Recombination of radiolysis gases in the air ejector offgas system forms water, which is condensed and returned to the main condenser. This tends to reduce the amount of tritium leaving in gaseous effluents. Reducing the gaseous tritium release results in a slightly higher tritium concentration in

the plant process water. Reducing the amount of liquid effluent discharged also results in a higher process coolant equilibrium tritium concentration.

Essentially, all tritium in the primary coolant is eventually released to the environs, either as water vapor and gas to the atmosphere, as liquid effluent to the plant discharge, or as solid waste. Reduction due to radioactive decay is negligible due to the 12 year half-life of tritium.

The U.S. Public Health Service study at Dresden 1 estimated that approximately 90% of the tritium release was observed in liquid effluent, with the remaining 10% leaving as gaseous effluent (Reference 11.1-5). Efforts to reduce the volume of liquid effluent discharges may change this distribution so that a greater amount of tritium will leave as gaseous effluent. From a practical standpoint, the fraction of tritium leaving as liquid effluent may vary between 60% and 90%, with the remainder leaving in gaseous effluent.

11.1.4 FUEL FISSION PRODUCTION INVENTORY AND FUEL EXPERIENCE

11.1.4.1 Fuel Fission Product Inventory

Fuel fission product inventory information is used in establishing fission product source terms for accident analysis and is, therefore, discussed in Chapter 15.

11.1.4.2 Fuel Experience

A discussion of BWR fuel experience including fuel failure experience, burnup experience, and thermal conditions under which the experience was gained is presented in References 11.1-6, 11.1-7 and 11.1-8.

11.1.5 PROCESS LEAKAGE SOURCES

Process leakage results in potential release paths for noble gases and other volatile fission products via ventilation systems. Liquid from process leaks is collected and routed to the liquid waste management system. Radioactive releases from the liquid waste management system are discussed in Section 11.2. Radionuclide releases via ventilation paths are at extremely low levels and have been insignificant compared to process offgas from operating BWR plants. However, because the implementation of improved process offgas treatment systems make the ventilation release relatively significant, GE has conducted measurements to identify and qualify these low level release paths. GE maintains an awareness of other measurements by the EPRI and other organizations, and routine measurements by utilities with operating BWRs.

Leakage of fluids from the process system results in the release of radionuclides into plant structures. In general, the noble radiogases remain airborne and are released to the atmosphere with little delay via the structure's ventilation exhaust ducts. The radionuclides are partitioned between air and water, and airborne radioiodines may plateout on metal surfaces, concrete, and paint. A significant amount of radioiodine remains in air or is desorbed from surfaces. Radioiodines are found in ventilation air as methyl iodide and as inorganic iodine, which is here defined as particulate, elemental, and hypoiodous acid forms of iodine. Particulates are also in the ventilation exhaust air.

Experience with airborne radiological releases from the BWR enclosure HVAC and the main condenser mechanical vacuum pump have been compiled and evaluated in NEDO-21159 (Reference 11.1-9). This report is periodically updated to incorporate the most recent data on

airborne emission. The results of these evaluations are based on data obtained by utility personnel and special in-plant studies of operating BWR plants by independent organizations and GE. An evaluation of the radioactive releases from ventilation systems for compliance with 10CFR50, Appendix I is given in Section 11.3. An evaluation of exposures due to airborne radioactivity is given in Section 12.2.2.

11.2 LIQUID WASTE MANAGEMENT SYSTEM

The liquid waste management system is designed to process and dispose of, or recycle all of the radioactive, or potentially radioactive liquid wastes generated in the operation of the plant. The liquid waste management system consists of equipment drain (low conductivity), floor drain (high conductivity), chemical waste, and laundry drain subsystems. These subsystems are shown on drawings M-62, M-63 and M-64. Equipment locations are shown on drawings provided in Section 1.2.

The plant drainage system, a major input source to the liquid waste management system, is described in Section 9.3.3. The equipment and floor drainage collection system is shown in drawing M-61. Sufficient treatment is available to process all waste water to condensate storage water quality or to preset quality limits acceptable for release to the environment. The liquid waste management system has no safety-related function.

11.2.1 DESIGN BASES

a. The system has the capability to process the maximum anticipated quantities of liquid wastes without impairing the operation or availability of the plant during both normal and expected occurrence conditions, to satisfy the requirements of 10CFR20 and 10CFR50.

b. Alternate process routes, subsystem cross-ties, and adequate volumes are designed into the system to provide for operational and anticipated surge waste volumes which could occur during refueling, abnormal leakage, decontamination activities, and equipment maintenance.

c. The system is designed so that no potentially radioactive liquids can be discharged to the environment unless they have been processed, monitored, and mixed with cooling tower blowdown. This results in an offsite release and radiation exposures to individuals and the general population (on an annual average basis) within the limits of 10CFR20 and 10CFR50.

d. The liquid waste management system design meets the requirements of GDC 60 and GDC 61.

e. The liquid waste management system is designed to keep the exposure to plant personnel as low as reasonably achievable (ALARA) during normal operation and plant maintenance, in accordance with Regulatory Guide 8.8.

f. The expected radionuclide activity concentrations in the liquid waste management process equipment are based on 60,000 μCi/sec noble gas release rate for one reactor unit after a 30 minute delay. The maximum expected radionuclide activity concentrations in the liquid waste management process equipment are based on 350,000 μCi/sec noble gas release rate for one reactor unit after a 30 minute delay.

g. All piping and equipment in the liquid waste management system are designed to seismic Category II requirements. The seismic category, quality group classification, and corresponding codes and standards that apply to the design of the liquid waste management system are discussed in Section 3.2.

h. Design features provided to reduce maintenance, equipment downtime, liquid leakage, or gaseous releases of radioactive materials to the enclosure atmosphere, to facilitate cleaning, or otherwise improve radwaste operations are discussed in Section 12.3.

i. All atmospheric liquid radwaste tanks are provided with an overflow connection adequately sized to accommodate expected tank inlet flow conditions. The overflow is connected below the tank vent and at least one inch above the high level, alarm trip point. Overflow liquid is routed to a redundant tank or to the nearest atmospheric drainage point, as shown in drawings M-62, M-63 and M-64.

j. Processed wastes are collected in sample tanks prior to their reuse in the condensate transfer system or are discharged in a controlled manner through the monitored discharge pipe into the cooling tower blowdown pipe for dilution, before entering the Schuylkill River.

k. The expected and maximum radionuclide activity inventories of liquid waste management system components containing significant amounts of radioactive liquids are shown in Tables 11.2-8 and 11.2-9, and are based upon the assumptions given in Table 11.2-1 and those listed below:

    1. Expected flow rates for streams (Figure 11.2-4) are given in Table 11.2-2.

    2. Reactor water radionuclide activity concentrations are as listed in Tables 11.1-1 through 11.1-5 for design conditions, and Table 11.2-3 for expected conditions.

    3. Decontamination factors within the liquid waste management system are as given in Table 11.2-4.

    4. While a process stream is collecting in a collection tank, the isotopes already in the tank are undergoing radioactive decay (see Table 11.2-5 for expected holdup times).

    5. One refueling shutdown per year per unit, not occurring simultaneously is assumed.

The expected daily inputs and activities for each of the subsystems is shown in Tables 11.2-6 and 11.2-7. An evaluation of the causes for the maximum expected inputs for each subsystem shows that operational modes exclude, and the unlikely occurrence of the same failure in both units minimizes, the potential for coincidental maximum input from both units into the same subsystem.

Control and monitoring of radioactive release in accordance with GDC 60 and GDC 64 is discussed in Sections 11.2.3 and 11.5.

11.2.2 SYSTEM DESCRIPTION

The liquid waste management system collects, monitors, processes, stores, and disposes of radioactive liquid wastes. The liquid waste management system piping, equipment, instrumentation, and flow paths are shown in drawings M-62, M-63 and M-64. Included

in the system are:

a. Piping and equipment carrying potentially radioactive wastes

b. Floor drain systems in controlled access areas which may contain potentially radioactive wastes

c. Tanks and sumps used to collect potentially radioactive wastes

The liquid wastes are collected in sumps located in all the enclosures housing radioactive equipment and are pumped to collection tanks located in the radwaste enclosure. Plant drainage systems, including measures taken to limit, control, and remove oil and other organic compounds, are discussed in Section 9.3.3.

The incoming wastes are classified, collected, and treated as floor drain, equipment drain, chemical, and laundry drain wastes.

Connections for tie-ins are provided, so that temporary equipment can draw suction from either the equipment drain surge tank (00T304) or floor drain surge tank (00T309) in order to process liquid radwaste when high demand is placed on the existing liquid radwaste processing equipment. After processing through the temporary equipment, the effluent stream will be recirculated back to either the equipment drain/floor drain surge tanks or routed to the equipment drain/floor drain sample tanks.

Equipment is selected, arranged, and shielded to minimize exposures to plant personnel during operation, inspection and maintenance. For example, sumps, pumps, valves, and instruments which may contain radioactivity are located in controlled access areas. Tanks and processing equipment that may contain significant quantities of radioactive material are shielded. Operation of the liquid waste management system is normally on a batch basis, as dictated by the waste generation rate from the plant. Protection against accidental discharge is provided by instrumentation for detection and alarm of abnormal conditions and by procedural controls.

The liquid waste management system is divided into several subsystems (Section 11.2.2.1), so that the liquid wastes from various sources can be kept segregated and processed separately. Cross-connections between the subsystems provide additional flexibility for processing of the wastes by alternate methods.

11.2.2.1 System Operation

The liquid waste management system consists of four process subsystems:

a. Equipment drain subsystem

b. Floor drain subsystem

c. Chemical waste subsystem

d. Laundry drain subsystem

11.2.2.1.1 Equipment Drain Subsystem

Low conductivity wastes from piping and equipment drains are collected in the equipment drain collection tank and/or the equipment drain surge tank. Other inputs received in the collection tank are listed in Table 11.2-7. Wastes collected in the equipment drain collection or surge tanks are processed on a batch basis through a precoat filter and mixed bed demineralizer and are then collected in one of two sample tanks.

From an equipment drain sample tank, wastes are normally returned to a CST for plant reuse. A recycle routing allows water which exceeds preset quality limits to be: recycled to the equipment drain collection tank for additional processing through the filter and demineralizer or recycled to the floor drain collection tank for additional processing. If the water inventory of the plant does not permit wastes to be returned to the CST, or if the wastes are unacceptable for plant reuse, then the wastes are routed to the floor drain subsystem and discharged from the plant after mixing with cooling tower blowdown.

11.2.2.1.2 Floor Drain Subsystem

Wastes originating mainly from the drywell, reactor, turbine, radwaste, and offgas enclosure floor drains are collected in the floor drain collection tank. In addition, high conductivity piping and equipment drains are also collected and treated with these wastes.

The wastes collected in the floor drain collection tank are processed through a precoat filter and, on an as needed basis, through the mixed bed demineralizer, bypassing floor drain sample tank No. 1, and discharged to floor drain sample tank No. 2 for final sampling and analysis. Provision is available to discharge directly to sample tank No. 1 for use when warranted. The basis for selecting the treatment path consists of water quality, equipment availability, and economic considerations. If the quality of the filtered waste in the sample tank No. 2 is unsuitable for plant reuse, then the flexibility exists to reprocess the batch through the floor drain system and floor drain demineralizer or to recycle it to the equipment drain collection tank.

Treated floor drain wastes are routinely discharged from the plant after mixing with cooling tower blowdown. If the treated wastes meet the specifications of water quality used in the plant (including reactor water chemistry parameters), and if the water inventory of the plant permits their recycle, then they may be returned to the CST for reuse.

11.2.2.1.3 Chemical Waste Subsystem

Chemical wastes collected in the chemical waste tank consist of laboratory wastes, decontamination solutions and other corrosive wastes. After being accumulated in the chemical waste tank, these wastes are chemically neutralized, if required, and transferred to the floor drain collection tank or floor drain surge tank for batch processing through the floor drain subsystem. The chemical waste subsystem is designed to permit addition of an evaporation system as an alternate means of waste processing. However, installation of this equipment was not completed for initial plant operation and the equipment has been abandoned.

11.2.2.1.4 Laundry Drain Subsystem

Laundry wastes consist of detergent-containing water from personnel decontamination facilities in the plant. These wastes are routed to two laundry drain tanks interconnected by an overflow line. In addition, rain water from within the yard dikes for Condensate Storage Tank (CST) tanks (Units 1 & 2) and Refueling Water Storage Tank may be routed to the two laundry drain tanks. From the tank, the wastes are processed through the laundry drain filter and collected in the sample tank for sampling and analysis.

Effluent from the sample tank is normally discharged through the monitored discharge pipe into the cooling tower blowdown pipe. High conductivity filtrate can be recycled to the laundry drain tanks or to the floor drain system.

The laundry drain system is no longer in service to process and discharge liquid waste. However, a valve remains open to a laundry drain tank for inputs from personnel decontamination facilities.

11.2.2.2 Process Equipment Description

Major components of the liquid waste management system are described below. A summary of the design parameters for major components is provided in Table 11.2-10.

11.2.2.2.1 Pumps

a. Sump Pumps

Liquid waste management system sump pumps are vertical, centrifugal-type pumps of standard design, cast iron construction. The top column closures on the pump support plates utilize vapor-tight gland-type seals. Each sump is provided with two pumps except the offgas enclosure floor drain sump which utilizes one pump.

Sump pumps start automatically when a predetermined high level in the sump is reached; the sump pump stops at a predetermined low water level.

b. Process Pumps

Liquid waste management system process pumps are vertical, in-line centrifugal pumps of ASME Section III, Class 3 design, stainless steel or carbon steel construction, and are provided with a mechanical-type seal.

11.2.2.2.2 Tanks

Tanks are sized to accommodate the anticipated volumes generated from the four liquid waste management subsystems. The tanks are constructed of carbon steel, stainless steel, or aluminum.

The tanks are provided with a mixing eductor and vented to the radwaste enclosure ventilation system. Refer to Section 9.4.3 for a discussion of the radwaste enclosure ventilation system.

11.2.2.2.3 Filters

a. Equipment and Floor Drain Filters

Equipment and floor drain filters are a precoat, removable, single element bundle-type design, using a powdered ion exchange resin or other filter media. Both filters are equipped with a common precoating tank and pump, and individual filter holding pumps.

Filter media lifetime is based on a pressure drop across the filter and not specific radioactive content. Both filters are backwashed to the waste sludge tank. The filter vessels are constructed of carbon steel and are designed to meet the

requirements of ASME Section III, Class 3. A corrosion-resistant lining is provided to minimize corrosion of the carbon steel vessels.

Each filter is located in a separate shielded room to minimize exposures to personnel during routine maintenance. Use of condensate water for backwashing and design of the filter internals ensure a minimum accumulation of radioactive material in the filters.

b. Laundry Drain Filter

The laundry drain filter is of a removable cartridge- type design. The filter vessel is constructed of stainless steel and designed to meet the requirements of ASME Section III, Class 3. Filter construction also permits "quick change" replacement of disposable cartridges to minimize personnel exposure to radiation.

11.2.2.2.4 Demineralizers

The equipment and floor drain demineralizers are deep-bed, mixed cation and anion-type, with flow rate capacities consistent with their associated filters.

A resin bed is replaced when effluent quality exceeds preset limits, as well as on high differential pressure.

The demineralizer vessels are constructed of carbon steel and are designed to meet the requirements of ASME Section III, Class 3. The vessels are equipped with a rubber lining. Fine mesh strainers are provided in the vessel discharge and in the piping downstream to prevent resin fines from being transferred to other portions of the system.

Both demineralizers were designed to be backwashed to their respective spent resin tanks. However, for normal plant operation, the demineralizers will be backwashed directly to the waste sludge tank via a bypass line (Section 11.4.2.1.1). New mixed dry resins are added to the demineralizer through a resin addition funnel and flow by gravity into the demineralizer to provide an even distribution. If desired, the capability exists for mixing the resin bed inside the vessel with air. Resins can also be supplied from the Deep Bed Condensate Demineralizer (DBCD) system. These resins are hydropneumatically transferred into the radwaste demineralizers (Section 10.4.6.2).

Each vessel is located in a separate shielded room to minimize exposures to personnel during routine maintenance of other equipment.

11.2.2.2.5 Radwaste Evaporators

Radwaste evaporators were not made operational for initial plant operation and have been abandoned (Section 11.2.2.1.3).

11.2.2.2.6 Piping

Liquid waste management system piping is routed to minimize crud traps. Radioactive piping is located in shielded areas to minimize personnel exposures. The floor drain, equipment drain, and laundry drain subsystem piping is constructed of carbon steel. The chemical waste subsystem piping is constructed of stainless steel. Liquid waste management system piping is designed to meet the requirements of ANSI B31.1.

11.2.3 RADIOACTIVE RELEASES

During processing of liquid wastes, radioactivity is removed so that the bulk of the liquid is restored to clean water, which is either recycled in the plant or discharged to the environment. The radioactivity removed from the liquids is concentrated in filters and ion exchange resins. These concentrated wastes are sent to the solid waste management system for treatment and eventual shipment to a licensed burial ground. If the liquid is to be discharged, the activity concentration is consistent with the discharge criteria of 10CFR20. Normally, most of the liquid passing through the liquid waste management system is recycled in the plant. However, the treatment in this system is such that these liquids can be discharged from the plant after monitoring, if required by plant water balance considerations or if the treated wastes do not meet the specifications of water quality used in the plant (including reactor water chemistry parameters). Activity concentration of tritiated water discharged from the system is consistent with the discharge criteria of 10CFR20. Normally, the liquid passing through the laundry drain subsystem is discharged directly, in accordance with 10CFR20 and 10CFR50 guidelines; however, it may be processed through the floor drain subsystem if necessary.

The expected annual activity releases for each waste stream are given in Table 11.2-11.

Design and administrative controls are incorporated into the liquid waste management system to prevent inadvertent releases to the environment. Controls include administrative procedures, operator training, redundant discharge valves, and discharge radiation monitors that trip alarms and initiate automatic discharge valve closure (Section 11.5). Prior to any discharging, activity concentrations are measured in samples taken from the various sample tanks. A single line is provided for plant discharges to minimize the potential for operator error. This line includes a loop seal with a siphon breaker to prevent inadvertent siphoning of the sample tanks.

The processed liquid waste that is not recycled in the plant is discharged into the cooling tower blowdown pipe on a batch basis. Flow rate measurement devices are provided in both the radwaste effluent line and the cooling tower blowdown line as shown on drawings M-63 and M-09, respectively. Processed liquid wastes are discharged at up to 280 gpm from the equipment and floor drain subsystems, and 10 gpm from the laundry drain subsystem. The discharges are mixed with the cooling tower blowdown flow to maintain the concentration of radionuclides at the release point below the limits of 10CFR20 (UFSAR Table 11.2-12). This mixing occurs within the site boundary and is used in determining specific activity concentrations for the releases. Expected average annual radionuclide concentrations are compared to 10CFR20 limits in Table 11.2-12.

The doses resulting from liquid effluents are a small fraction of the 10CFR20 dose limit of 500 mR/yr and well within 10CFR50, Appendix I design objectives as shown in Table 11.2-13.

Table 11.2-1 (Cont'd)

ITEM	VALUE OR REFERENCE
2. Holdup times for collection, processing, and discharge	Table 11.2-5
3. Capacities of tanks and processing equipment	Table 11.2-10
4. Decontamination factors	Table 11.2-4
5. Liquid source terms for normal operation	Table 11.2-6
6. Quantity of tritium - released in liquid effluents (2 units)	11 Ci/yr
7. Average fraction of process streams discharged to environment after processing[1]	
(a) Floor drain subsystem	0.10
(b) Equipment drain subsystem	0.01
(c) Chemical drain subsystem	0.10
(d) Laundry drain subsystem	1.00
8. Liquid waste management system demineralizer resin replacement frequency	
(a) Floor drain	25.8 days
(b) Equipment drain	125.8 days
9. Liquid waste management system demineralizer backwash volume	
(a) Floor drain	1500 gal
(b) Equipment drain	1500 gal

(1) These values are taken from NUREG-0016 (April 1976), section 1.5.2.9.5.

Table 11.2-2

LIQUID WASTE MANAGEMENT SYSTEM FLOWS

STREAM NO.[1]	AVERAGE BATCH INTERVAL FOR NORMAL OPERATION OF BOTH UNITS (days)	VOLUME PER BATCH (gal)	NOMINAL FLOW RATE (gpm)	AVERAGE VOLUME PER DAY FOR NORMAL OPERATION OF BOTH UNITS (gal)	NORMAL ACTIVITY CONCENTRATION (μCi/cc)	MAXIMUM ACTIVITY CONCENTRATION (μCi/cc)
Floor Drain Subsystem						
1	-	-	-	10400	6.2×10^{-2}	1.1
2	1.6	16800	280	10400	1.1×10^{-2}	2.9×10^{-1}

(1) The values in this table are calculated based on the GALE code in NUREG-0016 (April 1976).

* The N-16 values listed in the table are without Hydrogen Water Chemistry (HWC). Values with HWC are 4.80E+01 (water) and 2.50E+02 (steam).

Table 11.2-4

DECONTAMINATION FACTORS USED FOR EVALUATION OF RADIOACTIVITY RELEASES[1]

EQUIPMENT	IODINE	CESIUM AND RUBIDIUM	OTHERS
Equipment drain filter/ demineralizer[2]	10	2	10
Equipment drain demineralizer	100	10	100
Floor drain filter/ demineralizer[2]	10	2	10
Floor drain demineralizer	100	2	100
RWCU filter/demineralizer	10	2	10
Condensate filter/demineralizer	10	2	10
Laundry drain cartridge filter	1	1	1

(1) The values are taken from NUREG-0016 (April 1976), table 1-3.

(2) Powdered resin is used to precoat the filter/demineralizer; decontamination factor value of Powdex is used.

Table 11.2-5

EXPECTED HOLDUP TIMES FOR COLLECTION, PROCESSING, AND DISCHARGE USED FOR EVALUATION OF RADIOACTIVITY RELEASES

PROCESS SUBDIVISION	HOLDUP TIME (days)
Floor Drain Subsystem	
Collection	1.616
Processing	0.042
Sampling	0.042
Total	1.700
Equipment Drain Subsystem	
Collection	0.519
Processing	0.050
Sampling	0.042
Total	0.611
Chemical Drain Subsystem(1)	
Collection	5.000
Processing	0.063
Sampling	0.042

(1) Estimated releases are based on NUREG-0016, Revision 0, GALE Code evaluation.

(2) Increased the calculated LWS release by 0.15 Ci/yr per reactor using the same isotopic distribution as the calculated LWS releases to account for anticipated operational occurrences that result in unplanned releases.

(3) Activity of daughter products resulting from radioactive decay of the influent isotopes during the accumulation period.

(1) Location: Liquid Discharge Outfall Area

(2) The concentration limits shown are reflective of the 10CFR20 Appendix B values prior to the 1994 revision of 10CFR20, and are consistent with those used in the original licensing of the plant. Current effluent release limits are based on the post-1994 10CFR20 regulation and are controlled by the Radioactive Effluent Controls Program defined by the Technical Specifications. New 10CFR20 limits went into effect on Jan. 5, 1994. As part of the power rerate evaluation, a comparison of the uprated liquid release concentration with the new 10CFR20 limits was made. All the uprated release concentrations were found to be less than 1% of their new limit.

Maximum organ	1.82 mRem/yr (bone)	20 mRem/yr	9.08%

11.3 GASEOUS WASTE MANAGEMENT SYSTEMS

The gaseous waste management systems include all systems that process potential sources of airborne releases of radioactive materials during normal operation and anticipated operational occurrences. Included are the offgas system and various ventilation systems. These reduce radioactive gaseous releases from the plant by filtration or delay, which allows decay of radioisotopes prior to release.

The function of the offgas system is to collect and delay release of noncondensable radioactive gases removed from the main condenser by the air ejectors during normal plant operation. Plant ventilation systems process airborne radioactive releases from other plant sources, such as equipment leakage, maintenance activities, the mechanical vacuum pump, and the steam seal system.

The offgas system is described in detail in this section. The ventilation systems are discussed briefly in this section and in greater detail in Section 9.4.

11.3.1 DESIGN BASES

a. The gaseous waste management systems are designed to control and monitor the release of radioactive materials in gaseous effluents in accordance with GDC 60 and GDC 64.

b. The offgas system design basis and maximum expected source terms correspond respectively to 100,000 μCi/sec and 60,000 μCi/sec of radioactive noble gases after 30 minute delay.

c. The gaseous waste systems are designed to limit offsite doses from routine station releases to significantly less than the limits specified in 10CFR20 and to operate within the dose objectives established in 10CFR50, Appendix I.

d. The gaseous waste management systems are designed with sufficient capacity and redundancy to accommodate all anticipated processing requirements of the plant during normal operation, including anticipated operational occurrences.

e. Continuous monitoring is provided for all potential pathways of airborne radioactive releases, with annunciation at levels lower than normal release limits.

f. Design provisions are incorporated which preclude the uncontrolled release of radioactivity to the environment as a result of any single operator error or any single active component failure.

g. The gaseous waste management system is designed to keep the exposure to plant personnel as low as reasonably achievable (ALARA) during normal operation and plant maintenance, in accordance with Regulatory Guide 8.8.

h. Design features are provided in the offgas system to control leakage and to facilitate operation and maintenance in accordance with the guidelines of Regulatory Guide 1.143.

i. The offgas system is designed in accordance with the guidelines of Regulatory Guide 1.143, with exception as discussed in Section 3.2.

j. Filtration units in the ventilation systems are designed, operated, and maintained in accordance with the guidelines of Regulatory Guide 1.140. with exceptions as discussed in Section 9.4.

k. The offgas system is designed to maintain the concentration of hydrogen in the gases exhausted from the main condenser below flammable limits.

l. Instrumentation is provided in the offgas system to detect abnormal concentrations of hydrogen and other system malfunctions.

m. The offgas system is designed to withstand the effects of a hydrogen explosion without breach of the pressure boundary.

