and opened the seal-in contact.

The interface of the RPS trip logic and the scram contactors ensures that this design requirement is accomplished. The trip logic is normally energized and is sealed in by one of the contacts of the scram contactor. Once the trip logic has been open-circuited as a result of a process sensor trip channel becoming tripped or the depression of a manual scram push button, the scram contactor seal-in contact opens, and completion of protective action is directed without regard to the state of the initiating process sensor trip channel.

Reset of the RPS logic is permissible only after a 10 second time delay and requires deliberate operator action.

7.2.2.1.2.3.1.17 RPS - IEEE 279 (1971), Paragraph 4.17 - Manual Initiation

Four manual scram push button controls are provided on one control room panel to permit manual initiation of reactor scram at the system level. Failure of an automatic RPS function cannot prevent the manual portions of the system from initiating the protective action. The manual scram push buttons are wired as close as is practicable to the scram contactor coil circuits to minimize the dependence of manual scram capability on other equipment.

Additional backup to these manual controls is provided by the shutdown position of the reactor system mode switch.

No single failure in the manual or automatic portions of the system can prevent either a manual or automatic scram.

7.2.2.1.2.3.1.18 RPS - IEEE 279 (1971), Paragraph 4.18 - Access to Setpoint Adjustments, Calibration, and Test Points

During reactor operation, access to setpoint or calibration control is not possible for the SDV high water level trip. (The instrument is accessible, but the setpoint is not adjustable).

Access to setpoint adjustments, calibration controls, and test points for the following RPS trip variables is under the administrative control of plant personnel:

a. Main steam line isolation valve closure trip (accessible with radiation exposure)

b. Turbine stop valve closure trip (accessible with radiation exposure)

c. Turbine control valve fast closure trip (accessible with radiation exposure)

d. Turbine stop valve closure and turbine control valve fast closure trip bypass (accessible with radiation exposure)

e. Reactor vessel low water level trip

f. Left blank intentionally.

g. Neutron monitoring (APRM) system trip (including OPRM trip)

h. Neutron monitoring (IRM) system trip

i. Drywell high pressure trip

j. Reactor vessel high pressure trip

7.2.2.1.2.3.1.19 RPS - IEEE 279 (1971), Paragraph 4.19 - Identification of Protective Actions

When any one of the redundant sensors exceeds its setpoint value for the following RPS trip variables, a control room annunciator is initiated to identify the particular variable:

a. SDV high water level trip

b. Turbine control valve fast closure trip

c. Reactor vessel low water level trip

d. Left blank intentionally.

e. Neutron monitoring (APRM) system trip (including OPRM trip)

f. Neutron monitoring (IRM) system trip

g. Drywell high pressure trip

h. Reactor vessel high pressure trip

Identification of the particular trip channel exceeding its setpoint is accomplished as a typed record from the process computer or visual observation of the annunciators.