11.3.2 SYSTEM DESCRIPTION

11.3.2.1 Offgas System

11.3.2.1.1 General

Noncondensable gases are continuously removed from the main condenser by the SJAE during plant operation. The offgas will consist of activation gases, fission product gases, radiolytic hydrogen and oxygen, and condenser air inleakage.

The offgas system is designed to reduce offgas radioactivity to permissible levels for release under all site atmospheric conditions.

The offgas system uses catalytic recombination for volume reduction and control of hydrogen concentration. Selective adsorption of fission product gases on charcoal is used to provide time for delay before release.

The location of the offgas system components is shown in general arrangement drawings in Section 1.2.

The seismic categories, quality group classifications, and corresponding codes and standards that apply to the design of the gaseous waste management system are discussed in Section 3.2.

11.3.2.1.2 Process Flow Description

Figure 11.3-1 is the process flow diagram for the offgas system and contains process design data for startup and normal operating conditions.

Drawings M-69 and M-70 are the piping and instrumentation diagrams for the offgas system.

During startup the mechanical vacuum pump is used to draw a vacuum in the main condenser as described in Section 10.4.2. Once condenser vacuum has been established by the mechanical vacuum pump and reactor steam is available, one of the two-stage SJAE trains are placed in service. As an alternative, during startup, shutdown and power operation, auxiliary steam can be used for SJAE operation when available.

The first-stage SJAEs continuously remove noncondensable gases and some steam from the condenser and discharge them to the SJAE condenser where the steam is condensed and returned to the main condenser. The gases are removed from the SJAE condenser by the second-stage ejector and discharged to the gaseous radwaste recombination system together with the second-stage ejector motive steam. This steam provides sufficient dilution to maintain hydrogen concentrations below combustible concentrations. A complete description of the SJAE is given in Section 10.4.2.

The offgas stream from the second-stage ejector is treated first in the recombiner portion of the offgas system. The purpose of the recombiner is to reduce the offgas volume and reduce the hydrogen concentration to less than 4% concentration by volume on a dry basis. The offgas first passes through the preheater in order to vaporize any water droplets and to achieve a sufficient temperature to start the catalytic reaction. Steam used for preheating is provided from the reactor feed pump-turbine steam supply line or from auxiliary steam when available. The recombination process takes place inside a recombiner vessel. The temperature of the gases leaving the recombiner rises as a function of the influent hydrogen concentration. This temperature rise is due to the heat of reaction of the recombination process. The reaction temperature rises approximately 120°F for each 1% of H_2 recombined. The catalyst is a metal mat-type. The elements are made of crimped high nickel alloy ribbons coated with platinum/palladium. Each recombiner has two independent electric heater assemblies.

Steam flow leaving the recombiner vessel is condensed in the aftercondenser and the offgas stream is cooled. The remaining noncondensable gas (principally air with traces of krypton and xenon) is delayed in a 26 inch diameter, 125 foot long holdup pipe. At a flow rate of 75 scfm, this pipe provides approximately 6.3 minutes of delay for the offgas prior to entering the charcoal adsorption train. Piping from the delay pipe to the charcoal treatment system is heat traced to reduce the possibility of moisture collecting in the line.

Further offgas cooling and condensing of water vapor takes place in the shell side of the cooler condenser heat exchanger. A chilled glycol solution is circulated on the tube side of this heat exchanger. The offgas is cooled to a dew point below 45°F before leaving the cooler condenser. Water that has condensed is drained from the cooler condenser into the condensate accumulator. The temperature of the gas stream increases to ambient (approximately 65°F) as it flows from the cooler condenser to the guard bed, thus preventing condensation.

The glycol solution circulated on the tube side of the cooler condenser heat exchanger is cooled in a closed-loop pumped refrigeration circuit. Dual brine pumps and redundant refrigeration units are provided in the glycol system.

Before entering the main charcoal vessels, the offgas stream passes through a guard bed. The function of the guard bed is to protect the main charcoal adsorbers from moisture if a malfunction of moisture removal features occurs as well as to adsorb impurities in the process gas that might adversely affect performance of the main charcoal vessels.

After passing through the guard bed, the gas enters the main charcoal adsorption beds. The charcoal adsorption beds, maintained at about 65°F by redundant room air conditioning units, selectively adsorb and delay the xenon and krypton from the bulk carrier gas. This delay permits the xenon and krypton to decay in place. The offgas stream then passes through a HEPA afterfilter where radioactive particulate matter and any charcoal fines are retained.

During offgas system operation, the offgas stream must pass through the charcoal adsorbers. Bypass piping around the entire adsorber train does not exist. The offgas stream is directed to the turbine enclosure vent stack where it is diluted with a minimum of 183,000 scfm of air before being released from the north stack.

Table 11.3-1 indicates the estimated annual release rate from the offgas system.

All moisture removed from the process stream is returned to the main condenser hot well or clean radwaste.

11.3.2.1.3 System Design Considerations

11.3.2.1.3.1 Charcoal Holdup Time

The krypton and xenon holdup times are closely approximated by the following equation:

$$T = 0.26 \frac{KM}{V} \qquad \text{(EQ. 11.3-1)}$$

where:

T = hold-up time, hours

K = dynamic adsorption coefficient, cm^3/g

M = mass of charcoal adsorber, thousands of pounds

V = gas flow rate, scfm

Dynamic adsorption coefficients for krypton and xenon used to determine gaseous effluent releases are discussed in NUREG-0016 (Reference 11.3-1). The charcoal adsorber beds are designed for a delay time of 35 days for xenon under both of the following conditions:

a. 75 scfm flow rate using manufacturer's guaranteed adsorption coefficients (733 cm^3/g for xenon and 31.8 cm^3/g krypton)

b.. BWR GALE code assumptions (NUREG-0016, Revision 0)

The offgas system is capable of handling changes in noncondensable flow rates up to 215 scfm (Unit 1) and 205 scfm (Unit 2) with both units running, or 225 scfm (Unit 1) and 215 scfm (Unit 2) with only one unit running, without operator attention. Even though the offgas system is capable of handling these limits, the air in-leakage should not exceed 150 scfm since it is the maximum design capability of the steam jet air ejectors.

With a condenser air inleakage rate of 30 scfm, the charcoal treatment system provides a design holdup time of 52 hours for krypton and 38.6 days for xenon based upon NUREG-0016 assumptions. Since it is expected that the condenser air inleakage will be below the design value and that the charcoal adsorption coefficients will be higher than the values in NUREG-0016 (References 11.3-3 and 11.3-4), the actual charcoal holdup time should be considerably longer than the design holdup time. Additionally, experience with newer fuel designs (8x8 assemblies)

indicates that substantially lower source terms than those used for system design may be expected.

11.3.2.1.3.2 Detonation Resistance

All portions of the LGS offgas system are designed to withstand the effects of a hydrogen detonation or are provided with protective features to preclude the existence of a detonable mixture of gases.

Design for extremely short duration (microsecond) loadings which accompany hydrogen detonations is outside the scope of normal industry design codes (i.e., ANSI B31.1, ASME B&PV Code, etc). The industry has developed a methodology for detonation-resistant design of offgas system piping, pressure vessels, and other components based on extensive theoretical and experimental work.

The magnitude of pressure pulses accompanying a hydrogen detonation have been shown to be a function of component geometry (i.e., length/diameter ratio), initial system pressure, and proximity to reflection points (i.e., pipe elbows, etc). The basic methodology used in the design of detonation-resistant BWR offgas systems is described in appendix C of ANSI/ANS 55.4 (1979). That methodology, with slight variations between the AEs and industry equipment suppliers, has been followed since the early 1970s and was used in the LGS design. The analytical methods used are best described as "static analyses using dynamic material properties". An appropriate wall thickness is determined using peak dynamic pressure and dynamic material properties. For convenience, this wall thickness is often expressed in terms of its code static pressure equivalent. Application of this methodology provides a conservative design without the need for detailed and laborious analysis of the gas dynamics of the system. The methodology has been demonstrated to be adequately conservative by theoretical analysis and operating experience:

a. A true dynamic analysis of system pressures will typically require a wall thickness one-half that indicated by this approach.

b. No BWR offgas system pressure boundary failures had been observed despite the occurrence of considerably more than 100 system detonations.

An ASME Code Committee (Committee on Air and Gas Treatment, Gas Processing Subcommittee) is currently working towards the codification of the above described industry methodology. The guidance provided in SRP 11.3 (i.e., approximately 20 times operating pressure) has been demonstrated to be nonconservative in many applications. (The contents of this paragraph are historical in nature and do not reflect present day activities.)

All offgas system detonation-resistant piping and components upstream of the charcoal treatment system have been analyzed using the method of analysis employed by Bechtel. All charcoal treatment system components have been analyzed using the method of analysis employed by the system supplier (Reference 11.3-5). Both analytical methods closely parallel that described in ANSI/ANS 55.4 and give approximately equal results.

The following is a discussion of factors relevant to the detonation resistance of the LGS offgas treatment system:

a. The SJAEs are designed to withstand a hydrogen detonation occurring at normal system operating pressure (3.5 psia). Because leakage into the standby SJAE train

could cause a detonation at higher initial pressures, provisions have been made to maintain the standby SJAE train at main condenser vacuum.

b. The SJAEs that are used do not employ a second-stage condenser. Thus, the driving steam from the SJAE second-stage provides dilution steam such that a detonable mixture of gases will not exist between the SJAE discharge and the offgas aftercondenser. Protective circuits are provided such the offgas system is automatically shut down when loss of dilution steam is detected (low system flow or high recombiner outlet temperature).

c. All system valves use spark-resistant trim.

d. All system piping, valves, vessels, instruments, and other components are designed to withstand the effects of a hydrogen detonation except portions of the piping between the SJAE discharge and the preheater. Detonable mixtures of gases in this piping are precluded as discussed in Item (b) above.

11.3.2.1.4 Component Description

The recombiner and associated equipment are located in the lowest level of the control structure. Each recombiner system consists of a preheater, recombiner vessel, and aftercondenser. The materials of construction, design temperatures, and pressures are listed in Table 11.3-3.

11.3.2.1.4.1 Preheater

The preheater is a U-tube parallel heat exchanger. Main steam is used to heat process gas before entering the recombiner. The process gas enters at approximately 280°F and is heated as required to vaporize water droplets and achieve sufficient temperature for catalytic reaction. Auxiliary steam may also be available for heating the process gas flow, should main steam be unavailable. Condensate from the tube side of the heat exchanger is collected in a drain pot underneath the preheater and is routed back to the condenser.

11.3.2.1.4.2 Recombiner

The hydrogen and oxygen in the gas stream are recombined in the recombiner vessel by a catalyst of platinum/palladium. Electric heaters with automatic temperature control are provided on the shell of each recombiner. The heaters are used for preheating the recombiner during startup and maintaining it in a dry condition during shutdowns.

11.3.2.1.4.3 Aftercondenser

The aftercondenser is a straight tube heat exchanger. Service water is circulated through the aftercondenser tubes to condense the steam in the offgas flow. Noncondensable gases are collected in the aftercondenser, cooled in the air cooler section and vented to the holdup pipe. Control valves are used to automatically maintain proper condensate level in the aftercondenser shell. Condensate from the air cooler section is collected in a drain tank. Condensate from both sources is returned to the main condenser hotwell, or diverted to clean radwaste if main condenser vacuum is not available or the conductivity instrumentation indicates that a tube leak exists.

11.3.2.1.4.4 Holdup Pipe

The holdup pipe is approximately 125 feet in length and 26 inches in diameter. The purpose of this holdup pipe is to provide delay time to allow N-16 decay before entering the charcoal adsorption portion of the offgas system. Baffles are provided in each holdup pipe to assure adequate mixing and delay.

11.3.2.1.4.5 Charcoal Adsorption System

11.3.2.1.4.5.1 Cooler Condenser

The cooler condenser is a straight tube heat exchanger with a glycol/water solution flowing through the tube side. The glycol system is provided with redundant circulation pumps and redundant refrigeration units that are cooled by service water.

Moisture formed in the cooling process is collected in an accumulator. This condensate is normally routed to clean radwaste but is automatically diverted to chemical waste if the measured conductivity indicates that a glycol leak could exist.

11.3.2.1.4.5.2 Guard Bed

The function of the guard bed is to protect the main charcoal adsorbers from moisture in the event of a malfunction of the moisture removal equipment and to remove contaminants that may be in the process stream which could be detrimental to the main adsorber beds. The guard bed is designed with a removable cover and an internal basket which contains the charcoal adsorbent. The basket allows easy charcoal replacement if necessary. The guard bed contains approximately 190 pounds of charcoal.

11.3.2.1.4.5.3 Main Charcoal Adsorber Bed

The Unit 1 adsorber train consists of two 11 foot diameter tanks and five 10 foot diameter tanks. The Unit 2 adsorber train consists of one 11 foot diameter tank and eight 10 foot diameter tanks. The different configurations for Units 1 and 2 are the result of space limitations within the enclosure, which was constructed before final system design.

Each adsorber train contains approximately 321,000 lbs of charcoal. The tanks are connected at the top and bottom by 4 inch piping. Portions of each unit's offgas system use a parallel flow path through the main adsorber beds. Appropriate valves are provided to facilitate flow balancing as required .

The charcoal adsorber tanks are maintained at a temperature of 65°F or below by redundant air conditioning systems. The last adsorber tank in the Unit 1 train is not located in an air conditioned vault and will operate at room ambient temperature. In the unlikely event that both air conditioning units are unable to function, the radioactive emissions from the offgas system might increase slightly. However, since substantial margin exists in the offgas system design, the releases would still be well below acceptable limits for expected air inleakage rates, radioactivity source terms, and adsorption coefficients.

11.3.2.1.4.5.4 Outlet HEPA Filter

A HEPA filter is provided to collect any entrained particulates or charcoal fines prior to release. These filters were individually tested during the startup test program using the DOP method. The filters are equipped with hinged covers to facilitate removal and replacement of the filter element.

11.3.2.1.4.5.5 Leakage of Radioactive Gases

The offgas system operates at approximately 7 psig during startup and at approximately 2 psig during normal operation. The differential pressure between the system and atmosphere is small, thus limiting the potential for leakage of radioactive gases.

Leakage of radioactive gases from offgas containing lines in the offgas system is further limited by the use of welded construction, by plug valves with plug and shank seals, globe valves with back-seats and packless design, and by using double stem packed valves with a bleed-off connection that is pressurized by instrument air to slightly higher than the system pressure, wherever practical.

All drains in the offgas system with the exception of the condensate accumulator drain are directed either to the main condenser or clean radwaste during normal operation. The condensate accumulator drains are directed to clean radwaste or chemical waste, as discussed in Section 11.3.2.1.4.3.1. In order to eliminate the possibility of gas leakage to the waste collector tanks should a level controller fail, loop seals or drain pots are provided.

All loop seals are the self-resealing type.

11.3.2.1.4.6 Instrumentation and Control

The offgas system is monitored at appropriate locations for flow, temperature, pressure, humidity, conductivity, radiation, and hydrogen concentration to verify specified operation and control as well as to ensure that the hydrogen concentration is maintained below the flammable limit. Sufficient instrumentation is provided to permit system operation and monitoring from the main control room. Drawings M-69 and M-70 indicate the process instrumentation.

A radiation monitor located upstream of the holdup pipe continuously monitors gaseous radioactivity input to the charcoal adsorption system. This is representative of gaseous radioactivity released from the reactor and therefore indicates the condition of the fuel cladding. Provision is made for grab sampling of the influent gases for the purpose of determining isotopic composition.

A radiation monitor is also provided at the outlet of the charcoal adsorbers to continuously monitor activity released from the system. The offgas system process radiation instrumentation is further discussed in Section 11.5.

Dilution steam flow (second-stage SJAE motive steam) is monitored upstream of the preheater and recorded in the control room. Low dilution steam flow automatically shuts the first-stage SJAE gas suction valves to prevent high concentrations of hydrogen in the offgas piping between the second-stage SJAEs and the preheater.

The HWC control system requires an interface with the Gaseous Radwaste/Recombination System. An SJAE train/recombiner trip digital output is provided to trip the HWC system.

The steam supply to the gas preheater is controlled by the offgas outlet temperature.

The temperature of the recombiner vessel and the inlet and outlet gases are monitored by thermocouples. A high temperature alarm is provided for the recombiner vessel, and high and low

temperature alarms are provided on the inlet and outlet lines to alarm a temperature outside of the design range.

Aftercondenser outlet temperature is recorded, and high temperature is alarmed in the main control room. This temperature indicates if adequate cooling flow exists in the aftercondenser.

Three thermal conductivity-type hydrogen analyzers and two oxygen analyzers are used to measure the hydrogen and oxygen content of the offgas process stream at the discharge of the aftercondenser. The system is designed to ensure that there is sufficient oxygen available to combine with the hydrogen and yet ensure that the oxygen level does not get too high so as to impose an increased fire hazard for the offgas charcoal beds. One of the hydrogen analyzers can be switched to measure the hydrogen content of the offgas stream at the inlet to the recombiner. The sample gas is returned to the main condenser. The hydrogen analyzers are designed to withstand the effects of a hydrogen detonation. The analyzer cell is not capable of causing a detonation, and the analyzer is designed with a flame arrestor on the sample side to inhibit such detonation. The hydrogen concentration is annunciated both locally and in the control room for high and high-high hydrogen concentration (2% and 4%, respectively). A common trouble alarm for cell failure, analyzer cell low flow and low bypass flow, is also provided. Because the offgas system is designed to withstand the effects of hydrogen detonation, no automatic control functions are required. Each hydrogen analyzer is independently calibrated. Condensate from the analyzers is routed to the aftercondenser air cooler drain.

The condensate level in the preheater and aftercondenser is maintained at appropriate levels by level control systems. These level control systems provide drainage either to the main condenser or clean radwaste. During normal operation condensate is directed to the main condenser. A conductivity element is provided in the drain to detect aftercondenser tube leakage if high conductivity is detected. Because the condensate from the air cooler portion of the aftercondenser already has a high conductivity reading due to dissolved air, this portion of aftercondenser drainage is routed to bypass the conductivity cell to avoid a false high reading. As a result, tube leakage in the aftercondenser air cooler will not be detected. Tube leakage in the air cooler section is not anticipated due to the mild service environment that this section of tubes experiences.

Cooler condenser performance is monitored by outlet temperature and moisture. High process outlet temperature is alarmed in the main control room. A moisture element is located downstream of the cooler condenser. The moisture element senses the process offgas dew point temperature. This temperature is indicated both at the local panel and in the main control room. High moisture in the process stream is alarmed both locally and in the main control room.

Moisture condensed from the process offgas in the cooler condenser is collected in the condensate accumulator. The condensate level is maintained at appropriate limits by a level control system. Condensate is normally drained to clean radwaste. A conductivity element is provided in the drain to detect glycol inleakage. If glycol inleakage is detected, drainage is routed to the chemical waste tank.

The guard bed is provided with both differential pressure and temperature indication. High differential pressure and high temperature are alarmed in the control room.

The charcoal beds in the adsorber vessels are monitored by thermocouples. High temperature is alarmed in the control room and at the local panel. Individual adsorber charcoal temperature is indicated at the local control panel and recorded in the control room. Each vessel is provided with two spare thermocouples which can be used if the first thermocouple fails.

Differential pressure is measured across the HEPA filter. High differential pressure is alarmed in the main control room. Flow from the discharge of the second-stage SJAE can be recycled to the main condenser if transient flow conditions approach system maximum. Recycle line operation is described in Section 10.4.2.5 .

Process offgas flow rate is monitored downstream of the HEPA filter. High flow rate is alarmed in the main control room and at the local panel. Flow rate is indicated locally and recorded in the main control room.

Thermocouples are provided in each charcoal adsorber tank room. The thermocouples automatically operate the room air conditioning units to maintain room temperature at or below 65°F. Room temperature is indicated and alarmed at the local panel. Room temperature is also alarmed and recorded in the main control room.

11.3.2.1.4.7 Offgas System Operating Procedure

11.3.2.1.4.7.1 Startup

Before starting the offgas system, the following conditions are necessary: main steam or auxiliary steam is available for the SJAEs and the preheater; cooling water (condensate) is supplied to the SJAE intercondenser; the recombiner is preheated to approximately 300°F by the electric heaters; service water is supplied to the aftercondenser, glycol refrigeration units, and compartment refrigeration units; the glycol coolant is chilled, one glycol pump is running and circulating chilled glycol through the cooler condenser; the adsorber rooms are at 65°F or below, and air circulation fans are operating .

The system can be started either with the main condenser at 20 in Hg vac with vacuum having been drawn by the mechanical vacuum pump or at atmospheric pressure with the initial vacuum drawn by the 2nd stage SJAE using auxiliary steam. With main condenser vacuum established, the system is prepared for startup by admitting main or auxiliary heating steam to the preheater, and selecting and setting various instrument control stations at the main control room system panels. The SJAE train discharge and main steam or auxiliary steam supply valves are opened. The 2nd stage SJAE is placed into service and a vacuum is drawn in the SJAE intercondenser. The discharge flow heats the process piping down through the preheater, recombiner, aftercondenser, and holdup pipe before being recirculated to the main condenser. The 1st stage SJAE air suction valves are opened to allow the 2nd stage SJAE to draw condenser vacuum down to approximately 25 to 26 in Hg vac. The mechanical vacuum pump can then be secured. Full condenser vacuum is achieved by performing the following: close the 1st stage air suction valves, open the 1st stage steam supply valves, re-open the 1st stage air suction valves. Once the 1st stage air suction valves are opened (with either the 1st stage SJAE in or out of service) the recirculation line downstream of the holdup pipe to the main condenser is closed and flow is directed to the charcoal treatment system. Recycle lines at the discharge of the 2nd stage SJAE will return some flow to the main condenser should system back pressure exceed approximately 7 psig at startup flows.

If the 2nd stage SJAE is used to draw the initial vacuum, the startup sequence is the same as above. The only difference is that auxiliary steam must be used.

11.3.2.1.4.7.2 Normal Operation and Shutdown

After startup, the flow rate of noncondensables exhausted by the SJAE should stabilize, primarily as a function of reactor power level and condenser inleakage. The instrumentation discussed in Section 11.3.2.1.4.4 can be used to monitor system performance. Operator action is not required for steady-state system operation, including changes in offgas noncondensable flow rates up to 215 scfm (Unit 1) and 205 scfm (Unit 2) with both units running, or 225 scfm (Unit 1) and 215 scfm (Unit 2) with only one unit running. Even though the offgas system is capable of handling these limits, the air in-leakage should not exceed 150 scfm since it is the maximum design capability of the steam jet air ejectors.

Normal operation is terminated following a normal reactor shutdown or a scram by shutting the gas suction valves to the SJAEs and then stopping steam flow to the SJAEs. Steam is secured to the first-stage SJAEs and then to the second-stage. Normal practice is to run the offgas system throughout reactor pressure vessel depressurization. Main steam can support SJAE operation down to 205 psig reactor pressure. Auxiliary steam may be used at any time during shutdown operations.

11.3.2.1.4.7.3 Equipment Malfunction

An equipment malfunction analysis, indicating the consequences and design precautions taken to accommodate failure of various components of the offgas system, is presented in Table 11.3-5.

11.3.2.1.4.8 Operator Error

The potential for operator error resulting in high offsite releases while operating the offgas system is small. Offgas flow from the SJAEs must be directed through the recombiner and ambient charcoal systems. There are no system bypasses other than the mechanical vacuum pump. The systems are instrumented such that the operators can detect and correct failures of various components in the systems (Table 11.3-5).

11.3.2.1.4.9 Serviceability and Reliability

Reliability of the offgas system is accomplished through redundancy and the use of passive components.

Two redundant SJAE systems, including intercondensers, are provided. Redundant level control valves, flow control valves, and instrumentation are furnished for the preheater. Redundant level control valves and instrumentation are supplied for the aftercondenser, holdup pipe, and condensate accumulator drains. Redundant glycol cooling pumps, glycol refrigeration units, charcoal adsorber vessels' compartment refrigeration units, and compartment fan coil units are provided. Redundant control valves may be operated or isolated from the control room; redundant equipment can be placed in or out-of-service from the control room. The recombiner systems of the two units may also be cross connected into one charcoal train through a spool piece interconnection. Each charcoal train can process up to 300 scfm of offgas noncondensable flow.

The guard beds and first charcoal adsorber vessels in each train can be bypassed if they become contaminated with moisture. The HEPA filter may also be bypassed if a high differential pressure condition exists.

Redundant equipment for the preheater, recombiner, and aftercondenser is not installed. Piping connections are installed that allow for a second recombiner system to be connected to the existing system of each unit in the future.

Serviceability is accomplished wherever possible, by using passive components and by locating in accessible areas equipment and instruments which are not passive or which require periodic maintenance.

Instruments for the recombiner system that require periodic maintenance are located outside the recombiner rooms. Instruments for the ambient charcoal system are either located outside rooms containing radioactive equipment or are shielded from radioactive equipment. Instrumentation requiring calibration are accessible during system operation.

The guard beds and HEPA filters are located in individual rooms and are provided with system bypasses. The vessels are designed with removable covers. This arrangement allows replacement of the charcoal basket or filter element when the offgas system is operating.

11.3.2.2 Other Radioactive Gas Release Paths

There are three general areas that contain sources of radioactive gas: the primary and secondary containment, the turbine enclosure, the radwaste enclosure and Chemical Laboratory Expansion . The description of the ventilation systems for these enclosures is presented in Section 9.4. The enclosure volumes, flow rates, sources, and other information required to calculate the airborne concentrations of radioactive materials are contained in Sections 12.2.2, 12.3.3, and 12.4.

11.3.2.2.1 Primary and Secondary Containment

As indicated in Section 9.4, the two reactor enclosures and the common refueling area have been designated as HVAC Zones I, II, and III. The primary containment and secondary containment HVAC systems that are important for the treatment of potentially radioactive air are the following: Zone I and Zone II equipment compartment exhaust systems, the SGTS, and the RERS.

The equipment compartment exhaust systems process ventilation exhaust from the areas in Zones I and II which are most likely to have sources of airborne radioactivity. These areas are listed on drawing M-76. The exhaust system contains HEPA and 2 inch charcoal filters. Discharge air from other areas in HVAC Zones I and II is released unfiltered through the reactor enclosure air exhaust system. Radiation monitors in the exhaust duct-work cause HVAC isolation on high-high radiation and initiate the RERS and SGTS. These systems provide increased filtration and delay of airborne radioactivity before release. Equipment compartment exhaust systems are more completely described in Section 9.4.

Air from HVAC Zone III (the common refueling area) is normally exhausted unfiltered through the refueling area air exhaust fans. Radiation monitors are provided in the exhaust duct-work to isolate normal HVAC and initiate the SGTS on high-high radiation. There may be small quantities of radioactivity released unfiltered from the refueling area and the spent fuel pool, especially during the early stages of refueling. However, the quantities of iodine and particulates released from this unfiltered source are expected to be much less than the releases from equipment leakage, equipment maintenance, and drywell purge, all of which are filtered. Considering the uncertainties in the calculation of the reactor enclosure releases and the conservative use of a minimum 90% efficiency for the charcoal filtration systems, it is expected that the actual releases from the reactor enclosure to the atmosphere should be lower than the estimates used in this evaluation.

During power operation, radioactivity released from minor system leakage inside the primary containment is contained, except for minor releases necessary to control containment pressure.

Pressure is controlled by use of the low volume purge. In this purge mode, gas is supplied by the containment atmosphere control system through 1 inch lines and is exhausted from the primary containment through 2 inch lines connecting to the high volume purge exhaust lines. Low volume purge air is processed through the equipment compartment exhaust system prior to release to the environment. The containment isolation valves on the high volume and low volume purge lines are closed on a containment isolation signal.

Before a shutdown requiring containment entry, the containment is purged of nitrogen and airborne radioactivity by the drywell purge system, which uses the SGTS filters to reduce releases. When required, high volume purging of the containment continues while maintenance activities are conducted inside primary containment. The MSRVs are vented to the suppression pool. The activity released from the actuation of these relief valves is contained in the primary containment until its atmosphere is purged through the SGTS when preparing for personnel access.

11.3.2.2.2 Radwaste Enclosure and Chemistry Laboratory Expansion

The supply system delivers filtered and tempered air that is distributed throughout the enclosure in quantities sufficient to maintain required temperatures. The equipment compartment exhaust system consists of two 100% capacity fans and two 100% capacity filter housings. The Chemistry Laboratory Expansion air exhaust system consists of two 100% capacity fans and two 100% capacity filter housings. The fume hood exhaust air system consists of two 100% capacity fans and two 100% capacity filter housings. Each filter housing has a bank of prefilters and a bank of HEPA filters. This exhaust system is balanced to assure that the flow of air within the enclosure is into areas with higher potential for airborne radioactivity contamination. The tank exhaust system provides a means of filtering and venting air from tanks and equipment housed in the radwaste enclosure. A single fan and filter train are employed for this purpose. There are HEPA filters in this system. Since the flow of air from tanks and equipment varies, space air is admitted as required to maintain system volume. Noncontaminated areas of the radwaste enclosure are exhausted by the unfiltered radwaste enclosure air exhaust system.

A radiation monitor is provided on the combined radwaste enclosure air and equipment compartment exhaust systems. All radwaste enclosure and Chemistry Laboratory Expansion exhaust systems discharge to the north stack.

Each of the above exhaust systems and the respective supply system are interlocked so that failure of the exhaust system shuts down the supply system. This condition is alarmed in the radwaste control room.

11.3.2.2.3 Turbine Enclosure

As indicated in Section 9.4.4, the turbine enclosure ventilation system contains a filtration system with HEPA filters and an 8 inch deep charcoal filter. Enclosure air from those areas of the turbine enclosure, where equipment leakage and airborne activity are most likely, is processed through the filtration system before it is released through the north stack to the atmosphere. Air from noncontaminated areas is released through the north stack without filtration.

In the past, discharge from the steam packing exhausters has presented a source of gaseous radioactive releases in some BWR plants. At LGS however, clean steam from the steam seal evaporator is provided for gland seal purposes and, therefore, essentially no activity is released from this system. Section 10.4.3 provides a detailed description of the gland seal steam system.

During the startup of each plant, air is removed from the main condenser by a mechanical vacuum pump. This vacuum pump discharges through the turbine enclosure equipment compartment exhaust air filter assemblies. The vacuum pump exhaust can bypass the turbine enclosure equipment compartment exhaust filters under administrative control when it is determined that filtration is not required to limit offsite doses. A radiation detector continuously monitors the effluent from the turbine enclosure exhaust system via the north stack, and an alarm is actuated upon the detection of a high radiation level.

11.3.3 RADIOACTIVE RELEASES AND ESTIMATED DOSES

The activity released from the various vents is monitored to ensure that the airborne concentrations at offsite locations will be below the limits of 10CFR20. In addition, the yearly releases are kept ALARA in order to meet the dose guidelines 10CFR50, Appendix I. The expected annual activity releases are given in Table 11.3-1.

An evaluation of the gaseous radioactive releases to show compliance with the above guidelines has been performed. The assumptions used in this evaluation are summarized in Table 11.3-2. The fractions of radioiodine and particulates assumed to be released from the reactor enclosure, the turbine enclosure, and the radwaste enclosure are included. These assumptions were based on NUREG-0016, Revision 0. A further discussion of each assumption follows:

a. Reactor Enclosure

As indicated in Sections 11.3.2.2.1 and 9.4.2, the reactor enclosure is ventilated during normal operation by two systems: the reactor enclosure exhaust system and the reactor enclosure equipment compartment exhaust system. Only the latter system includes HEPA and charcoal filter systems. The design philosophy is to identify those areas with the potential for airborne contamination and to exhaust them through the filtered exhaust. Clean areas are exhausted without filtration. This minimizes the mixing of air between contaminated and noncontaminated areas and thus maintains the airborne doses to workers in noncontaminated areas to ALARA conditions. Drawing M-76 identifies the areas served by each of the systems. Because the sources of equipment leakage within the reactor enclosure (e.g., RWCU pumps, RHR system, etc) are served by the filtered exhaust, it was assumed that all reactor enclosure releases are filtered.

To use the NUREG-0016, Revision 0, GALE code estimates of releases, it was conservatively assumed that the reactor enclosure (containment/auxiliary building) contributions were all released through 2 inch, 70% efficient charcoal filters and 99% efficient HEPA filters.

b. Turbine Enclosure

The areas of the turbine enclosure containing radioactive sources that could leak and result in airborne activity have been identified as shown in Sections 11.3.2.2.3 and 9.4.4.2.5 and on drawing M-75. The turbine enclosure ventilation systems have been set up such that the air flows from the clean areas to the areas of potential contamination and then is exhausted through the 8 inch charcoal and HEPA filters of the equipment compartment exhaust system. In addition, air from the clean areas is exhausted or recirculated by the turbine enclosure ventilation system to keep the airborne doses ALARA to workers in noncontaminated areas and to

minimize the cost and doses during maintenance for a larger filter system. Because all identified sources of activity are served by the filter system, it was assumed that all turbine enclosure releases identified by NUREG-0016, Revision 0, and the GALE code are released through the 8 inch, 99% efficient charcoal filters and the 99% efficient HEPA filters.

c. Radwaste Enclosure and Chemistry Laboratory Expansion

As indicated in Sections 11.3.2.2.2 and 9.4.3 and on drawing M-79, HEPA filters are installed on tank vents, HEPA filters are installed on the equipment compartment exhausts and the fume hood exhaust system, and the clean areas are exhausted unfiltered. By directing air flow to contaminated areas from the clean areas rather than using a recirculation-type system, airborne contamination is minimized, and most of the released activity is filtered before it is released. For the analysis indicated in Table 11.3-2, it was assumed that all particulate releases are filtered through either the 99% efficient tank vent HEPA filter or the 99% efficient HEPA filter on the equipment compartments identified as having the greatest potential for leakage. The above assumptions are reflected in the release analyses summarized in Tables 11.3-1 and 11.5-4, and the dose analyses summarized in Tables 11.3-7 and 11.3-4.

Expected average annual radionuclide concentrations are compared to 10CFR20 limits in Table 11.3-7.

The doses resulting from gaseous effluents are a small fraction of the 10CFR20 dose limit of 500 mRem/year and are well within 10CFR50, Appendix I design objectives, as shown in Table 11.3-4.

All gaseous releases are through the following three release points: the north stack, the south stack (one per unit), and the hot maintenance shop.

a. Offgas system

b. Mechanical vacuum pump and gland seal condenser exhaust systems

c. Containment purge system

d. SGTS

e. Turbine enclosure ventilation system

f. Radwaste enclosure ventilation system

g. Chemistry Laboratory Expansion air exhaust system

h. Chemistry Laboratory Expansion fume hood air exhaust system

The south stack serves the refueling floor and reactor enclosure ventilation exhaust. The locations of the stacks are shown on reactor enclosure general arrangement drawings in Section 1.2.

The hot maintenance shop exhaust serves the hot maintenance ventilation exhaust system.

The height, flow rate, heat content, and dimensions of the three release points are shown on Table 11.3-6.

Table 11.3-5

OFFGAS SYSTEM EQUIPMENT MALFUNCTION ANALYSIS

EQUIPMENT ITEM	MALFUNCTION	CONSEQUENCES	DESIGN PRECAUTIONS
1. SJAE pressure control valves	Fail closed	Insufficient dilution of hydrogen in offgas.	Low flow signal will shut offgas suction valve. Low flow and low SJAE supply steam pressure will alarm in control room. Operator can start redundant SJAE train.
2. Piping from SJAE to and including holdup Pipe	Pressure boundary leakage	Increased local airborne radioactivity levels and increased releases from plant ventilation.	Area monitors in normally accessible areas will alarm. Ventilation releases will be filtered by turbine equipment compartment exhaust system and monitored. Low pressure system, radiographed welds, and system is designed to withstand hydrogen detonation.
3. Recombiner preheater	Steam leak from tube side into shell side.	1. Increased preheater outlet temperature	1. Temperature elements at preheater outlet would regulate steam flow to preheater
		2. Increased quantity of dilution steam	2. Additional steam flow would be condensed in the after condenser and returned to CRW or the main condenser.
	Liquid level instrument fails or level control valve fails	1. Level control valve opens. Preheater level drops. Steam recycles through drain line to main condenser.	1. Redundant level control instrumentation. Alarm on low condensate level in preheater. Operator closes level control valve or drain isolation valve from control room . Redundant level control valve provided.
		2. Level control valve closes.	2. Redundant level control valve provided. Will actuate automatically.

Table 11.3-5 (Cont'd)

EQUIPMENT ITEM	MALFUNCTION	CONSEQUENCES	DESIGN PRECAUTIONS
4. Recombiners	Catalyst deteriorates or is wetted	1. Recombiner outlet temperature drops.	1. Outlet temperature monitors record low temperature.
		2. High hydrogen concentrations at recombiner outlet.	2. Analyzers record hydrogen level and alarm at 2% and 4%. Operator isolates gas flow, or adjusts dilution.
5. Aftercondenser	Cooling water leak (tube to shell side)	The cooling water would leak to the shell side of the heat exchanger. Water flow would increase to the condenser.	Leakage would be detected by high conductivity in the drain line. High conductivity alarms in main control room . The aftercondenser drain can be swapped manually to clean radwaste. Excessive leakage would actuate aftercondenser high level alarm.
	Liquid level instrument fails or level control fails	1. Level control valve opens. Aftercondenser shell drain level drops or air cooler drain tank level drops. Steam or noncondensables recycle back to the main condenser, or clean radwaste.	1. Redundant level instrument alarms on low condensate level in aftercondenser. Operator closes level control valve or drain isolation valve from the control room. Loop seal provided on drain to clean radwaste to prevent offgas entering clean radwaste. Loop seal is self-resealing type.
		2. Level control valve closes.	2. Redundant level control valve provided. Redundant level control valve provided.
6. Piping from holdup pipe to HEPA filter exit	Pressure boundary leakage enclosure	Release of offgas mixture to radwaste or offgas enclosure will detect leakage.	Local radiation monitors in the radwaste Ventilation monitors in ducts from the offgas enclosure will detect leakage from offgas piping.

Table 11.3-5 (Cont'd)

EQUIPMENT ITEM	MALFUNCTION	CONSEQUENCES	DESIGN PRECAUTIONS
7. Holdup pipe	Liquid level instrument fails or level control valve fails	1. Level control valve opens. Holdup pipe drain pot liquid level drops. Offgas recycles through the drain line to the main condenser or to clean radwaste.	1. Redundant level instrumentation. Alarm on low condensate level in drain pot.Operator closes level control valve or drain isolation valve from control room. Loop seal provided on drain to clean radwaste to prevent offgas entering clean radwaste. Loop seal is of the self-resealing type.
		2. Level control valve closes	2. Redundant level control valve provided .
8. Glycol system	Mechanical failure (pumps or refrigeration units)	If glycol unit fails, the moisture content of the process stream will increase resulting in decreased adsorption.	The failure of the glycol system will activate alarms at local panel and alarms at main control room panel. Redundant glycol refrigeration units and glycol pumps are installed. Moisture instrumentation and temperature instrumentation is provided at the cooler condenser outlet. High outlet temperature and high moisture are alarmed at the local panel and in the main control room. In addition, system is oversized and glycol loop has sufficient thermal capacity which allows time to change over to redundant equipment.
9. Charcoal adsorbers	Moisture in gas stream	Charcoal adsorption performance will deteriorate gradually as charcoal gets wet. Holdup times decrease and plant gaseous releases will increase.	Increasing moisture in inlet stream will be detected by the moisture element. Various design precautions are included upstream to preclude moisture from entering adsorbers. Sacrificial guard beds are provided to protect main adsorber vessels.

Table 11.3-5 (Cont'd)

EQUIPMENT ITEM	MALFUNCTION	CONSEQUENCES	DESIGN PRECAUTIONS
10. Charcoal vault air conditioning units	Mechanical failure of refrigeration units or air coolers.	If ambient temperature increases, delay efficiency of charcoal beds decreases. Increased releases would occur depending on the fuel leakage rate.	Redundant air conditioning units are provided. Redundant fan and cooler for each cell provided. High ambient temperature alarms in main control room and local panel. Ambient temperature is recorded in the main control room. Refrigeration trouble alarm in main control room. Refrigeration system capacity is oversized for heat load.
11. Outlet HEPA filter	Plugging of filter media	Increasing differential pressure in HEPA will create higher system back pressure. SJAE bypass valve may open recycling offgas back to main condenser.	Differential pressure is alarmed in control room and indicated locally. DOP test connections are provided. HEPA filter can be bypassed for servicing.

[1] The concentration limits shown are reflective of the 10CFR20 Appendix B values prior to the 1994 revision of 10CFR20, and are consistent with those used in the original licensing of the plant. Current effluent release limits are based on the post-1994 10CFR20 regulation and are controlled by the Radioactive Effluent Controls Program defined by the Technical Specifications. New 10CFR20 limits went into effect on Jan. 1, 1994. As part of the power rerated evaluation, a comparison of the uprated atmospheric release concentrations with the new 10CFR20 limits was made. All the uprated released concentrations were found to be less than 1% of their new limit values.

11.4 SOLID WASTE MANAGEMENT SYSTEM

The applicant is committed to providing a solid waste management system that complies with the intent of BTP ETSB 11-3, "Design Guidance for Solid Radioactive Waste Management Systems Installed in Light-Water-Cooled Nuclear Power Reactor Plants.". A process control program that ensures suitability of packaged wastes for shipment and burial in consideration of applicable federal and state regulations and other requirements was submitted in conformance with the guidelines of SRP section 11.4 of NUREG-0800 (Reference 11.4-1). Process parameter tolerances were verified during preoperational testing of the solid radwaste system, and the final Process Control Program was submitted on March 7, 1985. Any revision to the program requires PORC approval.

The solid waste management system collects, monitors, processes, packages, and provides temporary storage facilities for radioactive spent bead and powdered resins and dry solid wastes for offsite shipment and permanent disposal. The solid waste management system does not have any safety-related functions. For the purpose of this section, the term "solid waste" is used for spent bead and powdered resins and dry solid waste produced from plant operation.

In addition, Class B and Class C Low-Level Radioactive Waste (LLRW) produced from plant operation may be shipped to Peach Bottom Atomic Power Station for storage.

Process and effluent radiological monitoring systems are discussed in Section 11.5.

11.4.1 Design Bases

a. The design objectives of the solid waste management system are:

   1. Provide collection, processing, packaging, and storage of solid wastes resulting from normal plant operations without limiting the operation or availability of the plant

   2. Provide a reliable means for handling solid wastes and allow system operation with ALARA radiation exposure to plant personnel

   3. Package solid wastes in suitable containers for offsite shipment and burial

   4. Prevent the release of significant quantities of radioactive materials to the environment so as to keep the overall exposure to the public well within 10CFR20 limits

b. Redundant and backup equipment, alternate routes, and interconnections are designed into the system to provide for operational occurrences such as refueling, abnormal leak rates, decontamination activities, equipment downtime, maintenance, and repair.

c. Equipment locations, compartments, drainage, ventilation, and components are designed to reduce maintenance, equipment downtime, leakage, and gaseous releases of radioactive materials to the structure atmosphere or to otherwise improve the system operations.

d. The solid waste management system is designed to package radioactive solid wastes for offsite shipment and burial in accordance with the requirements of applicable NRC and DOT regulations including 10CFR71 and 49CFR170 through 49CFR178. Final waste classification and waste form for offsite disposal will be consistent with the guidelines of 10CFR61. A shipping manifest consistent with 10CFR20.2006 will accompany the waste shipment. Waste stability for Class B and Class C wastes is provided by the use of high integrity containers which are designed in accordance with the "General Criteria for High Integrity Containers" established by the South Carolina Department of Health and Environmental Control on October 22, 1980. Concrete overpacks are used at the burial site to provide the compressive strength required for burial. This results in radiation exposures to individuals and the general population well within the limits of 10CFR20 and 10CFR50.

e. The solid waste management system is designed to seismic Category II requirements. The quality group classification and corresponding codes and standards that apply to the design of the solid waste management system are discussed in Section 3.2.

f. The expected and maximum radionuclide activity inventories of solid waste management system components containing significant amounts of radioactive liquids are shown in Tables 11.4-8 and 11.4-9.

    1. Expected flow rates for streams shown in Figure 11.4-3 are given in Table 11.4-4.

    2. Expected inputs and activities to the solid waste management system are shown in Tables 11.4-5 and 11.4-6.

g. A quality assurance program for the packaging and transportation of radioactive material shall be established which complies with the applicable requirements of 10CFR50, Appendix B, "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants", and 10CFR71, subpart H, "Packaging and Transportation of Radioactive Material, Quality Assurance".

11.4.2 SYSTEM DESCRIPTION

The solid waste management system P&IDs are shown in drawings M-66 and M-67. The process flow diagram is shown in Figure 11.4-3. Major equipment design parameters are listed in Tables 11.4-1, 11.4-2, and 11.4-3.

11.4.2.1 System Operation

The activities of the wastes entering the solid waste management system are dependent on the liquid activities in the various liquid systems such as the condensate, RWCU, fuel pool cleanup, equipment drain, and floor drain systems, whose activities are in turn a function of the reactor coolant activity. The activity of the reactor coolant is discussed in Section 11.1. Liquid waste management systems that supply input to the solid waste management system are discussed in Section 11.2.

The quantities of solid wastes generated are dependent on the plant operating factor, extent of equipment leakage, plant maintenance and housekeeping, and decontamination requirements.

Input to the solid waste management system is predominantly captured solids from filter/demineralizers and bead resins from deep-bed demineralizers. Powdered and bead resins are dewatered and then packaged in HICs or other approved containers for offsite disposal (Section 11.4.2.4).

11.4.2.1.1 Wet Solid Waste Processing

Wet solid wastes consist primarily of filtered solids from condensate filter/demineralizers and filtered solids, spent bead resins and powdered resins backwashed from RWCU, deep bed condensate demineralizers, floor drain, equipment drain, and fuel pool cleanup systems. Only spent resins from the RWCU system are expected to exceed LSA criteria. The rest of the solid wastes are expected to be low specific activity, as defined in 10CFR71.

The originally installed plant centrifuge system is no longer in service. Spent resins are transferred to the external processing station for dewatering through permanently installed plant systems/piping (Section 11.4.2.2.7).

The condensate filter/demineralizer are backwashed to the respective condensate backwash receiving tank and from there are pumped to one of two (per unit) phase separators. When the backwash material has settled in the phase separator, the clear water is decanted to the equipment drain tank for further processing. When a preset sludge level is reached in a phase separator, the other phase separator is used, while the sludge in the first phase separator is allowed to decay. After decay the sludge is pumped in slurry form to the external processing station for dewatering.

Backwash from the RWCU system is handled in a manner similar to the condensate filter/demineralizer system. There are two RWCU phase separators shared between two units. Each RWCU phase separator is sized for a normal 60 day collection (from both units) and 60 day decay time.

Spent bead resin from the DBCD can be transferred to the floor and equipment drain demineralizers for re-use (Section 10.4.6.2). DBCD system spent resin can also be processed externally (vendor process) by pumping resin from the DBCD system spent resin tanks (SRT) to the external processing station for collection in liners or high integrity containers.

Spent powdered resins from the equipment drain and floor drain filters and fuel pool cleanup filter/demineralizer are backwashed to the waste sludge tank, transferred to a condensate phase separator for processing and then pumped to the external processing station for dewatering. The waste sludge tank contents can also be processed directly to the external processing station for dewatering, based on plant conditions. Equipment and floor drain demineralizer spent resins were designed to be sluiced to their respective intermediate spent resin tanks before being pumped to the waste sludge tank. However, for normal plant operation, the spent resin tanks are not used. The exhausted bead resin from the liquid radwaste demineralizers will be sluiced directly to the waste sludge tank via a permanently installed bypass line.

The waste sludge tank holdup capacity does not approach the BTP ETSB 11-3 30 day criteria. However, the tank contents can be routed to the condensate phase separator for holdup and decanting in lieu of immediate dewatering by external processing. The use of redundant

dewatering process trains is expected to preclude the need for significant upstream waste slurry storage from a process equipment availability standpoint.

Slurries from the phase separators or the waste sludge tank are pumped to the external processing station. The slurry is approximately 5% by weight solid content and is dewatered to approximately 40% to 60% by weight solid content.

The vendor's external dewatering system shall be operated in accordance with the system's Topical Report and applicable procedures.

During initial system testing (preoperational), process parameters were established that provided reasonable assurance that the dewatered sludge contained essentially zero free liquid. Periodically during external waste processing, the free liquid parameters will be verified. Sludge samples may also be taken if an abnormal condition develops during waste processing. Records of process parameters will be maintained for individual waste batches. Dewatered waste shipments will comply with the applicable burial site criteria for maximum acceptable free liquid content, when shipped for burial.

11.4.2.1.2 Concentrated Liquid Waste Processing

Installation of the radwaste evaporators was not completed for plant operation and the system has been abandoned (Section 11.2.2.1.3). Because the solid waste management system does not include an installed solidification subsystem, any future concentrates produced would be solidified prior to offsite shipment by an acceptable mobile solidification system connected to the external processing station.

11.4.2.1.3 Dry Solid Waste Inputs

Dry wastes consist of air filters, miscellaneous paper, rags, etc, from contaminated areas; contaminated clothing, tools, and equipment parts that cannot be effectively decontaminated; and solid laboratory wastes. The activity of much of this waste is low enough to permit handling by contact. These wastes are collected in containers located in appropriate areas throughout the plant, as dictated by the volume of wastes generated during operation and maintenance. Compressible wastes are packaged manually into strong, tight containers. Noncompressible wastes are packaged manually in similar strong, tight containers or in other suitable containers. The filled containers are sealed and moved to a controlled access enclosed area for temporary storage. Because of its low activity, this waste can be stored until enough is accumulated to permit economical transportation to an offsite vendor for processing and/or to an offsite burial ground for final disposal.

11.4.2.1.4 Irradiated Reactor Internals

Irradiated reactor internals being replaced are removed from the RPV underwater and stored for radioactive decay in the spent fuel storage pool. Section 9.1.4 describes reactor vessel and in-vessel servicing equipment used for handling reactor components.

Some irradiated reactor internals are processed and then stored in Storage Containers (SCs) in free-standing storage racks in the cask loading pit prior to shipping. The rack compartments hold LLW including Control Rod Blades (CRBs), fuel channels in sheaths, LPRM strings, velocity limiters, filters, stellite ball bearing and other small components. During LLW processing, processing equipment will be placed in the cask loading pit or on the Refuel Floor.

An estimated average of seven of the control rod blades will be removed at each reactor outage (starting 10-15 years after operation) and stored on hangers on the fuel pool walls or in racks interspersed with the spent fuel racks. Offsite shipping is done in NRC licensed shipping casks.

An estimate of 30% of the power range monitor detectors will be replaced at each reactor outage. Actual power range monitor detector replacement is as required based on detector life. Spent incore detectors and dry tubes are cut or bent as required to facilitate subsequent storage. The incore detectors and dry tubes are stored with adequate water shielding on hangers on the fuel pool walls or within suitable storage containers. A cutting tool allows remote cutting of the incore detectors and dry tubes in the fuel pool or cask pit. The cut incore monitors and dry tubes and other small sized reactor internals are shipped offsite in suitable containers and/or shielded casks that can be loaded underwater.

A trolley-mounted disposal cask with an internal cable drum is supplied with the NSSS for source and intermediate range neutron monitor detector cables and the TIP wires.

11.4.2.2 Process Equipment Description

Major components of the solid waste management system include pumps, tanks, piping, centrifuges, discharge chute assemblies, capping machine, decontamination equipment, and handling equipment. The entire system is located in the radwaste enclosure with the exception of the condensate and reactor water cleanup backwash receiving tanks, which are located in the control enclosure and reactor enclosure, respectively. The designs of the radwaste, turbine, and reactor enclosures are discussed in Section 3.8.4. Equipment design parameters are listed in Tables 11.4-1, 11.4-2, and 11.4-3.

11.4.2.2.1 Pumps

Process pumps are vertical in-line centrifugal pumps of ASME Section III, Class 3 construction. All are made of carbon steel except the RWCU sludge discharge/mixing and the RWCU decant pumps, which are of stainless steel. All are provided with a mechanical-type seal.

11.4.2.2.2 Tanks

System collection and phase separator tanks are sized for normal plant waste volumes with sufficient excess capacity to accommodate equipment downtime and expected maximum volumes that may occur. Cross-connections between tanks are provided as appropriate for greater operational flexibility. Air spargers or recirculation lines are provided in the tanks to create a homogeneous slurry for pumping. All tanks are provided with overflow lines to route any inadvertent overflow to liquid radwaste collection sumps. All tanks are vented to their enclosures' respective ventilation system. See Section 9.4.3 for a discussion of the radwaste enclosure ventilation system.

All tanks are constructed to API 650. See Table 11.4-1 for tank materials.

11.4.2.2.3 Piping

The system piping material is carbon steel. The external processing station piping is stainless steel. Line sizing is based on maintaining adequate flow velocities to maintain slurries in suspension. The piping is laid out to avoid low points and other features that could create local "hot spots." The lines are normally flushed with condensate after a pumping or draining operation.

Process piping is constructed to ASME Section III, Class 3 or ANSI B31.1 (See Section 3.2 for further details).

11.4.2.2.4 Centrifuges

Two centrifuges were provided to dewater filter sludges and spent resins but are no longer in service. The water removed was returned to a condensate phase separator by gravity, and the dewatered sludges were directed to the HICs. The centrifuges are fabricated of stainless steel and are the continuous-feed, horizontal, solid bowl, sanitary-type.

11.4.2.2.5 Discharge Chute Assemblies

Discharge chutes from the centrifuges are equipped with telescoping fill chutes to interface with the HIC openings. A drip pot and sluice pan mechanism is positioned below the chute during chute flush and while HIC filling is not in progress. Major components with surfaces contacting radioactive materials are fabricated of stainless steel. This equipment is no longer in service.

11.4.2.2.6 Capping Machines

The capping machine automatically caps the HIC. Operation is controlled locally at the process cell viewed through the shielded glass window to verify proper closure. This equipment is no longer in service.

11.4.2.2.7 Solidification and Dewatering Equipment

The solid waste management system does not include a permanently installed solidification capability and the originally installed plant centrifuge system, designed for dewatering, is no longer in service. An external processing station has been provided to accommodate the use of a mobile solidification or dewatering system. Waste processing via a vendor's mobile solidification or dewatering system will be accomplished consistent with the vendor's process control procedures. Processed waste from the vendor's system will be packaged in suitable containers consistent with appropriate NRC and DOT regulations and receiving burial site requirements.

11.4.2.2.8 Decontamination Station Equipment

HICs were washed down with spray nozzles and air blast dried within an enclosed ventilated space within the decontamination cell to minimize the spread of contamination. A swipe sample mechanism and a contact radiation monitor are provided to verify decontamination and to determine the radiation level for shipping considerations. This equipment is no longer in service.

11.4.2.2.9

Information in this section has been deleted.

11.4.2.2.10 Handling Equipment

HIC handling is accomplished by an overhead crane and transfer carts.

The overhead crane moves HICs to and from storage cells and to trucks for offsite shipping. Operations can be viewed through a shielded glass window as well as on closed-circuit television monitors. Two area television cameras and one crane-mounted camera are provided.

HICs are moved in and out of process cells on railed, electric motor-driven transfer carts. If there is a motor failure, the carts can be manually placed in position by a push rod for HIC removal and for repair access. Cart operations are viewed and controlled from the shielded glass window of the process cell. Transfer carts are no longer in service.

11.4.2.3 Expected Volumes (Based on Original Plant Design Estimates)

It is estimated that approximately 12,720 cubic feet of dewatered waste will be generated per year. A breakdown of these wastes is given in Table 11.4-5.
Dry compressed waste is estimated at 28,500 cubic feet per year, representing about 3,886 fifty-five gallon drums per year. Noncompressible dry waste (filters, tools, etc) is estimated at 25,000 ft^3/yr. A breakdown of the dry waste from air filters is given in Table 11.4-6.

Table 11.4-10 presents the expected annual offsite shipment of solid wastes and their curie content.

11.4.2.4 Packaging

Low specific activity and other dewatered wastes, which meet the 10CFR61 classification as Class B and Class C waste, are packaged in large polyethylene HICs. The radioactivity contents of the shipping containers are listed in Table 11.4-7 for both expected and maximum conditions. Class A dewatered wastes may be packaged in HICs, strong, tight containers or other suitable containers. All wet wastes are consistent with the receiving burial site maximum free liquid criteria. Compressible dry waste is packaged in strong, tight containers. Noncompressible dry wastes are packaged in strong, tight containers or other suitable containers. All containers comply with applicable portions of 10CFR71, 49CFR170 through 49CFR178, and the receiving burial site container requirements, when shipped for direct burial.

11.4.2.4.1 HIC Service

The HIC is designed to contain concentrated radioactive waste materials generated during the removal of corrosion and activation products from plant process systems. The specific activity of these materials will range from trace quantities to no greater than 350 $\mu Ci/cm^3$. These values of specific activity include only radionuclides whose half-lives are greater than 5 years. In this specific HIC application, the predominant radionuclides are Co-60, Cs-137, Ni-63, Zn-65, Cr-51, and Mn-54.

The containerized waste form has three main constituents other than the corrosion activation products. These are:

a. Fibrous filter aid material derived from wood pulp fibers (cellulose) - this material is stable with respect to gas evolution in both acidic and basic solutions. In highly acidic solutions, cellulose will liquefy. High levels of ionizing radiation cause a break in the long molecular chains ($C_6H_{10}O_5$) with no significant loss of weight.

   This material is nonprotein and highly resistant to micro-organism ingestion.

b. Ion Exchange Bead Resin - This material consists of cation and anion exchange resins in bead form (O.4 mm to O.5 mm diameter spheres). The individual resin beads are formed from sulfonated polystyrene. The material exhibits chemical stability in pH ranges of O to 14.

c. Ion Exchange Resin Powder - This is identical to the above material; however, it is crushed to powder prior to use.

11.4.2.4.2 HIC Material

The container is to be molded polyethylene. The suitability of polyethylene for this particular application relies on its material characteristics: outstanding dielectric properties, excellent chemical resistance to solvents, acids, and alkalies, toughness, good barrier properties, high environmental stress cracking resistance, good cold impact strength, ultraviolet light stability, and radiation resistance.

11.4.2.4.3 HIC Integrity

Polyethylene is an extremely corrosion-resistant material with a high degree of chemical resistance both to the contents of the HIC and the earthen environment in which it will be buried. Testing will confirm the HIC's ability to withstand vibration, drop, compression, puncture, and pressure tests. Each container receives a variety of quality control checks to confirm individual HIC integrity.

The HIC is designed to maintain its physical integrity for 10 half-lives of the longest lived significant isotope. For routine resin wastes, this is Cs-137 which has a 30 year half-life. Therefore, the lifetime of this HIC is 300 years.

Concrete overpacks are used at the burial site to provide the compressive strength required for burial.

11.4.2.5 Storage Facilities

Storage is provided in storage bays for the HICs. Each HIC is located in its own shielded cubicle with a removable plug on top. There are 11 low specific activity and 12 high specific activity storage cubicles. At the expected waste generation rates presented in Table 11.4-5, the low specific activity storage bay provides a minimum storage capability of 30 days and the high specific activity storage bay provides a minimum storage capability of six months.

The storage compartments and process cell areas where the HICs are handled are equipped with floor drains for washdown of any spillage that may occur.

Compressible and other dry wastes are expected to be of low activity, and the strong, tight containers and other suitable containers will be stored in appropriately controlled unshielded areas throughout the plant before shipment. Storage area is available for at least one truckload of waste.

The general arrangements of the solid radwaste process cells, storage, and shipping areas are shown in Section 1.2.

Sources of radioactivity not stored inside the plant structures are discussed in Section 12.2.1.7.

				Total	8345

(1) The charcoal guard beds are not expected to be replaced during the life of the plant.
(2) Charcoal density: 30 lb/ft^3.
(3) Expected volumes are based on original plant design estimates.

(1) Container inventories are based on the specific activity levels of the source waste as processed by the external processing station and assume a filled container storage period prior to shipment of 15 days for low specific activity waste and 90 days for high specific activity waste.

(2) Low specific activity inventories are based on a prorated mixture of condensate sludge and waste sludge. High specific activity inventories are based on RWCU sludge. Container inventories assume 90% fill.

Table 11.4-7 (Cont'd)

(3) "Other" isotopes consist of daughter products resulting from radioactive decay of the influent isotopes during accumulation and storage periods.

(4) The prorated portion of low specific activity due to waste sludge is based on direct sluicing of exhausted bead resins from the liquid radwaste system to the waste sludge tank.

(5) Values are historical data based on original plant design estimates

(1) Activity inventories are given in curies.

(2) Activity inventory is based on chemical waste processing via the floor drain subsystem (Section 11.2.2.1.3).

(3) Activity of daughter products resulting from radioactive decay of the influent isotopes during the accumulation period.

(4) The floor and equipment drain spent resin tanks are not used for normal plant operation. Exhausted bead resin from the liquid radwaste sytems will be sluiced directly to the waste sludge tank (Section 11.4.2.1.1). The listed waste sludge tank curie inventory represents activity levels of the floor drain, equipment drain, and fuel pool filter/demineralizer backwashes. To determine the waste sludge tank inventory including an exhausted resin bed, the listed isotopic inventory from the appropriate spent resin tank should be added directly to the listed waste sludge tank inventory.

(1) Activity inventories are given in curies.

(2) Activity inventory is based on chemical waste processing via the floor drain subsystem (Section 11.2.2.1.3).

(3) Activity of daughter products resulting from radioactive decay of the influent isotopes during the accumulation period.

(4) The floor and equipment drain spent resin tanks are not used for normal plant operation. Exhausted bead resin from the liquid radwaste systems will be sluiced directly to the waste sludge tank (Section 11.4.2.1.1). The listed waste sludge tank curie inventory represents activity levels of the floor drain, equipment drain, and fuel pool filter/demineralizer backwashes. To determine the waste sludge tank inventory including an exhausted resin bed, the listed isotopic inventory from the appropriate spent resin tank should be added directly to the listed waste sludge tank inventory.

Table 11.4-10

EXPECTED ANNUAL SOLID WASTE MANAGEMENT SYSTEM CONTAINERS TO BE SHIPPED AND ACTIVITY CONTENTS

CONTAINER TYPE	CAPACITY	CONTENTS	EXPECTED ACTIVITY Ci/CONTAINER	ANNUAL QUANTITY OF CONTAINERS FOR SHIPMENT
High integrity	63 ft^3	Dewatered HSA sludge	(1) (3) 337	8
High integrity	120 ft^3	Dewatered LSA sludge	(1) (3) 6.4	118
Steel drum		55 gal dry waste	Compacted $2x10^{-2}$	(2) 3886
Wood box	100 ft^3	Uncompacted dry waste	(2) $6x10^{-3}$	250

(1) Assumes fill to 90% of container capacity.
(2) Estimates based on operational data from PBAPS.
(3) Values are historical data based on original plant design estimates.

11.5 PROCESS AND EFFLUENT RADIOLOGICAL MONITORING AND SAMPLING SYSTEMS

The process and effluent radiological monitoring and sampling systems, including the primary containment radiation monitoring system, are contained in the PRMS. The PRMS is provided to furnish information to operations personnel regarding radioactivity levels in principal plant process and effluent streams to assist in maintaining radiation levels as low as reasonably achievable. The system is also provided to verify compliance with applicable governmental regulations for the containment, control, and release of radioactivity in liquid and gaseous effluents generated as a result of normal or abnormal operation of the plant. The design objectives and criteria are primarily determined by the system designation of either:

a. Safety-related systems

b. Monitoring systems for plant operation, and operator information.

c. Postaccident monitoring and sampling systems

The PRMS is composed of the following process and effluent radiation monitors:

a. Safety-related systems

   1. Main steam line radiation monitors

   2. Reactor enclosure ventilation exhaust radiation monitors

   3. Refueling area ventilation exhaust radiation monitors

   4. Control room ventilation radiation monitors

   5. Control room emergency fresh air radiation monitors

   6. RHR service water radiation monitors

b. For plant operation and operator information

   1. North stack effluent radiation monitors

   2. South stack effluent radiation monitors

   3. Radwaste equipment rooms ventilation exhaust radiation monitor

   4. Charcoal treatment system process exhaust radiation monitors

   5. Recombiner room and hydrogen analyzer compartments exhaust radiation monitors

   6. Steam exhauster discharge and vacuum pump exhaust radiation monitors

   7. Radwaste enclosure and Chemistry Laboratory Expansion ventilation exhaust radiation monitor

8. Air ejector offgas effluent radiation monitors

9. Primary containment leak detector radiation monitors

10. Hot maintenance shop ventilation exhaust radiation monitor

11. Liquid radwaste discharge radiation monitor

12. Service water radiation monitors

13. Reactor enclosure cooling water radiation monitors.

c. Postaccident systems

1. Primary containment post-LOCA radiation monitors

2. North stack wide range accident monitoring system

3. Postaccident sampling system

11.5.1 DESIGN BASES AND SPECIFIC REQUIREMENTS

In general, the radiation monitoring systems are designed to measure and record radioactivity levels, to alarm on high radioactivity levels, and to prevent the release of radioactive liquids, gases, and particulates. The PRMS aids in protecting the general public and plant personnel from exposure to radiation or radioactive materials in excess of those limits allowed by the applicable regulations.

The main objectives of the PRMS for normal operation are as follows:

a. To provide surveillance of radioactivity levels in process and effluent streams from minimum detectable levels to levels commensurate with Technical Specification limits by indicating and recording these levels, by alarming at abnormal activity levels, and by initiating or causing the initiation of corrective action when applicable.

b. To provide data for estimating total released activity.

For some anticipated operational occurrences the PRMS activates necessary isolation or diversion valves, thereby terminating releases if radioactivity levels exceed pre-established setpoints.

The main objective of radiation monitoring systems required for safety is to initiate appropriate protective action to limit the potential release of radioactive materials from the reactor vessel and reactor enclosure refueling area, if predetermined radiation levels are exceeded.

All radiological effluent monitors that actuate an ESF system have been dynamically qualified to the requirements of IEEE 344 (1971). See Section 3.10. In addition, all safety-related radiological effluent monitors that are located in a harsh environment have been environmentally qualified to the requirements of NUREG-0588, Category II.

Radiological effluent monitors that actuate an ESF system were procured in accordance with the requirements of 10CFR50, Appendix B, as interpreted at the time of their procurement. The design

of these monitors and their system is consistent with the quality assurance criteria of Regulatory Guide 1.143, and the factors influencing instrumentation selection identified in ANSI 13.10 (1974) were considered.

Information regarding the process and effluent monitoring system's compliance with Regulatory Guide 1.97 (Rev 2) is provided in Section 7.5. LGS will meet the guidance of Regulatory Guide 4.15 (Rev 1) for roof vent and liquid effluent monitors.

11.5.1.1 General Design Criteria

Specific design criteria for monitoring systems are discussed under the system description when applicable. General criteria taken into consideration in the design of the PRMS are as follows:

a. The PRMS is designed to monitor pathways for release of radioactive materials to the environment in conformance with GDC 60, GDC 63, and GDC 64 and 10CFR50, Appendix I, and Regulatory Guide 1.21.

b. The PRMS provides early warning of increasing radioactivity levels indicative of equipment failure, filter failure, system malfunction, or deteriorating system performance by using a high alarm setpoint.

c. The PRMS initiates prompt corrective action, either automatically or through operator response, on high radioactivity level by using a high-high alarm setpoint.

d. Monitors and detectors are selected with sensitivities and ranges in accordance with radiation levels anticipated at specific detector locations.

e. In general, monitors register full-scale if exposed to radiation levels exceeding full-scale indication. Monitors that do not have this characteristic are designed such that the maximum levels from the DBA do not exceed their upper range with the exception of the north stack effluent normal range monitors when radiation levels exceed the range of the north stack effluent normal range monitors the wide range accident monitor provides indication.

f. Radioactivity levels are continuously indicated and recorded in the control room with the exception of liquid radwaste effluent activity (recorded in the radwaste control room), the PASS system radiation monitors (indicated locally), Steam Packing Exhauster/Mechanical Vacuum Pump discharge, and the hot maintenance shop ventilation exhaust activity (indicated via the RMDS computer locally). The control room air supply, emergency fresh air, hot maintenance shop ventilation exhaust activity, and north and south stack effluent activity are indicated and trended on demand in the control room or indicated locally.

g. Audible control room alarms are initiated on high radioactivity levels and on signal, circuit, or power failures.

h. Monitor components requiring calibration, maintenance and inspection are accessible, and spare equipment is commercially available.

i. Insofar as practical, self-monitoring of components is provided to the extent that power failure or component malfunction causes annunciation and channel trip.

j. Off-line (sampling-type) radiation monitoring systems are designed to be unaffected by background radiation levels of up to 2.5 mRem/hour. Off-line monitors are located in areas where the maximum background does not increase the minimum detectable concentration above the required monitor lower range. Accident dose rates have been considered in locating monitors that are required for safety or postaccident. In-line radiation monitoring systems will generally indicate changes in background radiation levels. Environmental qualification of safety-related components is discussed in Section 3.11.

k. Safety-related components of the PRMS required for safe shutdown are protected against the effects of extreme winds, floods, tornadoes, or missiles by locating them in a structure designed to withstand such conditions (Chapter 3).

l. Safety-related monitors are designed to seismic requirements consistent with the seismic design of the system being monitored.

m. Independence of redundant monitors that are safety-related is maintained by providing adequate separation of detectors, signal cabling, power supplies, and actuation circuits for isolation and diversion valves to meet IEEE 279 criteria.

11.5.1.2 Basis for Detector Location Selection

Normal and potential paths for release of radioactive material are selected for monitoring as follows:

a. Process lines that may discharge radioactive fluids to the environs, in order to indicate the radioactivity level and to alarm in the control room when established limits for the release of radioactive materials are reached or exceeded.

b. Process lines that do not discharge directly to the environs, in order to indicate possible process system malfunctions by detecting increases in radioactivity levels.

Monitored processes and detector locations are listed in Table 11.5-1 and shown in drawing M-26.

11.5.1.3 Expected Radiation Levels

The expected radioactivity concentrations in the process and effluent streams are such that radiation levels at the site boundary are a small fraction of 10CFR20 limits and will be ALARA.

11.5.1.4 Quantity to be Measured

The principal radionuclides to be monitored are indicated in Table 11.5-1. All channels measure gross radioactivity.

11.5.1.5 Detector Type, Sensitivity, and Range

The detectors are Geiger-Muller tubes, ionization chambers, or scintillation crystals that detect either beta or gamma radiation, depending on the application. In general, ion chambers are used in high intensity or high temperature applications, GM tubes are used for gross measurements, beta scintillators are used for relatively precise measurements of noble gases, and gamma scintillators are used for relatively precise measurement of iodines and particulates. The sensitivity

and range are selected so that the alarm setpoint is at least an order of magnitude higher than the detector threshold and so that the instrument reads on scale during normal operation. Detector type, sensitivity, and nominal ranges of each process and effluent monitor are indicated in Table 11.5-1.

11.5.1.6 Setpoints

Setpoints for effluent monitors are established to meet Offsite Dose Calculation Manual Limits as required by the Technical Specifications which encompass 10CFR20 limits and ALARA guidelines. Setpoints for process monitors are established to provide a warning of increased system activity and to initiate corrective action where appropriate. In all cases, the setpoints are established to maintain offsite radiological effects within applicable regulation limits.

Changing of the setpoints is under the administrative control of the plant manager or his authorized delegate.

Two independently adjustable radiation setpoints are provided for most monitors. The high setpoint normally activates only an alarm, while the high-high setpoint activates an alarm and initiates corrective action where appropriate. Setpoints are at least twice the background level if practicable to reduce the number of spurious trips. Radiation monitoring system setpoints and associated functions are provided in Table 11.5-2.

11.5.1.7 Annunciators and Alarms

All process and effluent radiation monitors indicate and audibly alarm in the control enclosure as shown in Table 11.5-2.

An operator can acknowledge the alarm and silence the audible alarm, but he cannot clear the annunciator window until the alarm condition has been cleared at the PRMS panels located in the control enclosure. Radiation alarms can be cleared only if the indication is less than the setpoint.

At the PRMS panels in the control enclosure, the channel that alarmed and the type of alarm are determined by the lights associated with three types of alarms. These alarm lights are as follows:

a. A high alarm light illuminates or a display indication is provided when the radioactivity exceeds preset limits that have been selected to provide an early warning.

b. A high-high alarm light illuminates or a display indication is provided when the radioactivity exceeds preset limits that have been selected to initiate appropriate corrective action. The high-high alarm actuates the trip auxiliaries in those applications where a control trip is automatic.

c. A low (failure) alarm light illuminates or a display indication is provided when the meter reaches a downscale trip point which indicates that there is a detector signal, circuit, or power failure. In certain cases, as shown in Table 11.5-2, this downscale alarm also actuates the trip auxiliaries.

11.5.1.8 Calibration, Maintenance, Inspection, Decontamination, and Replacement

All instruments are calibrated upon installation. Calibration sources are provided for periodic recalibration of the detectors.

Purge capability is provided to all off-line instrument racks. In event of severe contamination, the modules in question or the entire rack may be transferred to the hot maintenance shop for decontamination.

A schedule for periodic replacement of instrument components, such as photomultiplier tubes and detectors, is based on manufacturer's recommendations. Instrument rack installation facilitates access for inspection, testing, maintenance, and repairs.

Components of the radiological monitoring systems are designed for convenient replacement. The assemblies are designed for a minimum life of 40 years when maintained in accordance with the manufacturers' recommendations including periodic parts replacement.

11.5.2 SYSTEM DESCRIPTION

Specific information on the PRMS is tabulated in Tables 11.5-1 and 11.5-2 and arrangements are shown in drawing M-26.

11.5.2.1 Systems Required for Safety

11.5.2.1.1 Main Steam Line Radiation Monitoring System

This system monitors the gamma radiation level exterior to the main steam lines. The normal radiation level is produced primarily by coolant activation gases plus smaller quantities of fission gases being transported with the steam.

The system consists of four redundant instrument channels. Each channel consists of a local detector (gamma-sensitive ion chamber) and a control room radiation monitor with an auxiliary trip unit. Power for two channels (A and C) is supplied from RPS bus A and the other two channels (B and D) from RPS bus B. Channels A and C are physically and electrically independent of channels B and D. One 2-pen recorder allows the output of any two selected channels to be recorded.

The detectors are physically located near the main steam lines just downstream of the outboard main steam line isolation valves in the space between the primary containment and secondary containment walls. The detectors are geometrically arranged so that this system is capable of detecting significant increases in radiation level with any number of main steam lines in operation. Table 11.5-1 lists the sensitivity and range of the detectors.

Each radiation monitor has four alarm circuits: two upscale (high-high and high), one downscale (low), and one inoperative. Each alarm is visually displayed on the PRMS panels located in the control room. A high-high or inoperative signal results in a high-high/inoperative alarm, mechanical vacuum pump shutdown and mechanical vacuum pump suction valve closure. A high alarm actuates a main steam line high radiation annunciator common to all channels. A downscale alarm actuates a main steam line downscale annunciator common to all channels. Each radiation monitor visually displays the measured radiation level.

The MSL-RMS is safety-related and is discussed in detail in Section 7.6.

11.5.2.1.2 Reactor Enclosure Ventilation Exhaust Radiation Monitoring System

This system monitors the radiation level of the air in the reactor enclosure ventilation system exhaust duct prior to its discharge from the structure.

The system consists of four redundant instrument channels. Each channel consists of a local detection assembly (a sensor and converter unit containing a GM tube and electronics) and a radiation monitor. Power for two channels (A and C) is supplied from RPS bus A and the other two channels (B and D) from RPS bus B. Channels A and C are physically and electrically independent of channels B and D. Two 2-pen recorders allow the output of the channels to be recorded continuously. The detection assemblies are located outside the exhaust duct upstream of the ventilation isolation valves.

Each radiation monitor has three alarm circuits: high-high, high, and low. Two high-high trips in channels A and B initiate closure of the reactor enclosure ventilation isolation valves and the startup of the RERS and SGTS train A. The same conditions for channels C and D initiate closure of the corresponding tandem isolation valves and startup of the RERS and SGTS train B. Alternate inboard and outboard valves are actuated independently by the two sets of trip channels. The same logic configuration of the four channels also initiates closure of the primary containment purge and vent valves.

An upscale trip is visually displayed on the affected radiation monitor and actuates a reactor enclosure ventilation high-high radiation annunciator common to all channels. A downscale trip is also visually displayed on the radiation monitor and actuates an annunciator common to all channels. An additional alarm for high radiation is provided by the recorder and actuates a common reactor enclosure ventilation high radiation annunciator. Each radiation monitor visually displays the measured radiation level.

The location and monitoring characteristics of the reactor enclosure ventilation radiation monitoring channels are adequate to provide detection capability for abnormal amounts of radioactivity in the reactor enclosure ventilation exhaust and to initiate isolation. The redundancy and arrangement of channels are sufficient to ensure that no single failure can prevent isolation when required. The upscale trips meet the design requirements of IEEE 279 (1971) as described in Section 7.3.2.2.

11.5.2.1.3 Refueling Area Ventilation Exhaust Radiation Monitoring System

This system monitors the radiation level in the ventilation exhaust duct from the refueling area, including the area over the fuel pool. The monitoring system is identical to the REVE-RMS with the same channel trip logic and protective action initiation, with the exception of the initiation of the RERS.

During refueling operation (including criticality tests), the monitoring system acts as an emergency safety feature against the consequences of a refueling or control rod-drop accident. The response of the REVE-RMS to the refueling accident is discussed in Chapter 15.

11.5.2.1.4 Control Room Ventilation Radiation Monitoring System

This system monitors the radiation level in the supply air to the control room. No measurable activity is expected to be present; however, in the event of a DBA, fission gases could escape from the plant structures and be drawn into the supply air intake. In the Control Room Radiation Isolation Mode HEPA/charcoal filter will remove radioactive particulates and iodines.

There are four independent monitors, separated in accordance with IEEE 279 (1971), that monitor air inside the control enclosure intake duct. These in-line monitors respond to the gross radioactivity in the vicinity of the detectors. Each monitor provides three alarm conditions: low, high, and high-high. The low, high, and high-high alarms trip the control room annunciator. The high-high alarm trips the control room fresh air isolation valves and starts the CREFAS, which provides for the filtration of the incoming air through HEPA/charcoal filters. The trip of any monitor A, B, C, or D shuts off the control room fresh air supply, and the trip of either monitors A and C, or B and D, starts the CREFAS. (See Section 6.4 for a more detailed discussion of control room isolation on detection of high radiation.)

11.5.2.1.5 Control Room Emergency Fresh Air Radiation Monitoring System

Upon initiation of the CREFAS system, this monitor indicates radioactivity concentration levels downstream of control room ventilation HEPA/charcoal filters. Radioactive noble gas concentration is measured. These in-line monitors detect gross radiation only. Two monitors, separated in accordance with IEEE 279 (1971), monitor sample air from the control room emergency fresh air duct.

Each monitor provides three alarm conditions: low, high, and high-high. These alarms trip annunciators in the control room.

11.5.2.1.6 RHR Service Water Radiation Monitoring System

This system is comprised of two monitors for sampling the combined RHRSW loop return flows to the spray pond or cooling tower. One monitor serves Loop “A”, the other serves Loop “B”.

Each monitor provides three alarm conditions: high-high/INOP/DNSCL, high radiation, and high/low sample pump flow. These signals trip annunciators in the control room, and the high-high/INOP/DNSCL trips the RHRSW pumps. Should a monitor failure occur, grab samples are used to measure radioactivity in the fluid.

These monitors are qualified as IEEE Class 1E.

The monitors for sampling the combined RHRSW loop return to the spray pond or cooling tower are safety-related.

11.5.2.2 Systems Required for Plant Operation

11.5.2.2.1 North Stack Effluent Radiation Monitoring System

The NSE-RMS is comprised of two subsystems:

a. North stack effluent monitors for normal plant operation

b. Wide range accident monitoring subsystem

The objectives of the normal plant operation subsystem are to indicate whether the limits of actual release of radioactive material to the environs are reached or exceeded, and to measure the quantity of release of radioactive material during normal plant operation, in compliance with 10CFR50 and Regulatory Guide 1.21.

The NSE-RMS, including the isokinetic sampling system and the wide range accident monitoring subsystem, is designed to carry out the following functions:

a. To provide continuous isokinetic and representative samples of the stack flow in compliance with the requirements of GDC 64, Regulatory Guide 1.21, and ANSI 13.1 (1971).

b. To continuously record releases of radioactive particulates, iodines and noble gases to the environs so that the total quantity of radioactive material released can be evaluated.

c. To alarm, in event that specified rates of release of radioactive material are exceeded.

d. To provide continuous real-time indications of radioactive releases during the accident and postaccident modes of operation.

e. Provide an isolation signal to the containment purge valves in the event of high radiation in the north stack effluent.

The north stack exhausts from the following systems:

a. Unit 1 turbine enclosure exhaust

b. Unit 1 turbine enclosure equipment compartment exhaust (including mechanical vacuum pump exhaust)

c. Unit 2 turbine enclosure exhaust

d. Unit 2 turbine enclosure equipment compartment exhaust (including mechanical vacuum pump exhaust)

e. Radwaste enclosure equipment compartment exhaust

f. Chemistry Laboratory fume hood exhaust

g. Chemistry Laboratory air exhaust

h. Control structure battery compartment exhaust

i. Unit 1 steam packing condenser and effluents from the recombination system

j. Unit 2 steam packing condenser and effluents from the recombination system

k. SGTS enclosure exhaust

l. Unit 1 battery compartment exhaust

m. Unit 2 battery compartment exhaust

n. Control structure toilet room exhaust

o. SGTS filter exhaust

p. Drywell purge system exhaust

q. Offgas treatment system exhaust

r. Radwaste enclosure air exhaust

Sampling stubs are provided on the exhaust ducts of most of the systems listed above for the purpose, of extracting grab samples as needed (see drawing M-26 for specific locations).

11.5.2.2.1.1 Isokinetic Sampling and Radiation Monitoring Systems

Units 1 and 2 share the north stack and consequently the same RMS. Under normal plant operation, the stack flow rate varies from about 350,000 cfm for Unit 1 only in operation to about 668,450 cfm for both units in operation. The expected composition and concentrations of the effluent under normal plant operation are given in Table 11.5-4. Following an accident flow may be reduced.

Under this condition, the flow rate will be below the range capability of the isokinetic sampling system of the north stack normal range monitors, but the wide range accident subsystem will continue to provide representative data. The north stack is provided with three equally spaced honeycomb grids that serve the purpose of stabilizing, equalizing, and collimating the stack flow in order that the exhaust flow rate can be measured accurately and representative air sampling can be achieved. A flow rate sensing array is provided, consisting of 128 uniformly spaced total pressure sensors and 32 uniformly spaced static pressure sensors for providing an instantaneous traverse across the stack. A differential pressure sensor connected to this sensing array provides the stack flow rate signal. To allow maintenance without losing monitoring capability, a redundant stack flow rate signal is provided by nine thermal-type velocity sensors connected to an averaging network. A local switch allows selection of one of the two stack flow signals to be input to the microprocessor-based north stack effluent and wide range accident monitors for isokinetic control of the sample flow rates. The stack flow rate and sampling flow rates are indicated on demand in the control room via the wide range accident monitoring subsystem readout module or the RMDS display consoles (Section 11.5.6).

Two independent sampling arrays, each consisting of a set of 64 uniformly spaced isokinetic nozzles are provided for extracting representative samples at the stack cross-section. One array provides a sample for the normal plant operation radiation monitoring subsystem and the other for the wide range accident monitoring subsystem. Sample bypasses with associated pumps and flow controls are provided to allow the sampling array flow to follow the stack flow rate isokinetically without exceeding the maximum sample flow range of the monitors. The system has the capability to maintain isokinetic conditions with variations in stack flow rate of ±25%. The sample is split into parallel paths. Each half is passed through a particulate filter provided with a radiation detector indicating the corresponding integrated measurement of the particulate effluent, an iodine filter provided with an in-place detector, and a noble gas monitoring chamber. Thus, each of the two redundant monitoring racks provide the following outputs:

a. Sampling flow rates

b. Particulate radioactivity, integrated

c. Iodine radioactivity, integrated

d. Noble gas radioactive concentration

From these data and the stack flow measurement, the total radioactive effluent may readily be evaluated. Readouts from the detectors are fed into microprocessors, which in turn provide outputs to the RMDS display consoles in the control room. The microprocessors are provided with memory retention capability to preclude the loss of data in event of a power failure.

There are one downscale and two upscale common alarms which annunciate abnormal conditions on either monitor in the control room. The upscale alarms indicate high and high-high radiation in any of the three detector channels, and the downscale alarm indicates instrument malfunction.

For the normal plant operation mode, the characteristics of the isokinetic sampling system and radiation monitoring subsystem provide plant operations personnel with complete and accurate data of radioactive materials released to the environs from the north stack. The system thus enables personnel to control activity release rates. Sufficient redundancy is provided to allow maintenance and checking of one channel without losing monitoring capability.

11.5.2.2.1.2 Wide Range Accident Monitor

The wide range accident monitoring subsystem is independent of the normal plant operation monitoring subsystem and operates continuously. Effluent samples are drawn via two sample flow paths. During normal plant operation, one sample, drawn from the second 64 nozzle array described above, is passed through a particulate filter, iodine filter, and low range noble gas detector assembly. This provides redundancy to the normal plant operation monitoring subsystem. If the low range detector approaches its upscale limit, the system automatically starts pumping effluent sample from a separate comb-type probe located downstream of the isokinetic nozzle arrays. This sample is passed through shielded particulate and iodine filters and a midrange and high range noble gas detector assembly. When the midrange detector reaches a preselected point, the low range detector is automatically purged and flow through it is stopped. Purging ensures that the low range detector can resume monitoring when activity again decreases. A similar automatic purge/shutdown cycle is performed on the midrange and high range detectors when activity decreases.

The low range detector assembly consists of a shielded chamber and a beta-sensitive plastic scintillation detector. The midrange and high range detectors use cadmium telluride solid-state sensors housed in a shielded chamber. Detector outputs are fed into the microprocessor that applies conversion factors, determines if alarm setpoints have been exceeded and retains data for each detector channel in history files. In addition, the microprocessor automatically calculates effluent release rate per unit time based on detector measurement and stack flow rate. Background subtraction is provided based on manually entered background values. Outputs of the microprocessor are transmitted to a readout module, the RMDS display consoles, and recorders in the control room. One 3-pen recorder provides indication of radioactivity concentration in the low range, midrange, and high range channels, while effluent release rate is recorded in a digital recorder. The RMDS display consoles can also provide trend printouts on demand of the microprocessor history files. The microprocessors have memory retention in event of loss of power. One downscale and two upscale alarms annunciate abnormal monitor conditions to the control room. The wide range accident monitoring subsystem also provides a nonsafety-related

isolation signal to the containment purge valves on high-high radiation and loss of control power to the system.

The monitor is initially calibrated by the manufacturer using gaseous and solid sources including Sr-90. Transfer sources are then used to transfer this calibration data base to the plant by realigning each detector to the conditions established during primary calibration. Calibration is performed periodically in the plant at designated intervals according to the plant Technical Specifications.

Dissemination of information from this monitor via the RMMS data links to the control room, TSC, and EOF, as well as consideration of radionuclide distribution as a function of time after shutdown in dose assessment is discussed in Section 11.5.6.

The particulate and iodine filters of the wide range accident monitoring subsystem are used as grab sample modules to provide the capability of collecting representative samples of iodines and particulates for onsite analysis during and following an accident. The sample lines are heat traced to preclude entrained moisture in the effluent stream that could degrade the filters. Three removable filter modules are provided in both sample flow paths to allow continuous collection. This also allows the control room operator to select a clean set of filters in order to prevent appreciable concentrations of noble gases produced by iodine decay in a loaded filter, which could be falsely interpreted by the noble gas detectors as high activity in the effluent stream. Controls are provided in the control room to select filters, to grab samples locally and remotely, and to initiate automatically timed grab sampling. Filters on the high activity sample flow path are housed in shielded enclosures designed for ease of removal and replacement of filter media. Filter removal is provided by means of quick disconnect couplings. After removal, the filter is placed in a shielded cask for transport to the onsite analysis facility. The filter enclosure and transport cask have been designed and the access routes have been selected in accordance with the requirements of NUREG-0737 to keep personnel exposure in sample handling and transport below the GDC 19 limits of 5 rem whole body exposure and 75 rem to the extremities during the duration of the accident. The sample filter, constructed of silver zeolite, has a collection efficiency of 99% for iodine and for 0.3 micron particles.

11.5.2.2.2 South Stack Effluent Radiation Monitoring System

The objectives and functions of the SSE-RMS are the same as those of the north stack normal plant operation monitoring subsystem. A system for postaccident monitoring is not provided because any HVAC exhaust to this stack containing accident effluents is automatically isolated.

The south stack encloses two independent exhaust ducts servicing the reactor enclosures for Unit 1 and Unit 2, respectively. The stack exhausts ventilation air from the following systems:

a. Unit 1 Duct

    1. Unit 1 reactor enclosure exhaust

    2. Unit 1 reactor enclosure equipment compartment exhaust

    3. Refueling floor Unit 1 side exhaust

b. Unit 2 Duct

1. Unit 2 reactor enclosure exhaust
2. Unit 2 reactor enclosure equipment compartment exhaust
3. Refueling floor Unit 2 side exhaust

Each of these two ducts is monitored by means of two redundant monitors. Consequently, four independent sets of data are obtained of stack flow rates and corresponding sampling rates.

Flow rates in each of the two ducts vary from about 43,000 cfm to about 223,000 cfm. The expected composition and concentrations of the effluent under normal plant operation are given in Table 11.5-4. The stack flow is collimated to provide a uniform velocity distribution over the entire cross-section to assure representative sampling. Flow rate in each duct is measured by a manifold containing 64 uniformly spaced total pressure sensors and 16 static pressure sensors to provide an instantaneous ongoing velocity traverse. A differential pressure sensor connected to the manifold provides the flow rate signal to both monitors associated with each duct for isokinetic control of the sample flow rate. Sampling is done by an array of 32 uniformly spaced isokinetic nozzles.

Radiation detection in each monitor is done by means of a particulate filter, iodine filter and noble gas chamber in series. Each of these items is shielded and provided with a dedicated detector. The gas chamber has a beta scintillation detector consisting of a beta-sensitive crystal optically connected to a photomultiplier tube.

The other two detectors are similar in construction except that the iodine detector is gamma-sensitive. The output from the preamplifier is fed to a microprocessor, which in turn provides output to the RMDS display consoles in the control room. Digitized outputs are also available locally. Stack flow rates, sampling flow rates, and concentration of particulates, iodines, and noble gases are indicated on demand.

There are one downscale and two upscale common alarms that are annunciated in the control room for abnormal conditions in any of the four monitors. The downscale alarm indicates instrument malfunction and the upscale alarms indicate high and high-high radiation in any of the three detector channels.

11.5.2.2.3 Radwaste Equipment Rooms Ventilation Exhaust Radiation Monitoring System

The common duct that collects exhaust air from the charcoal offgas treatment equipment compartments ventilation ducts is continually monitored for airborne radioactivity. High-high, high, and low radiation are annunciated in the control room. Although particulate/iodine concentration is not anticipated, the monitors are provided with particulate/iodine filters as backups. In the event of a high radiation alarm, the ventilation exhaust from each compartment can be monitored separately.

11.5.2.2.4 Charcoal Treatment System Process Exhaust Radiation Monitoring System

Two charcoal offgas trains (Unit 1 and Unit 2) exhaust the processed gases via HEPA filters to the north stack. Each of the exhaust pipes is monitored to detect malfunction in the corresponding offgas train. Low, high, and high-high radiation are annunciated in the control room.

11.5.2.2.5 Recombiner Room and Hydrogen Analyzers Exhaust Radiation Monitoring System

RRHAC-RMS monitor detects airborne radioactivity in the ventilation ducts of the recombiner compartments, drain sump rooms, and hydrogen analyzer compartments in the control structure. Exhaust air in the common duct from the recombiner compartments and drain sump rooms and the common duct from the hydrogen analyzer compartments is continuously monitored prior to return to the turbine enclosure equipment compartment ventilation filters for eventual release through the north stack. Low, high, and high-high radiation are annunciated in the control room. The source of the radiation can be identified by means of a hand selector switch/solenoid valve arrangement which allows switching the sample line to the individual return duct of potentially contaminated compartments.

11.5.2.2.6 Steam Exhauster Discharge and Vacuum Pump Exhaust Radiation Monitoring System

The SEDVP-RMS monitor provides an indication of radioactivity in the discharge of the steam packing exhauster to the north vent stack. The sampling arrangement allows the capability to also monitor the mechanical vacuum pump exhaust at the water separator discharge when this equipment is operated during startup.

11.5.2.2.7 Radwaste Enclosure and Chemistry Laboratory Expansion Ventilation Exhaust Radiation Monitoring System

Monitoring of the main exhaust duct of the radwaste enclosure and Chemistry Laboratory Expansion provides for general surveillance of gaseous effluents from equipment compartments and access areas of these structures prior to discharge to the north stack. The REV-RMS instrumentation also provides backup for the RERV-RMS monitor. Low, high, and high-high radiation alarms annunciate in the control room.

11.5.2.2.8 Air Ejector Offgas Effluent Radiation Monitoring System

The AEOE-RMS monitors radioactivity in the main condenser offgas after it has passed through the SJAE condenser, recombiner and aftercondenser. This is representative of gaseous radioactivity released from the reactor and therefore indicates the condition of the fuel cladding.

A continuous sample is extracted from the offgas pipe via a stainless steel sample line and passed through a sample chamber and a sample panel before being returned to the suction side of the SJAE. The sample chamber is a steel pipe that is internally polished to minimize plateout. It can be purged with room air to check detector response to background radiation. The sample panel measures and indicates sample line flow. Heat tracing is provided in the sample line between the sample chamber and panel to prevent moisture condensation in the sample panel.

The sample chamber is monitored by three channels. Each channel has a gamma-sensitive ionization chamber mounted outside the sample chamber. Two channels have logarithmic radiation monitors with low, high, and high-high alarm outputs that annunciate in the control room.

The third monitoring channel has linear radiation sensing capability designed to detect radioactive fragments resulting from fuel cladding deterioration. Small changes in the offgas gross fission product concentration can be detected by the continuous use of the linear radiation monitor. The linear radiation monitor is not a process monitor such as the channels described above, but is utilized as an expanded scale device for aiding in measurement of small changes in the offgas radiation level. The detector is a gamma-sensitive ionization chamber that monitors the same sample as the logarithmic monitors. The system uses a linear readout with a range switch instead of a logarithmic readout. The output from the monitor is recorded on a 1-pen recorder.

Grab samples can be obtained for determining isotopic composition by using the semiautomatic vial sampler panel. To draw a sample, a serum bottle is inserted into a sample chamber, the sample lines are evacuated, and a sample valve is opened to allow offgas to enter the bottle. The bottle is then removed and the sample is analyzed in the counting room with a multichannel gamma pulse height analyzer to determine the concentration of the various noble gas radionuclides. A correlation between the observed activity and the monitor reading permits calibration of the monitor.

11.5.2.2.9 Primary Containment Leak Detector Radiation Monitoring System

The design objective of the PCLD-RMS is to detect leakage in the primary containment. The leak detection monitor is designed to monitor and alarm for gaseous radioactivity (Section 5.2.5.2.1.4).

The monitoring system is provided with four main control room annunciated alarms (high-high, high, downscale, and abnormal sample flow). Rate meter output is recorded on a recorder in the main control room.

11.5.2.2.10 Hot Maintenance Shop Ventilation Exhaust Radiation Monitoring System

Equipment serviced in the hot maintenance shop is expected to be contaminated with residual particulate radioactivity. A small quantity of radioactive iodine might also be present. No radioactive gases are anticipated.

Continuous isokinetic sampling of the maintenance shop exhaust duct, downstream of the HEPA filters, is conducted in accordance with ANSI N13.1. The flow controller in the monitor skid maintains isokinetic sample flow proportional to the constant exhaust duct flow. This sample is passed through fixed particulate and iodine filters. Separate detectors measure the gross radioactivity accumulated on these filters. The microprocessor-based monitor calculates radioactivity concentration based on the value of sample flow in memory and measured accumulated radioactivity over a time period. A recording of this radioactivity concentration is made locally, and an annunciator alarms in the event of discharges in excess of limits specified in the radioactive Effluent Controls Program defined in the Technical Specifications. All instrumentation is mounted locally.

11.5.2.2.11 Liquid Radwaste Discharge Radiation Monitoring System

Waste liquid may be discharged on a batch basis from sample tanks in the liquid waste management system as discussed in Section 11.2.3. Prior to discharge, the liquid in the tank is recirculated, sampled, and analyzed for radioactivity, and the release and dilution rates are determined. The expected composition and concentrations of the effluent from each sample tank under normal plant operation are given in Table 11.5-5. The liquid radwaste effluent discharges into the cooling tower blowdown line. The LRD-RMS monitor measures activity in the discharge line to prevent concentration in the cooling tower blowdown line from exceeding ten-times the 10CFR20, Appendix B, Table 2 activity limits (post-1994).

Monitoring is performed in an off-line sample rack in preference to in-line monitoring. This arrangement affords improved sensitivity and precludes the necessity of shutting down the radwaste discharge line in order to purge accumulated radioactive sludge from the monitoring system.

The monitoring channel consists of a gamma scintillation detector/ preamplifier, a rate meter in the auxiliary equipment area, and a 1-pen recorder in the radwaste control room. A low alarm trip will initiate discharge valve closure because the trip circuit has been designed to "fail-safe" in the event of a loss of power. The high trip alarms in the radwaste control room and the high-high trip initiates discharge valve closure. Since the radwaste release is based upon batch analysis, the basis for the alarm setpoint on the monitor is that an alarm be given on a gross release in the range 10^{-6} μCi/cc to 10^{-2} μCi/cc as a gross check against significant operator error. The alarm setpoint may vary from batch to batch depending upon the activity concentration of the batch and the available cooling tower discharge flow that is used to dilute the fluid effluent prior to leaving the site boundary.

11.5.2.2.12 Service Water Radiation Monitoring System

Plant service water return flow discharges to the cooling tower. The return flow is monitored by the SW-RMS monitor. No activity attributable to reactor operation is expected to be present in this line. For radioactivity to be present, leakage would have to occur simultaneously in equipment cooled by the RECW system and in the RECW heat exchanger. Thus, this monitor provides a backup for the RECW-RMS monitor.

Off-line monitoring is selected to facilitate decontamination without shutdown of the service water system. The channel consists of a detector, preamplifier, a rate meter in the auxiliary equipment room, and a 1-pen recorder in the control room. The rate meter provides a high and high-high alarm in the control room. Annunciation due to low sample flow rate also is provided. The alarm setpoint is based upon detecting leakage into the service water with the setpoint set sufficiently above background to preclude spurious alarms.

11.5.2.2.13 Reactor Enclosure Cooling Water Radiation Monitoring System

The RECW system cools components that may contain radioactive liquids, but does not normally carry any radioactive materials unless the cooled components leak. A radiation monitor is provided to measure radioactivity in the system.

An off-line monitor is employed, to facilitate decontamination without shutdown of the reactor enclosure cooling water system. The channel consists of a gamma scintillation detector, preamplifier, rate meter, and 1-pen recorder. The channel is provided with a high and high-high alarm that annunciate in the control room. The high alarm setpoint is set sufficiently above background to preclude spurious alarms. A low flow annunciator also is provided.

11.5.2.2.14 Process Sampling System

A process sampling system is provided to allow grab sampling for evaluation of water quality and radioactivity levels in liquid process waste streams. The sample analysis results will provide operators with information for taking necessary corrective actions. This system is designed to provide representative samples from process streams at central sample stations for use in minimizing leakage, spillage, and potential radiation exposure to operational personnel. Where applicable, means are provided for sample water cooling and for maintaining a fixed or measured sample flow rate. This system is described in Section 9.3.2.

No provisions have been made for sampling and analysis of laboratory and sample waste systems because all laboratory and sample station drains are routed to either the liquid radwaste, normal

waste, or condensate systems, depending on their origin and quality. Processing takes place in their respective systems.

There are no liquid radwaste tanks outside buildings. The condensate and refueling water storage tanks that are located outside of buildings are sampled downstream of their respective transfer pumps via connections to the process sampling system.

Although the process sampling system is designed to provide liquid samples from many plant process streams, radionuclide sampling will be periodically performed on the following process systems:

a. FPCC

b. RECW

c. Liquid radwaste - equipment drain processing

d. Liquid radwaste - floor drain processing

e. Liquid radwaste - chemical and laundry processing

11.5.2.3 Postaccident Systems

11.5.2.3.1 Primary Containment Post-LOCA Radiation Monitoring System

The PCPL-RMS is comprised of four ion chamber sensors for the primary containment in the event of a LOCA. After such a postulated accident, the monitoring system measures the gross radioactivity present in the containment atmosphere. This information is transmitted to control room personnel to provide them with a basis for making safety-related decisions. The PCPL-RMS provides a trip signal to the containment sump pumps on an upscale alarm indication. A downscale annunciator is provided to indicate instrument malfunction.

The sensors are located in separate areas of containment to provide independent measurements and to view large fractions of the containment volume (drawings N-119 and N-134). Consideration to accessibility for maintenance and calibration was given in the selection of the sensor locations. The sensors are located in relatively open areas to prevent shielding that could impair their detection function.

The monitoring system provides energy response from 60 KeV to 3 MeV, with uniform response within ±20% from 80 KeV to 3 MeV. Onsite calibration of the monitors will be performed with a calibrated 100 millicurie Cs-137 gamma source that will provide an effective dose rate of approximately 10 R/hr. A built-in current source is provided in the monitors to allow calibration checks through electronic signal substitution for the decades above 10 R/hr.

Under high drywell temperature conditions, Insulation Resistance (IR) leakage current will cause a system error. Because the instrument signal at low radiation levels is very weak, high temperature IR leakage current significantly affects the accuracy of the indicated readings up to a maximum of 112.5 Rad/hr at the maximum design drywell temperature of 340°F. As a result, the indicated readings below 112.5 Rad/hr may not be within the factor of two accuracy recommendation of Regulatory Guide 1.97 Rev. 2. The induced error decreases exponentially with drywell temperature and becomes insignificant below 230°F. This induced error is significant only under low radiation conditions coincident with high drywell temperatures, whereas the system will operate to perform

its principal function under normal and varying temperature conditions during and following an accident.

11.5.2.3.2 North Stack Wide Range Accident Monitoring System

The north stack wide range accident monitoring system is discussed in Section 11.5.2.2.1.

11.5.2.3.3 Postaccident Sampling System

The PASS is discussed in Section 11.5.5.

11.5.3 EFFLUENT MONITORING AND SAMPLING

The requirements of GDC 64 are implemented with respect to effluent discharge paths by means of the following monitoring stations:

a. Gaseous Effluents:

1. Reactor enclosure ventilation exhaust (Section 11.5.2.1.2)

2. Refueling area ventilation exhaust (Section 11.5.2.1.3)

3. Standby gas treatment system (Section 11.5.2.2.1)

4. North stack ventilation exhaust (Section 11.5.2.2.1)

5. South stack ventilation exhaust (Section 11.5.2.2.2)

6. Charcoal offgas system compartments ventilation exhaust (Section 11.5.2.2.3)

7. Charcoal offgas system effluent (Section 11.5.2.2.4)

8. Recombiner, hydrogen/oxygen analyzers, and equipment drain sump (Section 11.5.2.2.5)

9. Steam seal effluent (Section 11.5.2.2.6)

10. Radwaste enclosure and Chemistry Laboratory Expansion ventilation exhaust (Section 11.5.2.2.7)

11. Hot shop ventilation exhaust (Section 11.5.2.2.10).

Sampling stubs are provided on all major exhaust ducts for the purpose of extracting grab samples as required.

b. Liquid Effluents:

1. Residual heat removal service water (Section 11.5.2.1.6)

2. Liquid radwaste discharge (Section 11.5.2.2.11)

3. Plant service water (Section 11.5.2.2.12).

11.5.4 PROCESS MONITORING AND SAMPLING

The requirements of GDC 60 are implemented with respect to the automatic termination of gaseous and liquid effluent discharges by means of the following monitoring systems:

a. Main steam line (Section 11.5.2.1.1)

b. Reactor enclosure ventilation exhaust (Section 11.5.2.1.2)

c. Refueling area ventilation exhaust (Section 11.5.2.1.3)

d. Residual heat removal service water (Section 11.5.2.1.6)

e. Liquid radwaste discharge (Section 11.5.2.2.11).

The requirements of GDC 63 are implemented with respect to the monitoring of radiation levels in radioactive fuel and waste storage systems by means of the following monitoring systems:

a. Area radiation monitor channels 31 and 32 (Section 12.3.4.1)

b. Refueling area ventilation exhaust (Section 11.5.2.1.3)

c. Radwaste enclosure and Chemistry Laboratory Expansion ventilation exhaust (Section 11.5.2.2.7)

d. Liquid radwaste discharge (Section 11.5.2.2.11).

The following liquid process systems are provided with grab sample stations for laboratory measurement of radioactive concentrations for satisfying the requirements of GDC 63 and GDC 64:

a. Liquid radwaste systems (Sections 11.5.2.2.14.c, 11.5.2.2.14.d, and 11.5.2.2.14.e)

b. Reactor enclosure cooling water (Section 11.5.2.2.14.b)

c. Spent fuel pool treatment system (Section 11.5.2.2.14.a)

d. Residual heat removal service water (Section 11.5.2.1.6)

11.5.5 POSTACCIDENT SAMPLING SYSTEMS

The PASS is designed to obtain representative liquid and gas grab samples from the primary coolant system and from within the primary and secondary containments for radiological and chemical analysis under accident conditions. The grab samples are subsequently transported to the Chemistry Laboratory Expansion and counting facility for chemical and radioisotopic analyses, or shipped offsite for analysis.

The PASS was designed to satisfy certain requirements of NUREG-0737 (Item II.B.3).

Limerick license amendment numbers 166/129 approved the elimination of the requirement to have and maintain the Post Accident Sampling System. The following items were committed to as part of the license amendment numbers 166/129.

1. Limerick has developed contingency plans for obtaining and analyzing highly radioactive samples of reactor coolant, suppression pool, and containment atmosphere. The contingency plans are contained in the Limerick chemistry procedures. Establishment of contingency plans is considered a regulatory commitment.

2. The capability for classifying fuel damage events at the Alert level threshold has been established at a level of core damage associated with radioactivity levels of 300 micro-curies/gm dose equivalent iodine in the primary coolant system. This capability is described in Limerick's emergency plans and emergency plan implementing procedures. The capability for classifying fuel damage is considered a regulatory commitment.

3. Limerick has established the capability to monitor radioactive iodines that have been released offsite to the environs. This capability is described in the emergency plans and emergency plan implementing procedures. The capability to monitor radioactive iodines is considered a regulatory commitment.

The following information contained in the UFSAR regarding the regulatory requirements for post accident sampling is retained for historical purposes.

The system design minimizes operating complexities and "in-line" instrumentation, is modular for maintenance and contamination control purposes, and is compact in size to reduce the amount of shielding required. The system can be used to provide samples under all plant conditions, ranging from normal shutdown and power operation to postaccident conditions.

The PASS P&ID is shown in drawing M-30. The equipment includes isolation and control valves, piping racks, shielded sample stations (gas and liquid), liquid chillers, and control panels. The seismic category, quality group classification, and corresponding codes and standards that apply to the design of the PASS are discussed in Section 3.2. A separate PASS is provided for each unit with common demineralized water and nitrogen support systems.

11.5.5.1 System Description

11.5.5.1.1 Sample Points

a. Wetwell and Drywell Atmospheres

Sample lines are installed to obtain atmosphere samples from two separate areas in both the drywell and wetwell. Drywell samples are taken at el 291' and el 242'. Wetwell samples are taken at el 222' on opposite sides of the containment. The sample lines tap into the CAC system sample lines outside the primary containment and outboard of the second containment isolation valve. Containment gas samples will be representative of conditions throughout the primary containment because the containment is not compartmentalized and the atmosphere is fully mixed.

b. Secondary Containment Atmosphere

A sample line is provided to allow sampling of secondary containment atmosphere noble gases to aid in determining postaccident accessibility of the reactor enclosure. Samples are taken in the vicinity of access doors 191 (Unit 1) and 287 (Unit 2) on el 217'.

The reactor enclosure is not a vital area requiring post accident access as defined in Section 1.13. For design basis events the reactor enclosure is largely inaccessible due to airborne noble gas activity. With use of self-contained breathing apparatus (SCBA), noble gases are the limiting factor throughout the accident. Once accessibility is determined using PASS, reactor enclosure airborne iodine activity can be determined using portable equipment available to HP personnel, in order to assess the need for SCBA in long term accident recovery operations.

c. Reactor Coolant and Suppression Pool

When the reactor is pressurized, reactor coolant samples are obtained from a tap off the jet pump pressure instrument system. The sample point is on a noncalibrated jet pump instrument line outside the primary containment and downstream of the excess flow check valve. This sample point location is preferred over the normal reactor sample points on the RWCU system inlet line and recirculation line because the RWCU is expected to remain isolated under accident conditions, and it is possible that the recirculation line containing the sample line may be isolated. The jet pump pressure tap is in a location protected from damage and debris. This sample point provides representative samples of reactor coolant under various reactor conditions:

1. Normal operation/small pipe break: Reactor water level can be maintained at or near normal water level. With a nearly normal water level, or at least water in the upper plenum, natural circulation will occur with a large loop from the downcomer to the shroud region via the jet pumps. With thermal conditions pumping water up through the core and back down past the tap from which the PASS sample is taken, a representative relationship will exist which will allow the results of the sample to be related to the condition of the core.

2. Large Pipe Break: A large pipe break, such as a recirculation pump suction line break, may occur wherein the water level may be controlled only by the height of the jet pumps and the ability to add water to the vessel. The sample taps are located sufficiently low to permit sampling at a reactor water level even below the lower core support plate. As reactor pressure decays, LPCI is initiated into the core region. This water volume supplies more coolant than is boiled off by the decay heat. This excess water will flow down past the core, up through the jet pumps, and out through the postulated break, assuring a representative sample at the sample point.

To ensure a representative liquid sample from the jet pumps at low (<1%) power conditions for small break or nonbreak events, the reactor water level will be raised to the level of the moisture separator when this action is not inconsistent with station EOPs. This will fully flood the separators and will provide a thermally induced recirculation flow path for mixing. Alternatively, operating at least one reactor recirculation pump 1(2)A-P201 or 1(2)B-P201 at minimum speed or higher will provide sufficient mixing.

Samples will be taken from the reactor via the jet pump pressure instrument lines as long as possible. This allows a more direct and therefore faster response to core conditions. Upon decay or loss of reactor pressure, the jet pump sample point is lost, and the RHR loops sample points must be employed for sampling. Reactor coolant and/or suppression pool samples may be taken from the RHR sample lines, depending on the mode of RHR operation. These sample lines tap off downstream of the second system isolation valve in the RHR system sample lines at the discharge of each RHR heat exchanger.

1. LPCI: Suppression pool water is injected into the core, flows up through the jet pumps, and back to the suppression pool via the postulated break. The system will be operated for an estimated 30 minutes minimum prior to sampling of the suppression pool water to ensure that a representative sample is obtained at the sample taps.

2. Shutdown Cooling: The RHR system, aligned in the shutdown cooling mode, provides cooling and circulation of reactor coolant through the core, resulting in a representative sample at the RHR sample taps.

3. Suppression Pool Cooling: The RHR system, aligned in the suppression pool cooling mode, provides cooling and circulation of the suppression pool water. The system will be operated for an estimated 30 minutes minimum prior to sampling of the suppression pool water to ensure that a representative sample is obtained at the RHR sample taps.

11.5.5.1.2 Isolation Valves and Sample Lines

Containment isolation for the drywell and wetwell gas sample lines is provided by the existing CAC system sample line isolation valves. Jet pump instrument line containment isolation is provided by the existing restricting orifice and excess flow check valve upstream of the sample tap. Containment isolation for the RHR sample lines is provided by the existing RHR sample line automatic isolation valves. All automatic isolation valves can be overridden from the control room. PASS remote-operated sample line valves are controlled from local panels located adjacent to the sample stations.

All safety-related solenoid isolation and control valves that are part of the PASS are environmentally qualified for the conditions in which they must operate. Table 3.2-1 contains a description of the safety-related portions of the PASS, and Section 3.11 contains a description of the equipment qualification program.

Nonsafety-related valves that are part of the PASS are not included in the LGS equipment qualification program. However, those valves that are not accessible for repair after an accident do not contain materials that, if degraded, would prevent the PASS from performing its sampling function.

Sample line routings are as direct and short as practical. Recirculation flow rates in the liquid sample lines are maintained in the turbulent flow regime. The gas sample lines are equipped with heat trace which was originally intended to prevent plate-out of iodine vapor. The PASS is not used for iodine sampling. Therefore, the heat trace is not required for proper gas sampler operation.

11.5.5.1.3 Piping Rack

The piping rack, which is installed within the reactor enclosure, includes sample coolers and control valves that determine the liquid sample flow path to the sample station. The rack provides a flow path to recirculate liquid samples, bypassing the sample stations, until a representative sample condition is obtained. The cooling water is supplied by the RECW system.

11.5.5.1.4 Sample Station and Control Panels

The sample station consists of a floor stand, frame, and sample enclosures, and is mounted flush against the outside of the secondary containment wall. Included within the sample station are equipment trays that contain modularized liquid and gas samplers. The liquid sample portion of the sample station is shielded with 6 inches of lead brick, whereas the gas sampler has 2 inches of lead shielding. The various sample and return lines enter the sample station enclosure through the back by way of a penetration through the reactor enclosure wall. Control instrumentation is installed in two control panels mounted side-by-side. One of these panels contains the conductivity and radiation level readouts. The other control panel contains the flow, pressure, and temperature indicators, and various valve controls and switches. A graphic display is provided directly below the main control panel which shows the status of the pumps and valves. A radiation monitor provides an indication of dose rates in the immediate vicinity of the control panel and is used to limit operator exposure.

11.5.5.1.4.1 Gas Sampler

The gas sample system is designed to operate at pressures ranging from subatmospheric to the design pressures of the primary containment one hour after a LOCA. The sample flow is chilled to remove moisture, and a 15 cc nominal grab sample can be taken for determination of gaseous activity and gas composition by gas chromatography. The gas is collected in an evacuated vial using hypodermic needles. When purging the drywell and wetwell gas sample lines to obtain a representative sample, the flow is returned to the wetwell. During purging of the secondary containment line and when flushing the sample panel lines with nitrogen, flow is returned to secondary containment. The sample station design allows for sample gas or nitrogen flushing of the entire sample panel line downstream of the four-position selector valve. This capability will minimize cross-contamination between the various samples.

11.5.5.1.4.2 Liquid Sampler

The liquid sample system is designed to operate at pressures from 0-1150 psi. The design flow rate of 0.2 to 1 gpm is sufficient to maintain turbulent flow in the sample line and serves to minimize cross-contamination between samples. The flow is returned to the suppression pool. The liquid sampling system is designed to allow demineralized water flushing of the system lines from a point in the piping station through the sampling needles. A radiation monitor in the sample enclosure monitors the sample return to provide assessment of sample activity level and the effectiveness of the demineralized water flush after sampling.

a. Diluted Liquid Sample

All liquid samples are taken into nominal 15 milliliter septum bottles mounted on sampling needles. In the sampling lineup, the sample flows through a conductivity cell (0.1-1000 μmho/cm) and through a ball valve bored to nominal 0.10 milliliter volume. After flow through the sample panel is established, the ball valve is rotated

90°, and a syringe is used to flush the sample and a measured volume of diluent (generally 10 milliliters) through the valve and into the sample bottle. This provides an initial dilution of up to 100:1 nominal. The sample bottle is contained in a shielded cask and remotely positioned on the sample needles through an opening in the bottom of the sample enclosure.

b. Nondiluted Liquid

The sample station can provide depressurized samples of the primary coolant. Ten milliliter aliquots nominal of degassed liquid may be taken for offsite (or onsite depending on activity level) analyses, which requires a relatively large undiluted sample. This sample is obtained remotely using the large volume cask and cask positioner through a needle on the underside of the sample station enclosure .

The PASS system was originally designed to obtain dissolved gas samples from the primary coolant as a means of assessing core damage per NUREG-0737. However, core damage assessment is accomplished by use of the CAC system as described in UFSAR Section 6.2.5. Therefore, this PASS feature is not used.

11.5.5.1.4.3 Sample Station Ventilation

The sample station enclosure is vented to a Zone V room in the secondary containment. Ventilation is facilitated by differential pressure between the control structure and reactor enclosure. The ventilation rate required for heat removal and proper sweep velocity during operation is about 40 scfm. A pressure gauge is attached to the sample station enclosure to monitor the pressure differential between the enclosure and the general sampling area in the control structure. The pressure differential will assure the operator that airborne activity in the sample enclosure will be swept into secondary containment.

11.5.5.1.4.4 Sample Station Sump

The sample station is provided with a bottom sump to collect liquid leakage. This sump can be isolated, pressurized, and discharged into the sample station liquid return line to the suppression pool.

11.5.5.1.4.5 Sample Handling Tools and Transport Containers

Appropriate sample handling tools and transporting casks are used. Gas vials are installed and removed by use of a vial positioner through the front of the gas sampler. The vial is manually lowered into a shielded cask directly from the positioning tool. This allows the operator to maintain a distance of about three feet from the unshielded vial. The cask provides about 1-1/8 inches of lead shielding. A 1/8 inch diameter hole is drilled in the cask so that an aliquot can be withdrawn from the vial with a gas syringe without exposing the analyst to the unshielded vial.

The small volume (diluted) liquid sample cask is a cylinder with a lead wall thickness of about 2 inches. The cask weighs approximately 50 pounds and has a handle which allows it to be carried by one person.

The nominal 10 milliliter undiluted sample is taken in a 700 pound lead shielded cask which is transported and positioned by a four-wheel dolly. The sample is shielded by about 5½ inches of lead. A licensed shipping cask for transport of the undiluted samples to the offsite analysis facility

(Section 11.5.5.2.2) has been procured in conjunction with a group of other utilities. This cask will be placed in a centrally located, continuously attended warehouse facility.

11.5.5.1.4.6 Sample Station Power Supply

The PASS isolation and control valves, sample station control panels, and auxiliary equipment are connected to an instrument ac distribution panel which is powered from an engineered safeguard system bus. Following a LOOP, the engineered safeguard system bus is powered from the onsite diesel generators. The RECW system, which is needed for the sample coolers, is also powered from the emergency diesel generators following a LOOP.

All electrically operated components associated with the PASS are capable of being supplied with power and operated within 30 minutes of an accident in which there is core degradation, assuming a LOOP.

11.5.5.2 Description of Sample Preparation/Chemistry and Nuclear Counting Facilities

After the samples are obtained from the sample station, they will be transported to the Chemistry Laboratory Expansion where they will be diluted as necessary and appropriate aliquots taken for chemical and radioisotopic analysis. The radioisotopic analysis will be done in an area where background radiation can be kept to a minimum. The primary facility for performance of these analyses is the chemistry laboratories and counting room in the Chemistry Laboratory Expansion. In addition to these onsite facilities, which are intended to handle the gas samples and the diluted liquid samples, prior arrangements will be made with an offsite laboratory for supplemental and confirmatory analysis of samples as required.

11.5.5.2.1 Onsite Facilities

The chemistry lab is equipped to handle the gas samples and the nominal 0.1 ml diluted liquid samples. The maximum activities of these samples will be 0.50 Ci and 0.32 Ci, respectively, using one hour decay and the fractional releases of core inventory as discussed in Section 11.5.5.5.

The laboratory will maintain a dedicated inventory of items such as lead bricks for shielding, gas syringes, gloves, reagents for analysis, etc., which will be needed in case of an accident. The laboratory will be equipped with a gas chromatograph, pH meter, conductivity meter, turbidimeter and other instrumentation needed to perform the required analyses. This equipment, however, may not be dedicated exclusively to postaccident analysis. Supplied air or self-contained breathing masks will be available in the event of high activity levels in the ventilation supply or accidental spills in the laboratory.

The primary counting facility located adjacent to the chemistry laboratories in the Chemistry Laboratory Expansion is equipped to handle the gamma spectra analyses required for postaccident samples. The detectors in the counting room are equipped with lead shields connected to computer based analyzer systems which have automatic peak search and isotope identification capabilities. The capability to purge the volume within the shield with compressed gas is available for at least one detector assembly. This will help prevent atmospheric noble gas activity released during an accident from swamping the detector.

It is expected that the first set of postaccident samples will be analyzed in the chemistry lab/counting room facilities located in the Chemistry Laboratory Expansion approximately two hours after the start of an accident. At this time, the chemistry lab will be a Zone III area and therefore accessible for performing the required chemical analyses. The lab becomes a Zone II

area within 20 hours following an accident. The counting room is a Zone II area within two hours, and a Zone I area within 6 hours following an accident. Shielding for the PASS is further discussed in Section 1.13.2 (Item II.B.2).

The most direct route from the sampler location to the chemistry lab is through the control structure and Unit 1 turbine enclosure to the radwaste enclosure on el 217' and then through the doorway (ramp) of the west wall of the radwaste building to the Chemistry Laboratory Expansion. However, during the first 20 hours following an accident, high radiation in portions of this access path require that an alternate route from sampler to labs be taken. Operators must exit through the north of the turbine enclosure, travel around the west end of the radwaste building, and enter the lab/counting room area in the Chemistry Laboratory Expansion through the doorway of the west wall radwaste building.

11.5.5.2.2 Arrangements for Offsite Analyses

A part of the LGS approach to postaccident sampling is the establishment of prior arrangements with an offsite laboratory for confirmatory and supplemental analyses.

11.5.5.3 Sample Collection and Transport Procedures

It is anticipated that the first set of samples will be taken within one hour following a LOCA, with samples taken approximately every 4 hours for the remainder of the first 24 hours. Following day one, it is expected that three samples per day may be taken for the remainder of the first week, with samples once per day following the first week for the duration of the accident.

The following is a conservative time sequence for sampling, transport, and analysis to demonstrate that samples can be obtained and analyzed within the specified 3 hour period:

a. Recirculate sample, install sample vial - 15 min

b. Operate sample station - 15 min

c. Transport sample to lab - 20 min

d. Analyze sample - 60 min

Atmosphere sample lines from the CAC system and liquid samples from the RHR system are automatically isolated following a containment isolation signal. The sample station operator(s) must confirm with the control room personnel that the necessary isolation valves are opened. A telephone extension to the control room is provided near the PASS control panel.

Controls for all other PASS sample line valves are located on or adjacent to the PASS control panel. All controls for valves that are a part of the sampler or piping rack are located on the PASS control panel.

Following a series of presampling checks and procedures, including adjustment of the enclosure damper to ensure adequate ventilation, checks of demineralized water and nitrogen supplies, flushing of system with demineralized water, draining the trap and sump, etc., the system is ready for obtaining the samples.

11.5.5.4 Chemical/Radiochemical Procedures

The PASS provides a means of obtaining primary coolant, suppression pool, and primary and secondary containment air samples for radiochemical and chemical analysis following a major reactor accident. Because of the extremely high radioactivity levels associated with extensive fuel damage, the PASS was developed to provide the capability of obtaining the necessary samples and performing analyses, as required, for immediate plant needs, or as defined by regulatory requirements. Procedures have been established for shipping samples to appropriate facilities to perform detailed analyses on multicurie level samples.

11.5.5.4.1 Sample Preparation

All sample bottles, etc., will be identified prior to sampling to eliminate unnecessary exposure resulting from handling high level samples. A centralized logging system will be developed to track sample aliquot identification, dilution factors, sample disposition, etc.

Liquid samples will be taken at the sample station in septum-type bottles and transported to the analysis facility in lead containers.

Sample aliquots are taken from the septum bottles for analysis or further dilution. Aliquoting and transfer will be performed using shielded containers, or behind a lead brick pile. Calibrated hypodermic syringes will be used for aliquoting the higher activity samples. Tongs or other holding/clasping devices will be available for holding the sample bottle during the transfer and dilutions to reduce hand and body exposure. Unless prohibited by the intended analysis, dilutions will be done using very dilute (about 0.01 N) nitric acid as the diluent to minimize sample plateout problems.

Primary coolant samples obtained from the sampling station are diluted by a factor of 100 (0.1 ml coolant diluted to 10 ml). Under severe accident conditions, a calibrated syringe would be used to obtain an aliquot for this sample for further dilutions. At the maximum expected primary coolant activity level (3 Ci/cc), a dilution factor of 1×10^5 would be required for gamma spectroscopy.

Direct counting of the initial nominal 100:1 dilution sample would allow analysis at coolant activity levels down to 1 μCi/cc. In addition, the degassed, undiluted nominal 10 ml sample available from the sample station could be used for analysis of samples in the 10^{-2} μCi/cc to 10^{-3} μCi/cc range. Thus, useful samples may be obtained from the postaccident sampling station for coolant activity levels ranging from DBA source terms to well below the maximum level that can be tolerated at the normal reactor sample station.

Gas samples are taken at the sample station in a nominal 15 milliliter septum bottle. A lead carrier is furnished with a small hole at the septum end so that a gas sample can be withdrawn from the carrier using a hypodermic syringe without having to handle the bottle.

Samples taken from the gas sample bottle will either be injected into a gas chromatograph for analysis or diluted for gamma spectroscopy. The dilutions will be performed in a manner analogous to the liquid samples. Fractional milliliter samples can be transferred to new 15 ml gas bottles without concern for sample leakage due to pressurization. For larger volume aliquots, a gas syringe will be used to draw a partial vacuum in the bottle prior to sample transfer.

11.5.5.4.2 Chemical Analysis

Approved chemistry procedures are chosen on the basis of simplicity, stability, minimum of radiation exposure and least likelihood to cause major contamination problems. They have been

tested for radiation sensitivity and are suitable for use at the PASS design basis source term of 3.13 Ci/gm, and where applicable, with the design basis 0.1 ml to 10 ml nominal dilution at the sample station.

a. Gross activity, gamma spectra analyses will be accurate within at least a factor of two over a coolant activity range of 10 μCi/cc to 10 Ci/cc (Additional information is provided in Section 11.5.5.4.1).

b. Boron concentrations will be determined by an approved Chemistry procedure. Concentrations between 50 ppm and 1100 ppm are of interest for BWR reactivity control in the event sufficient control rods are not inserted to shutdown the reactor. The approved method with the 100:1 diluted sample will have an accuracy of ±10% over the described range.

   Tests have been performed to verify that none of the expected post accident chemical constituents (I, Cs^{+}, Ba^{+2}, La^{+3}, Ce^{+4}, Cl^{-}, B, Li^{+}, NO^{-3}, NH^{+4}, K^{+}) will interfere with this analysis method.

c. The chloride analysis performed onsite will be accomplished using an approved Chemistry procedure. The use of the method with the nominal 100:1 diluted sample will result in a accuracy of at least ±10% for coolant concentration over the range of 500 ppb to 20 ppm.

   Tests have been performed to verify that none of the expected post accident chemical constituents listed above will interfere with the results of this analysis for the procedures and equipment which will be employed.

   Offsite provisions for chloride analysis will be accurate ±10% over the range 0.5 ppm to 20 ppm and ±0.05 ppm below concentrations of 0.5 ppm.

d. A combination electrode will be used to measure the pH of coolant samples. Testing performed by GE has verified that expected levels of irradiation result in a shift of less than 0.3 pH units.

e. The postaccident sample station is equipped with a 0.1 cm^{-1} conductivity cell. The conductivity meter has a linear scale with a six-position range selector switch to give conductivity ranges of 0-3 μmho/cm, 0-10 μmho/cm, 0-30 μmho/cm, 0-100 μmho/cm, 0-300 μmho/cm, and 0-1000 μmho/cm when using the 0.1 cm^{-1} cell. This conductivity measurement system will be used to determine the primary coolant or suppression pool conductivity. During normal operation the LGS Technical Specifications require maintaining the primary coolant below 1.0 μmho/cm (at 25°C), and conductivity measurements are the primary method of coolant chemical control.

   Conductivity measurements are, of course, nonspecific, but they serve the important function of indicating changes in chemical concentrations and conditions. Perhaps even more important, in the case of the BWR primary coolant, the conductivity measurements can establish upper limits of possible chemical concentrations and can eliminate the need for additional analyses.

The conductivity measurement can also be used to bound the possible range of pH values.

11.5.5.4.3 Radiochemical Analysis/Gamma Ray Spectroscopy

After the samples have been brought to the chemistry laboratory and appropriately diluted, they can be carried without shielding to the counting room which is adjacent to the chemistry laboratory. The appropriate dilution factors will be somewhat dependent on the detector and shelf arrangements available. A prior determination of the maximum desirable dose rates for the various shelf configuration will be made to minimize this problem. The present Gamma Spectrometer in the onsite counting room will handle the analysis of these samples within 3 hours from the time a decision is made to sample.

The gas samples will be counted in the PASS gas sample vials, and the liquid samples will be counted in the standard sample bottles used during normal operation because calibration curves for these geometries will be available and regularly updated. In general, the counting of the postaccident sample will follow the normal counting room procedures. The peak search and identification library will contain the principal gamma rays of the following isotopes in addition to the standard activated corrosion products:

a. Noble gases: Kr-85, Kr-85m, Kr-87, Kr-88, Xe-131m, Xe-133, Xe-133m, Xe-135

b. Iodines: I-131, I-132, I-133, I-135

c. Cesiums: Cs-134, Cs-137

d. Others: Ba/La-140, Ce-141, Ce-144, Ru-106, Te-129, Te-129m, Te-131, Te-131m, Np-239

If the levels of noble gases in the ambient atmosphere surrounding the detector are high enough to cause significant interference or to overload the detector, a compressed air or nitrogen purge of the detector shield volume will be maintained.

The onsite radiological and chemical laboratory facilities are equipped with gamma spectral analysis equipment to quantify the radionuclides present in gas and liquid samples. Shielding is provided for the radiation detectors to minimize the effect of background radiation. Initial dilutions are performed in the process of taking liquid samples at the sample stations. Any additional dilutions required will be performed in the laboratory fume hood behind a lead brick pile.

11.5.5.4.4 Gas Analysis

A gas chromatograph will be used to measure hydrogen and oxygen concentrations in containment atmosphere. The accuracy of the containment gas analysis will be at least ±5% between 0.1% and 30% (volume) of the constituent.

11.5.5.4.5 Determination of Extent of Core Damage

A generic procedure to assess the extent of core damage based on radionuclide concentrations and other parameters has been prepared by the BWROG and transmitted to the NRC by letter from T.J. Dente (BWROG) to D. Eisenhut (NRC) dated June 17, 1983. A licensee procedure based on this methodology has been prepared and transmitted to the NRC.

11.5.5.4.6 Storage and Disposal of Sample

Short-term sample storage areas will be provided in the chemistry laboratory and counting room facilities. The area to be used for long-term storage of the samples is the source storage room, number 244, in the radwaste enclosure. Low level wastes generated by the chemistry procedures will be flushed to radwaste. Ultimate procedures for disposal of the samples will be determined later; however, after a sufficiently long decay period, the activity levels will be significantly reduced. This will ease exposure problems during disposal.

11.5.5.4.7 System Testing and Operator Training

Equipment used for post-accident sampling and analyses will be calibrated and tested per an approved preventive maintenance program. The testing program is designed so that sampling operations are conducted approximately every twenty-four months.

11.5.5.5 Dose Rate Analysis

The post-LOCA core inventory of fission products was calculated assuming a three year irradiation, 100% availability, and reactor operation at 102% of rated power. Fractional releases of fission products from the fuel to the reactor water, suppression pool, and containment atmosphere were based on Regulatory Guide 1.3 and Regulatory Guide 1.7 assumptions. The resulting source terms were used in the design of PASS shielding and in determining doses to operators.

The sampling and analysis provisions at LGS have been designed such that it will be possible to obtain and analyze a sample following an accident without exceeding the criteria of GDC 19. Time sequences and calculated dose rates to verify compliance for a sample taken one hour post-LOCA are given in Table 11.5-3.

11.5.6 RADIATION AND METEOROLOGICAL MONITORING SYSTEM

11.5.6.1 General Description

The RMMS is a system consisting of data acquisition computers with report generating capabilities designed to perform the following functions:

a. Collect radioactivity level information from selected microprocessor-based process radiation monitors throughout the plant

b. Remotely operate radiation monitors

c. Display radiation levels

d. Generate radioactive effluent reports for compliance with Regulatory Guide 1.21

e. Calculate offsite dose consequences from normal plant operation releases

f. Calculate offsite dose consequences from accident conditions in accordance with NUREG-0654.

g. Meteorological data is transmitted from the met towers to Unit I PMS for display, averaging and transmission to EPDS.

11.5.6.2 RMMS Hardware Description

Deleted

11.5.6.2.1 Radiation Monitoring and Display System

The RMDS is a dual-computer system that monitors, stores, and displays information obtained from selected process radiation monitors described in Section 11.5.2.

The RMDS also transmits radioactivity concentration and stack flow rate information obtained from the process radiation monitors to the EPDSto be used in calculating offsite doses.

The RMDS dual-computer configuration is designed with one computer being the primary computer. The computer collects data from the process radiation monitors and displays the data on RMDS workstations. The second computer is redundant and will take over the functions of the primary computer, if the primary computer fails. The dual hardware configuration gives increased assurance of the availability of radiation monitoring data to plant personnel through the RMDS workstations and to the EPDS through a data link.

In the RMDS dual-computer configuration, each computer is capable of storing dynamically created data. RMDS workstations located in the control room and TSC are interfaced to the RMDS computers to allow the access of information from the computers and process radiation monitors and to display process radiation monitors status.

The RMDS has data links that communicate with process radiation monitors located throughout the plant. The RMDS also has a data link that communicates with the EPDS. The EOF has access to RMDS data through the EPDS. The two RMDS computers communicate with each other and with the workstations over a local area network.

The RMDS provides process radiation monitors status and RMDS status through annunciation of alarm conditions at the RMDS display consoles to supplement the process radiation monitors alarms at the plant annunciator panel. The operator is alerted of abnormal conditions through visual alarms located at each RMDS display console. Trend displays of the process radiation monitors data are available as demand prints are available for display or hard copy at the RMDS display consoles.

11.5.6.3 RMMS Software Description

11.5.6.3.1 RMDS Software Description

The RMDS software is designed to help the plant operator display and retrieve information from the RMDS and the process radiation monitors memory, and to initiate process radiation monitors control functions. The RMDS software also handles the communications interface between the process radiation monitors and the RMDS and between the RMDS and the EPDS.

The RMDS software consists of the following programs:

a. Operator interface programs to allow operator communications via the RMDS workstations

b. Alarm log and display programs

c. System fail-over software

d. Communications software and control programs.

e. Collect, quality check (evaluate), and report radiological effluent release data from onsite monitors

11.5.6.3.2 Effluent Release Software Description

The Effluent Dose Calculation Computer Program is designed to help the plant operators and health physicists meet NRC regulatory requirements for measuring, evaluating, and reporting releases of radioactive materials in gaseous and liquid effluents and for classifying and reporting the categories and the curie content of radioactive solid wastes. The software functions are grouped into the following two categories:

a. Generate a data base and store data in a retrievable form

b. Compute short-time or accumulated offsite radiation doses from various effluent discharge pathways caused by the release of gaseous and/or liquid radioactive materials.

In performing the above functions, the procedures used adhere to specific guidelines. Calculations of liquid dispersion use either site specific factors or equations that conform to the standards of Regulatory Guide 1.113; and calculations of radiation doses conform to Regulatory Guide 1.109 (Rev 1). Effluent release summaries and the environmental pathway dose summary are prepared in accordance with Regulatory Guide 1.21 (Rev 1). The above regulatory guides and 10CFR50, Appendix I were used to develop the Effluent Dose Calculation software.

The functions that the Effluent Dose Calculation software performs are related to routine operations. The operator is provided with the capability to inspect the contents of the data base and to perform dose calculations. The operator can perform both gaseous and liquid effluent calculations. The method used to perform gaseous calculations is based on hourly averages of meteorological and effluent data. Liquid calculations are based on batch release data.

To satisfy NRC reporting requirements for routine operation, the Effluent Dose Calculation Software has the capability to generate two reports:

a. An effluent release summary, describing releases of gaseous and liquid effluents and shipments of solid waste

b. An environmental pathway dose summary, showing total body and body organ doses by age group for environmental pathways for gaseous and liquid effluents.

The dose assessment model performs calculations of atmospheric dispersion and dose for accidental release of gaseous effluent. To perform calculations of atmospheric dispersion (X/Q values), the dose assessment model prompts the operator to enter meteorological data.

Meteorological data is used to compute the dispersion conditions for a given release point. Dose calculations can be done using radiological release data obtained automatically from the EPDS or entered manually by the operator.

The dose assessment model is described in detail in the Emergency Plan.

The results of the accidental dose calculations, in addition to being available at the control room, TSC, and EOF, are available to local, State, and Federal emergency officials.

Table 11.5-1

PROCESS AND EFFLUENT RADIATION MONITORING SYSTEMS

MONITORED PROCESS	TOTAL NO. OF CHANNELS (BOTH UNITS)	DETECTOR TYPE	DETECTOR LOCATION	CHANNEL RANGE	SENSITIVITY	PRINCIPAL RADIONUCLIDES MEASURED
Main steam line	8	Gamma-ion chamber	Immediately downstream of main steam isolation valve	1 to 10^6 mrem/hr	1 mrem/hr	Coolant activation gases
Reactor enclosure exhaust	8	Gamma-GM	Reactor enclosure exhaust duct	0.01 to 10^2 mrem/hr	0.01 mrem/hr	Kr-85
Refueling area exhaust	8	Gamma-GM chamber	Refueling area exhaust duct	0.01 to 10^2 mrem/hr	0.01 mrem/hr	Kr-85
Control room supply	4	Beta-scint	Main intake ventilation duct	10^{-4} to 10^1 μCi/cc	$1x10^{-6}$ μCi/cc (Xe-133)	Kr-85
Control room emergency fresh air	2	Beta-scint	Emergency fresh air supply duct	10^{-4} to 10^1 μCi/cc	$1x10^{-3}$ μCi/cc (Xe-133)	Kr-85
RHR service water	2	Gamma-scint	Common RHRSW/ESW Discharge Lines	10 to 10^6 counts/sec	$1.29x10^{-7}$ μCi/cc (Cs-137)	Cs-137 Co-60
North stack				(1)

(1) NA designation in this column means that an associated alarm is not provided.
(2) Monitoring system inoperative alarms are also provided for this process. The alarm performs the same function as the high-high alarm.
(3) In addition to the alarms shown, these processes also are provided with high/low flow alarms that annunciate in the control room.
(4) In addition, low sample pump flow alarms annunciate in the control room.
(5) This system is used for particulate/iodine monitoring only.
(6) Setpoints are determined after normal background values are established during startup testing. The high setpoint is set at twice the background value if practicable.
(7) Setpoints are factory set based on parameters of the detector.
(8) A bias source is provided in this monitor to maintain minimum indication when the ambient radiation is below channel range.
(9) Low setpoint is set below expected radioactivity concentration for normal operation. High setpoint is set at twice this value if practicable.
(10) Setpoints are set significantly above background to prevent nuisance alarms (Section 5.2.5.2.1.5).
(11) This monitor is used for information only. Setpoints may be set for operator information above normal radioactivity concentration values established during startup testing.
(12) Setpoint not to exceed 2100 mR/Hr.

Table 11.5-3

POSTACCIDENT SAMPLING
DOSE ASSESSMENT[1][2]

Liquid Sample	Time (min)	Background Dose Rate (mR/hr)	Sample Dose Rate (mR/hr)	Integrated Dose Rate (Rem)
Recirculate Sample	5	722	27	0.06
Operate Sampler	5	722	112	0.07
Transport Sample Cask	10	3766	8	0.63
Handle Sample	10 sec	9	182	0.01
Analyze Sample	20	9	91	0.03
Total				0.80
Gas Sample				
Recirculate Sample	5	722	75	0.07
Operate Sampler	5	722	289	0.08
Handle Bottle	1	722	332	0.02
Transport Sample Cask	10	3766	43	0.63
Analyze Sample	20	9	37	0.01
Total				0.82
Total (All samples)				1.62

(1) Doses listed are 1 hour post-LOCA, except for those associated with MSIV Leakage Alternate Drain Pathway. Worst case doses resulting from this pathway peak are at 4 days and are:

	Liquid Sample	Gas Sample	Iodine/Particulate Sample	Total
WHOLE BODY(REM)	0.036	0.037	0.036	0.11
BETA SKIN(REM	0.0007	0.0008	0.0007	0.0032
THYROID (REM)	0.20	0.20	0.20	0.60

(2) Some additional dose to extremities will result from the limited handling of samples in the laboratory. Because of the use of sample dilutions, small volume samples, shielded casks, lead brick piles, and laboratory extension devices (i.e., tongs), doses to the extremities are estimated to be 100 mR to 200 mR for each sample.

Table 11.5-4

GASEOUS EFFLUENTS COMPOSITION AND CONCENTRATIONS

		Concentrations[1] (μCi/cc)	
		South Stack	North Stack
Noble Gases	Ar-41	7.18×10^{-9}	[4]
	Kr-83m	[3]	[4]

(1) Concentrations are prior to dilution in the cooling tower blowdown, and may increase in proportion to power. Sample tank pump capacities are presented in Table 11.2-10.
(2) Equipment drain sample tank discharges are routed to the cooling tower blowdown line via the floor drain system.

CHAPTER 12- RADIATION PROTECTION

12.1 ENSURING THAT OCCUPATIONAL RADIATION EXPOSURES ARE AS LOW AS REASONABLY ACHIEVABLE

12.1.1 POLICY CONSIDERATIONS

12.1.1.1 Management Policy

It is the licensee's policy to maintain occupational radiation exposure ALARA at LGS. This includes maintaining the annual dose to individuals working at the station ALARA, and keeping the annual integrated dose to station personnel ALARA. The management of this company is firmly committed to performing all reasonable actions to ensure that radiation exposures are maintained ALARA.

Sections 12.1.2 and 12.3 discuss the ALARA considerations that have been incorporated into the design of the LGS.

LGS will be operated and maintained in such a manner as to ensure that occupational radiation exposures are ALARA and that protection against radiation is in accordance with 10CFR20. The health physics provisions which accomplish this goal are described in Section 12.5.

12.1.1.2 Management Responsibilities

Chapter 13 describes the Limerick Generating Station operating organization and the licensee's corporate organization.

The President and Chief Nuclear Officer has the ultimate responsibility for operation of the Limerick Generating Station. This responsibility includes those activities necessary to ensure that radiation exposures are maintained ALARA. Responsibility is delegated to the Senior Vice President - Nuclear Operations and to the Vice President - Station Support (for all activities performed by the Station Support Department), and to the Vice President - Limerick Generating Station for all activities performed at the station. The Station Support Department provides technical support as needed to the Limerick Generating Station health physics organization in an effort to maintain the highest standards of exposure minimization. The Vice President - Limerick Generating Station delegates responsibility for the ALARA program through the Plant Manager to the Radiation Protection Manager who has responsibility for all actions required to maintain station exposures ALARA. The responsibilities of the Station Support Division staff, the Plant Manager, and Radiation Protection Manager in regard to ALARA are further described in Section 13.1.2.1.2. These responsibilities correspond to the applicable functions described in Regulatory Guide 8.8, Rev. 3 and Regulatory Guide 8.10, Rev.1.

12.1.1.3 Policy Implementation

The licensee provides the environment and support for the ALARA policy to function. The company's commitment to this policy is manifested in the plant design, established procedures, the provisions for review of procedures and plant design, provisions for subsequent procedure revisions and plant modifications, and the establishment of extensive varietal training programs.

General Employee Training, which encompasses radiological health aspects, is described in Sections 13.2.1.2. Such training enhances personnel awareness of licensee management's policy

of maintaining exposures ALARA, of actual and potential problems, and of the need to develop proper attitudes. The training stresses the individual's responsibility to cooperate in maintaining exposures ALARA and the importance of adhering to approved procedures. The content of the training is adjusted in recognition of the duties, responsibilities, and anticipated radiation exposure of those receiving instruction and includes information on the biological effects of such exposure. The staff of the Radiation Protection Manager has well defined functions, responsibilities, and authorities to ensure proper supervision and implementation of health physics procedures. The Radiation Protection Manager has the authority to prevent unsafe practices and to direct steps to prevent any unnecessary radiation exposures. The plant staff health physics group assures that communication with supervisors of the various station service groups (e.g., maintenance, construction, instrument technicians, contractors) and operating supervisors occurs for the purpose of evaluating a course of action regarding ALARA for specific station activities. Such evaluation includes the review of appropriate procedures; the extent of existing or potential hazards, occupationally and to the general public; and the merits of applying special techniques to the performance of a job. Such communication with work forces is an effective means to respond to worker questions and concerns and to obtain information on actual working conditions, such as mobility, access, habitability, and necessary tooling, which can lead to future improvements.

The plant staff health physics group is knowledgeable of the origins of radiation exposure in the plant and its magnitudes. They recognize which jobs or locations cause the highest exposures. This information is obtained via area surveys, Radiation Work Permits (or equivalent), and personnel dosimetry. Analysis of these and other data for repeat or similar activities is performed to determine whether exposures are being decreased or at least prevented from increasing. There is prompt investigation of exposures of record which exceed expected values. Judicious application of dose extensions is exercised by review of prior data and analysis of the need for the exposure. The health physics procedures provide for appropriate documentation of reviews, surveys, analyses, and investigations such that corrective action or modification may be accomplished and subsequent data may be compared to the original data to verify effectiveness of the change. The need for modification to satisfy ALARA shall be based on consideration of the economics of equipment modification in relation to benefits to health and safety and other societal and socioeconomic considerations, including the utilization of atomic energy in the public interest.

To verify that the health physics operations at the station are functioning within the ALARA concept, a formal review shall be performed under the cognizance of the Station ALARA Council every three years (based upon the date of commercial operation of Unit 1). The review shall include review of applicable station procedures and practices, exposure records, the content of training programs which affect ALARA considerations, and consultation with the plant staff health physics group. The objective of the review is to evaluate the adequacy of the ALARA effort and, as appropriate, to determine means to lower exposures. The results of the review shall be documented, including identification of the procedures and records reviewed, the review team's evaluation, and any recommendations for improvements.

12.1.2 DESIGN CONSIDERATIONS

This section describes those considerations which are applied to the plant design for the purpose of incorporating features which provide for maintaining occupational radiation exposures ALARA.

Refer to Sections 12.3.1, 12.3.2, and 12.3.3 for details of design for maintaining personnel radiation exposures ALARA.

Experiences and data from operating plants are evaluated to decide if and how equipment or facility designs can be improved to reduce overall plant personnel exposures. During plant design,

operating reports and data such as that given in WASH-1311, NUREG-75/032, NUREG-0109 and Compilation and Analysis of Data on Occupational Radiation Exposure Experienced at Operating Nuclear Power Plants (References 12.1-1 through 12.1-4, respectively), are reviewed to determine which operations, procedures or types of equipment were most significant in producing personnel exposures. Methods to mitigate such exposures have been implemented wherever possible and practicable.

12.1.2.1 General Design Considerations

The objectives of the plant design for ALARA purposes are: to minimize the need for, and duration of, personnel access into high radiation areas, and to establish radiation levels as low as practicable in routinely occupied areas.

Both equipment and facility designs are considered in achieving these objectives during plant operations including normal operations, maintenance and repair, refueling operations, fuel storage, inservice inspection, waste handling and disposal, and other anticipated operational occurrences.

In addition to equipment and facility designs, system designs are considered to ensure that exposures are maintained ALARA. For example, both the primary coolant system and the condensate system are provided with cleanup capability to reduce the inventory of circulating corrosion products. This is one of the methods employed to minimize both the activation of these corrosion products and their subsequent deposition on the interior surfaces of piping and equipment.

The project design organization is responsible for ensuring that the design and construction of the facility are such that occupational exposures are ALARA. To the extent practicable, this includes:

a. Design concepts and station features that reflect consideration of the activities of station personnel that might be anticipated and that might lead to personnel exposure to substantial sources of radiation; and assurance that station design features have been provided to reduce the anticipated exposures of station personnel to these sources of radiation.

b. Specifications for equipment that reflect the objectives of ALARA, including among others, considerations of reliability, durability, serviceability, and limitations of internal accumulations of radioactive material.

12.1.2.2 Equipment Design Considerations

Considerations for equipment design include:

a. Reliability, long service life, maintenance and calibration requirements, durability.

b. Convenience for servicing, including disassembly and reassembly, modular design concept for rapid component replacement, removal for servicing in lower radiation area.

c. Remote operation, inspection, monitoring, servicing, and repair including the use of special tools or equipment.

d. Redundant equipment to reduce the urgency for immediate repairs, thus providing time for planning repairs with ALARA in mind.

e. Isolation, draining, flushing, or decontamination of systems to reduce crud deposition and thus reduce radiation levels.

f. Isolation of components from contaminated process fluids.

g. Use of high quality components, such as valves, which minimize or preclude the leakage of radioactive material.

h. Use of closed drain systems for contaminated process fluids to preclude the creation of airborne contamination that is due to spillage.

12.1.2.3 Facility Design Considerations

Considerations for facility design include:

a. Location of equipment according to the need for access to maintain, inspect, monitor, or operate so as to minimize radiation exposure.

b. Use of valve stem extensions, articulated if necessary, to operate valves from behind shield walls.

c. Transport of contaminated components for service in lower radiation areas or for reuse in other parts of the plant.

d. Separation of sources of radiation such as pipe runs, storage tanks, and filters from normally occupied areas.

e. Use of permanent shielding between sources of radiation and access and service areas.

f. Maintaining ventilation flow paths from clean areas to contaminated areas.

g. Use of surface coatings to facilitate decontamination.

h. Use of labyrinth entrances to shielded cavities.

12.1.2.4 ALARA Design Review

For the operating plant, procedures provide for review of subsequent plant design and modifications by the radiation protection group, when applicable, and documentation of an ALARA design review. Procedures are described in Section 12.1.3. The following material describes the ALARA design review for the initial plant design and construction and is historical in nature.

Bechtel, as agent for the licensee, has developed an "In-Plant Radiation Exposure ALARA Review Specification". This specification was applied during all construction phases to perform multidisciplinary reviews of the plant to assure a design that:

a. Maintains the annual operating and maintenance radiation doses to individuals ALARA

b. Keeps the annual integrated radiation doses to all personnel ALARA.

This specification defined the purpose of the review; established the project ALARA review team; and described the discipline ALARA review process, the extent and format of ALARA review meetings, and the method of noting and resolving ALARA design changes. This specification is consistent with design guidelines given in Regulatory Guide 8.8.

The Bechtel Project Mechanical/Nuclear Group was responsible for the overall coordination of the ALARA design review and the interaction between the various Bechtel project disciplines, Bechtel Construction, the Bechtel Staff Radiation Protection Group, and the licensee.

The groups involved in the ALARA review program and their relationships are shown on Figure 12.1-1.

An experienced engineer from the Mechanical/Nuclear Group served as the project ALARA coordinator and was responsible for overall coordination of the ALARA reviews. Duties included maintaining the ALARA Review Specification and the ALARA documentation file, expediting the ALARA reviews, and resolving any ALARA inconsistencies. The project ALARA coordinator obtained input and expertise from the licensee, the Radiation Protection Group, and other Bechtel groups, as required.

An engineer was assigned from each engineering discipline to serve as the discipline ALARA representative. The discipline ALARA representatives coordinated and conducted the ALARA reviews within the discipline, interfaced between the discipline and the project ALARA coordinator, and expedited any design changes that resulted from the ALARA review.

Engineers from the field were assigned as construction ALARA representatives. They were responsible for reviewing field designs and field modifications to existing designs for consistency with the ALARA Review Specification. The construction ALARA coordinator coordinated the ALARA reviews in the field and interfaced between construction and engineering.

Experienced radiation protection specialists from the staff of the chief nuclear engineer provided health physics and radiation protection design input to the project. A radiation protection specialist was assigned to support the project design and ALARA review and was responsible for interfacing between the group and the project ALARA coordinator. The radiation protection specialist represented the staff radiation protection group during the ALARA reviews.

The licensee’s ALARA coordinator was a licensee engineer who represented the licensee during the ALARA reviews. One of the responsibilities was to advise the project ALARA coordinator of potential ALARA problems based on the licensee's experience from operating plants, by receiving input from the licensee’s Health Physics and Operations groups. The licensee’s ALARA coordinator also reviewed and provided input to the ALARA Review Specification, reviewed exceptions to the ALARA design criteria, and provided licensee input for resolving ALARA inconsistencies that were identified during the ALARA review.

To facilitate documentation and coordination of the ALARA review effort, a scheduled system and activity design review approach was followed. Maximum review effort was expended on those systems and activities as identified in Table 12.1-1 that in the past had resulted in the highest occupational radiation exposures in operating plants. Each system and activity was divided into plant areas. The ALARA design review was conducted by reviewing each of these areas.

The design review was conducted in the home office by the discipline ALARA representatives, project ALARA coordinator, and the radiation protection specialist. The major tools used in the design review were the ALARA design review considerations checklist, which identified design features that were judged to be generally cost effective with respect to maintaining occupational radiation exposures ALARA, and the ALARA design review considerations sign-off sheet. The sign-off sheet documented the review of the design by the responsible discipline(s). The discipline ALARA representatives and the radiation protection specialist verified that the design considerations assigned to their groups were met.

The ALARA review of field designs and modifications was conducted by the construction ALARA representatives. The discipline responsible for the new design or modification was responsible for documenting that it had been reviewed for ALARA. The project ALARA coordinator coordinated any reviews that affected other disciplines or groups.

Compliance with the ALARA design review considerations was documented by the reviewer on the design review considerations sign-off sheets, which are kept on file. Any exceptions to the considerations were reviewed on a case-by-case basis.

12.1.2.5 ALARA Design Considerations for Decommissioning

The design features necessary to maintain radiation exposures ALARA during decommissioning operations are, in general, the features that have been implemented to keep exposures ALARA during the operational life of the plant. These are discussed in Sections 12.1.2.1, 12.1.2.2, 12.1.2.3, and 12.3. Some of these features that are especially applicable to decommissioning are discussed below.

a. Flushing and draining connections will provide for removal of radioactive fluids, allow rinsing to reduce residual activity, and provide an entry point for introduction of decontamination solutions.

b. Ventilation systems to minimize the spread of airborne radioactivity will be particularly useful in preventing exposures to internal radioactivity during decommissioning when large quantities of airborne radioactive particulates can be generated by cutting, sawing, and demolition.

c. The space envelopes reserved around equipment to facilitate maintenance will also allow for more rapid dismantling because cutting machines and other decommissioning equipment can be quickly installed with correspondingly lower exposure time.

d. The use of flanged connections on pumps in radioactive waste systems, and the removal provisions built into some major plant components, will reduce exposures to personnel during removal of these items.

e. Separation of radioactive from nonradioactive systems, and location of active components of nonradioactive systems in low radiation areas, will permit dismantling of normally clean systems with minimal exposure to personnel.

f. The availability of a complete, shielded radwaste facility will allow efficient low dose processing of residual fluids and decontamination solutions, as well as the packaging and shipping of solid radioactive materials. Other existing facilities, such

as access control stations and decontamination areas, will also perform their intended functions in helping to keep exposures ALARA.

g. The use of liners and protective coatings will lower exposures by minimizing decontamination times and by reducing the quantities of materials that must be handled as radioactive waste.

12.1.3 OPERATIONAL CONSIDERATIONS

This section describes the development and implementation of operating procedures, including procedures for radiation protection and the ALARA program.

Plant procedures are further described in Section 13.5. Health physics operations are described in Section 12.5.

12.1.3.1 Procedure Development

Various procedures are written for the different activities associated with plant operations. These include procedures for operating, maintenance, surveillance testing, fuel handling, emergencies, radiation protection, and administration. The development of each variety of procedure is described in the administrative procedures.

The different procedures are prepared by personnel having experience and expertise in that particular area. The experience gained from operation of the PBAPS units and other plants is incorporated into procedure development. Each procedure is reviewed and approved per Administrative procedure process. Health physics personnel review procedures for activities which can affect radiation exposure.

Procedures are subject to revision whenever improved techniques or increased safety are indicated.

12.1.3.2 Exposure Reduction Procedures

The ALARA concept is first and foremost practiced on the job by communication between health physics technicians or health physics supervisors and the workers. The health physics representatives are aware of the radiation conditions and advise the workers accordingly.

Specific radiation procedures describe the techniques to determine the radiological conditions in an area. Once determined, procedures describe the actions necessary to incorporate exposure reduction techniques as required.

12.1.3.3 General ALARA Techniques

The predominant exposure dose is received during outages. Although ALARA considerations are not limited to outage work, the activities conducted during outages are the most significant for dose reduction.

During the outage planning stages, an ALARA representative is designated by Health Physics supervision to review the jobs planned and evaluate the need for an ALARA effort. Examples of some techniques that apply to an ALARA evaluation are:

a. Reducing dose rate from a system by draining, flushing, filling, decontaminating.

b. Installing permanent or temporary shielding if the net result is reduction in man-rem.

c. Training workers to improve proficiency, thus reducing stay time in the radiation area.

d. Maintaining the work force in radiation areas to the minimum required to perform the job efficiently and safely.

e. Establishing control points in low radiation areas.

f. Avoiding excess conservatism in prescribing protective clothing and respirators to avoid undue stress and decreased efficiency of the workers.

g. Using special tools for remote handling of components.

h. Planning and preparing techniques and tools needed to accomplish the job before the job is started.

i. Using historical data for comparable jobs as guidelines and to establish an expected dose limit for the job.

j. Using remote monitoring/alarming dosimeters in high radiation areas to maintain close checks on personnel exposures.

k. Providing adequate communications to facilitate performance of the job and to alert workers to adverse changes in radiation conditions.

l. Source identification and use of routine or special survey data.

m. Construction of contamination containment devices such as glove boxes and tents.

n. Removing components to low radiation areas for servicing or repair.

o. Planning for adequate space and auxiliary services, such as lighting, welding leads, service air lines, and TV cameras, as necessary to accomplish the work quickly.

p. Establishing auxiliary ventilation/filtration systems.

q. Wet transfer or storage of contaminated components to prevent airborne contamination.

r. Contingency planning to account for known personnel hazards or accidents which may occur.

s. Isolating systems to be worked on or possible load reductions or plant shutdowns to reduce doses.

The ALARA representative communicates with other disciplines (maintenance, operating, instrument and control, etc.) as appropriate to discuss the implementation of ALARA techniques. The cooperation of more than one discipline is usually required for most jobs.

The dosimetry program consists of DLRs or equivalent badges processed by a National Voluntary Laboratory Accreditation Program (NVLAP) accredited contractor for official data of record. Additionally, direct reading dosimeters are used as the unofficial dosimetric device. The computerized dosimetry record system and the ability to process the unofficial dosimetric device onsite provide a powerful tool for maintaining surveillance and managing each worker's dose accumulation. The direct reading dosimeters provide immediate readings and are available to obtain estimated exposures whenever there is concern. Workers' assignments to radiation areas can then be limited if administrative guidelines or regulatory limits are approached.

This same system produces tabulated lists of workers' exposures-to-date for each supervisor. These lists are provided routinely so the supervisors can know the dose accumulation of their workers, observe trends, and assign work duties more efficiently. Changes to the dosimetry program, such as contractor service versus onsite processing, frequency of badge changes, and types of dosimetric devices are made periodically to enhance the value of the program. Annual exposure reviews will be performed by the Engineer - Health Physics and Chemistry in order to identify groups with the highest exposure.

12.1.3.4 Operating Experience

Experience gained during operation of PBAPS Units 2 and 3 serves as a basis for procedures, techniques, and administrative controls for LGS. Exposure data from specific jobs previously performed at PBAPS have caused design changes during construction of LGS. The LGS Hot Maintenance Decontamination Shop design incorporates lessons learned from PBAPS.

12.2 RADIATION SOURCES

In this section the sources of radiation that form the basis for shield design and the sources of airborne radioactivity required for the design of personnel protective measures and for dose assessment are discussed and identified.

12.2.1 CONTAINED SOURCES

The shielding design source terms are based on a noble gas fission product offgas release rate of 0.35 Ci/sec (after 30 minutes of decay) and the corresponding fission, activation, and corrosion product concentrations in the primary coolant. The guidance provided in ANSI N237 was not used to determine the shielding design source terms for LGS. The specific alternate methods used for calculating source term magnitudes are described in Section 11.1. The shielding design source terms in the primary coolant are listed in Tables 12.2-1 through 12.2-5. Throughout most of the primary coolant system, activation products, principally nitrogen-16, are the primary radiation sources for shielding design.

Basic reactor data and core region descriptions used for this section are listed in Tables 12.2-6 through 12.2-8.

The shielding design source terms are presented by enclosure location and system. Locations of the equipment discussed in this section are shown on the shielding and radiation zoning drawings, drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130 N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-140, N-141, N-142, and N-143. Detailed data on source descriptions for each shielded area are presented in Tables 12.2-11 through 12.2-13.

Shielding source terms presented in this section and associated tables are based on conservative assumptions about system and equipment operations and characteristics to provide reasonably conservative radioactivity concentrations for shielding design. For all systems transporting radioactive materials, conservative allowance is made for transit decay while at the same time providing for daughter product formation. Assumptions from NUREG-0016 (Reference 12.2-1) were also used where applicable. Therefore, the shielding source terms are not intended to approximate the actual system design radioactivity concentrations.

12.2.1.1 Primary Containment

12.2.1.1.1 Reactor Core

The radiation within the drywell during full power operation includes neutron and gamma radiation resulting from the fission process in the core. Tables 12.2-9 and 12.2-10 list the multigroup neutron and gamma ray fluxes at the outside surfaces of the RPV and the primary shield at the core midplane. The gamma fluxes include those resulting from capture or inelastic scattering of neutrons within the RPV, the core shroud, and the primary shield, as well as gamma radiation resulting from prompt fission and fission product decay. The largest radiation sources after reactor shutdown are the decaying fission products in the fuel. Table 12.2-14 lists the fuel assembly source terms. Secondary sources include the structural material activation of the RPV, its internals, and the piping and equipment located in the primary containment; and the activated corrosion products accumulated or deposited in the internals of the RPV, the primary coolant piping, and other process system piping in the primary containment.

12.2.1.1.2 Reactor Coolant System

Sources of radiation in the RCS used for shielding design are fission products estimated to be released from fuel and activation and corrosion products that are circulated in the reactor coolant. These sources are listed in Tables 12.2-1 through 12.2-5. The N-16 concentration in the reactor coolant, with HWC, is bounded at 4.8×10^{-5} Ci/gm of coolant at the reactor recirculation outlet nozzle.

12.2.1.1.3 Main Steam System

Radiation sources in the main steam system piping include activation gases, principally N-16, and the corrosion and fission products carried over to the main steam system.

The N-16 concentration without HWC in the steam is assumed to be 5.0×10^{-5} Ci/gm of steam leaving the reactor vessel at the nozzle. Fission product radioactivity corresponds to an offgas release rate of 0.35 Ci/sec at 30 minutes decay from the reactor nozzle. Partition factors for carryover of radioactivity into the main steam system are 100% for gases, 2% by weight for halogens, and 0.1% by weight for particulates. These partition factors are applied to the reactor water shielding source terms as given in Tables 12.2-1 through 12.2-5.

Hydrogen injection by the HWC system causes the reactor water chemistry to become less oxidizing which results in a re-distribution of the N-16 normally produced by radiolysis in the reactor core. Under HWC conditions more of the N-16 is carried over into the steam and less remains in the reactor water. Under HWC conditions the N-16 concentration in the steam is 2.50×10^{-4} Ci/gm.

12.2.1.1.4 Drywell Sumps

The concentrations of radioisotopes used for shielding design for the drywell equipment and floor drain sumps are listed in Table 12.2-15.

12.2.1.2 Reactor Enclosure and Refueling Area

12.2.1.2.1 Reactor Water Cleanup System

Radiation sources in the RWCU system consist of those radioisotopes carried in the reactor water. The activity inventory is based on component transit times. The radioisotopes for the RWCU recirculation pumps, regenerative and nonregenerative heat exchangers, filter/demineralizers, holding pumps, and the backwash receiving tank are the accumulated fission, activation, and corrosion products, based on the inlet reactor coolant concentrations given in Tables 12.2-1 through 12.2-5, allowing for decay due to transit time. Tables 12.2-16 through 12.2-23 provide the shielding design source terms for these components.

12.2.1.2.2 Residual Heat Removal System

The pumps, heat exchangers, and associated piping of the RHR system are carriers of radioactive materials. For plant shutdown, the RHR pumps and heat exchangers are the radiation sources, resulting from the radioisotopes carried in the reactor coolant after four hours of decay following shutdown. The source terms listed in Table 12.2-24 are used for the shielding calculations for this system.

12.2.1.2.3 Reactor Core Isolation Cooling System

Components of the RCIC system that contain radiation sources are the RCIC turbine and steam inlet and exhaust piping. The steam radioactivity, as discussed in Section 12.2.1.1.3, without decay correction for transit from the RPV steam nozzles, is used for the shielding calculations for this system and is listed in Table 12.2-25.

12.2.1.2.4 High Pressure Coolant Injection System

The radiation sources for the HPCI system are the HPCI turbine and the steam inlet and exhaust piping. The steam radioactivity, as discussed in Section 12.2.1.1.3, decayed for the appropriate transit time, is used for the shielding calculations for this system and is listed in Table 12.2-26.

12.2.1.2.5 Core Spray System

The core spray system components, during testing, use condensate from the CST which contains very low radioactivity concentrations (Table 12.2-87); therefore, no shielding is required.

12.2.1.2.6 Spent Fuel Storage and Transfer

The predominant radiation sources in the spent fuel storage and transfer areas are the spent fuel assemblies. For shielding design purposes only, the spent fuel pool is assumed to contain 2862 fuel assemblies. These spent fuel assemblies are conservatively assumed to have 48 hours of decay. Shielding design source terms are shown in Table 12.2-14.

12.2.1.2.7 Fuel Pool Cooling and Cleanup System

Sources of radiation in the FPCC system result from the transfer of radioisotopes from the reactor coolant and crud deposits on spent fuel assemblies into the spent fuel pool during refueling operations. The shielding design source terms for the FPCC system are presented in Table 12.2-27. These source terms then undergo subsequent decay and accumulation on the FPCC filter/ demineralizers. Table 12.2-28 shows the FPCC filter/demineralizers shielding design source terms. The shielding design source terms for the FPCC heat exchanger are shown in Table 12.2-29.

12.2.1.2.8 Reactor Enclosure HVAC System

Components of the reactor enclosure HVAC system that contain sources of radioactivity are the equipment compartment exhaust air filters. Table 12.2-30 shows the reactor enclosure equipment exhaust air filters shielding design source terms.

12.2.1.2.9 Control Rod Drives

Shielding design source terms for the CRD mechanisms after removal from the RPV are shown in Table 12.2-31.

12.2.1.3 Turbine Enclosure

12.2.1.3.1 Primary Steam and Power Conversion Systems

Radiation sources for piping and equipment that contain primary steam are based on the radioisotopes carried over into the main steam from the reactor coolant and include fission product gases and halogens, particulate fission and corrosion products, and gaseous activation products

as discussed in Section 12.2.1.1.3. Steam density variations and steam transit times through equipment and pipes are factored into the shielding source term evaluation to account for volumetric dilution effects, radiological decay, and daughter product generation. Tables 12.2-32 through 12.2-36 show the shielding design source terms for the following components that use main steam; moisture separators, cross-around piping, feedwater heaters, steam seal evaporator, and the reactor feed pump-turbine.

12.2.1.3.2 Condensate and Feedwater Systems

The radiation sources in the condensate and feedwater systems are based on decayed main steam radioactivity (Section 12.2.1.1.3). Eighty percent of the N-16 and 100% of the noble gases are assumed to be removed from the condensate and feedwater systems by the main condenser air removal system. The gaseous radiation sources in the hotwell are shown in Table 12.2-37; they are negligible in the remainder of the condensate and feedwater systems. The hotwell is designed for a two minute holdup of condensate, and therefore N-16 radioactivity at the condenser outlet is negligible. Particulate fission products, activated corrosion products, and the particulate daughter products from the decay of fission product gases in transit through the turbine and condenser are the inlet radiation sources to the condensate system. These shielding design source terms, as shown in Table 12.2-38, are present in the condensate pumps and piping and accumulate on the condensate filter/ demineralizers. Table 12.2-39 provides the shielding design source terms for the condensate filter/demineralizer and the condensate backwash receiving tank. The shielding design source terms for the feedwater system are listed in Table 12.2-40.

12.2.1.3.3 Gaseous Radwaste Recombination System

Shielding design sources in the gaseous radwaste recombination system originate from noble gases and other noncondensable gases removed from the main condenser, and the radioactivity entering with the extraction driving steam to the SJAEs. The radioactivity entering is based on the primary steam radioactivity as described in Section 12.2.1.1.3, decayed for the expected transit time to the SJAEs. Eighty percent of the N-16 and 100% of the noble gases are assumed to be removed from the condenser by the SJAEs. The specific activities or quantities of radioactivity, including particulate daughters, in the SJAE condenser, mechanical vacuum pump, offgas pipe, preheater, recombiner, recombiner catalyst, aftercondenser, and H_2 analyzers, to be used for shielding design calculations, are shown in Tables 12.2-41 through 12.2-48.

12.2.1.3.4 Turbine Enclosure HVAC System

Components of the turbine enclosure HVAC system that contain sources of radioactivity are the equipment compartment exhaust air filters and the SGTS air filters. Tables 12.2-49 and 12.2-50 show the turbine enclosure equipment exhaust air filters and the SGTS air filters shielding design source terms.

12.2.1.4 Radwaste Enclosure

12.2.1.4.1 Liquid Waste Management System

Liquid radwaste is collected and processed as discussed in Section 11.2. The liquid waste management system shielding design sources are radioisotopes, including fission and corrosion products, present in the reactor coolant. The components of this system contain varying amounts of radioactivity, depending on the system and equipment design.

The concentrations of radioisotopes used for shielding design for pipes, tanks, filters, demineralizers, abandoned and unused evaporators (Section 11.2.2.1.3), and equipment and floor drain sumps may be derived from or are listed in Tables 12.2-51 through 12.2-69. Shielding for each component of the liquid waste management system is based on reactor coolant concentrations given in Tables 12.2-1 through 12.2-5.

12.2.1.4.2 Solid Radwaste System

The solid radwaste system collects, monitors, processes, packages, and provides temporary storage facilities for radioactive spent bead and powdered resins and dry solid wastes for offsite shipment and permanent disposal. The system is described in Section 11.4.

The high integrity containers used for packaging resin wastes are washed free of external surface contaminants and stored in concrete shielded compartments before shipment. The aforementioned operations are accomplished using remote container loading, transfer, and an overhead crane. Shielding design source terms for the solid radwaste system components are based on reactor coolant concentrations given in Tables 12.2-1 through 12.2-5 and are presented in Tables 12.2-70 through 12.2-77, and 12.2-101 through 12.2-103.

12.2.1.4.3 Radwaste Enclosure HVAC System

Components of the radwaste and offgas enclosures HVAC system that contain sources of radioactivity are the equipment compartment exhaust air filters. Table 12.2-78 shows the radwaste and offgas enclosure equipment exhaust air filters shielding design source terms.

12.2.1.5 Offgas Enclosure

12.2.1.5.1 Gaseous Radwaste Charcoal Treatment System

The gaseous radwaste charcoal treatment system as described in Section 11.3 is located in the offgas enclosure and receives effluent from the gaseous radwaste recombination system for further decay before release.

The shielding design terms for the charcoal treatment system components are based on the expected transit times for noble gases and the formation and accumulation of noble gas daughter products. These gases pass through the charcoal treatment system and out the turbine enclosure stack. The shielding design source terms for the piping, filters, and charcoal treatment system equipment are presented in Tables 12.2-79 through 12.2-82.

12.2.1.5.2 Offgas Enclosure HVAC System

See Section 12.2.1.4.3 for the offgas enclosure HVAC shielding design source terms.

12.2.1.6 Shielding Design Sources Resulting from Design Basis Accidents

The shielding design for the control room is based on radiation sources resulting from DBAs. Control room shielding design considers radiation sources from the primary containment, the reactor enclosure, the turbine enclosure and control structure, and the SGTS filters. The shielding design source terms for these areas are given in Tables 12.2-83 through 12.2-86.

With regards to the Independent Spent Fuel Storage Installation, a postulated accidental sealing failure can potentially produce a gaseous effluent. This effluent is limited by the requirements of

10CFR72.106, which does not require consideration of simultaneous contributions to dose from the plant.

12.2.1.7 Stored Radioactivity

The only sources of radioactivity not stored inside the plant structures are the refueling water storage tank, the CST, 10CFR20.2002 storage area, the radwaste storage pad and designated material laydown areas in the protected area.

During normal operation of the Independent Spent Fuel Storage Installation only direct radiation is emitted from loaded dry storage containers. The radiation dose is limited by the requirements of 10CFR72.104, which considers the direct dose from the storage containers in combination with the normal plant sources and effluents.

The CST contains low concentrations of radioisotopes. A dike is provided around the CST so that unrestricted access is limited to areas with a dose rate less than 2 mRem/hr. The CST source terms are shown in Table 12.2-87.

The refueling water storage tank also has low concentrations of radioisotopes when water is returned from the refueling pool. The refueling water storage tank is surrounded by a dike which limits unrestricted access to areas with a dose rate less than 0.2 mRem/hr. The refueling water storage tank source terms are shown in Table 12.2-88.

Provisions have been made to recycle the water from both the condensate and refueling water storage tanks through the condensate filter/demineralizers.

The 10CFR20.2002 storage area is an area north of the radwaste storage pad and northwest of the spray pond. The area is approximately 1.5 acres in size and approved for storage of slightly contaminated soils, sediment and sludges as approved by the 10CFR20.2002 application. Annual and maximum limits for the amount of material and radioactivity concentration are established by the 10CFR20.2002 application for the material stored there. The offsite dose at the nearest residence will not exceed 0.101 mrem/year from the radioactive waste material stored at the 10CFR20.2002 storage area.

The radwaste storage pad is located outside the protected area, but within the site restricted area, southwest of the spray pond and northwest of the Unit 1 cooling tower. The waste material on the pad consists of low level waste being stored on a temporary (interim) basis, awaiting offsite shipment, and contaminated reusable material. Storage pad boundary dose rates are set such that exposure of personnel in unrestricted areas is in accordance with 10CFR20.1301 requirements. The normal offsite dose to any member of the public will not exceed 1.0 mR/year from the radioactive waste material on the storage pad and 1.0 mR/year from storage of contaminated reusable material.

Designated area within the protected area are used for temporary storage of very low level contaminated material. This material consists of reusable materials to support plant operations and maintenance activities, and materials awaiting processing or offsite shipment for subsequent recycling, recovery, or free release to the extent achievable. The normal offsite dose from this category of material is included in the 1.0 mr/yr limit from storage of contaminated reusable material on the radwaste storage pad.

No other radiation sources aside from the Independent Spent Fuel Storage Installation (ISFSI) are normally stored outside the plant structures. Spent fuel is stored in the spent fuel pool until it is placed in the spent fuel shipping cask for offsite transport or into the ISFSI Transfer Cask or HI-TRAC VW cask for placement at the ISFSI for interim storage. Space is provided in the radwaste enclosure for storage of spent filter cartridges and solidified spent resins. Radiation sources stored inside the plant structures are shielded to provide a dose rate of less than 2 mRem/hr for all areas outside plant structures.

12.2.1.8 Special Sources

Special materials used in the radiochemistry laboratory and sealed sources used for calibration require special handling equipment and are shielded accordingly. Unsealed sources and radioactive samples are handled in conventional hoods that exhaust to the ventilation system. Design features provided are discussed in Section 12.3.1.

The TIP system gamma detector and its drive cable become radiation sources following activation by neutrons in the reactor. The level of the radiation source depends upon the material compositions of the components, the irradiation history and decay time. The material composition of the gamma TIP is shown in Table 12.2-89. The radiation levels from the detector and cable are shown in Table 12.2-104 for a range of decay times after the TIP is retracted from the reactor vessel.

The reactor startup sources are shipped to the site in special shielded casks. The sources are transferred from the cask to the source holders. The source holders are then loaded underwater into the reactor. The sources are removed from the reactor and placed in the spent fuel pool or sent offsite.

12.2.2 Airborne Radioactive Material Sources

12.2.2.1 Sources of Airborne Radioactivity

The sources of airborne radioactivity found in the various areas of the plant are mostly from process leakage of the systems carrying radioactive gases, steam, and liquids. Depending on the type of the system and its physical condition, such as system pressures and temperatures, leakage is in the form of a gas, steam, liquid, or a mixture of these.

12.2.2.2 Production of Airborne Radioactive Materials

Radioactive materials become airborne through a number of mechanisms. The most common production mechanisms are spraying, splashing, flashing, evaporation, and diffusion.

12.2.2.3 Locations of Sources of Airborne Radioactivity

Practically all the sources of airborne radioactivity are found in the reactor, turbine, and radwaste and offgas enclosures. Within these structures the radioactivity is released in equipment cubicles, valve and piping galleries, sampling stations, radwaste handling and shipping areas, cleaning and decontamination areas, and repair shops.

12.2.2.4 Control of Airborne Radioactivity

Ventilation is an effective means of controlling airborne radioactive materials. Ventilation flow paths are such that air from low potential airborne areas flows into higher potential airborne areas. This flow pattern ensures that radioactivity released in the above mentioned source locations, which usually have low personnel access requirements, has little chance to escape into areas with a high personnel occupancy such as corridors, working aisles, and operating floors. Levels of airborne radioactivity are periodically checked by surveys of the plant by the radiation protection staff.

12.2.2.5 Methodology for Estimating the Concentration of Airborne Radioactive Material Within the Plant

To estimate the airborne radioactive material concentrations at locations within the plant, the following methodology was used:

a. Estimate the total airborne releases (in curies per year) for each of the plant enclosures.

b. Estimate a distribution for these releases among the various equipment areas of each enclosure based on operating data and engineering judgement.

c. Determine the annual exhaust flow from each equipment area.

d. Calculate the resultant airborne radionuclide concentration (Ci/cc) in each equipment area based on the release distribution (Ci/yr) and exhaust flow rate (cc/yr).

The following sections discuss each step in the above procedure in more detail.

12.2.2.6 Estimation of Total Airborne Releases Within the Plant

The estimated quantities of airborne radioactive material produced in the plant enclosures are given in Table 12.2-93. These releases were based upon BWR-GALE (Reference 12.2-1), a computerized mathematical model for calculating the release of radiological materials in gaseous and liquid effluents. Assumptions applicable to the development of Table 12.2-93 from BWR-GALE are as follows:

a. The reactor enclosure releases are taken to be the sum of the auxiliary enclosure and containment enclosure releases calculated by BWR-GALE.

b. Turbine enclosure releases from BWR-GALE are assumed to include any airborne radioactive material produced in the control structure.

c. The radwaste enclosure releases from BWR-GALE are "per reactor" and consequently are doubled for LGS. Offgas enclosure releases are assumed to be included in the radwaste enclosure releases.

d. Tritium releases from BWR-GALE are divided equally between the reactor and turbine enclosures.

e. Since the BWR-GALE code for gaseous releases is based on actual operating plant data, releases for both normal operations and anticipated operational occurrences are assumed to have been included.

12.2.2.7 Distribution of Airborne Releases Within the Plant

In the approach taken to determine the anticipated distribution of gaseous effluents, it is assumed that all airborne radioactive material originates only within the equipment areas of the plant. It is further assumed that a major percentage of the release is generated within a few specific areas of each enclosure, with the remainder coming from other equipment areas. Eighty percent of each enclosure's release is distributed as described below among the major contributing areas, and 20% is assigned to the "other equipment areas" category. Releases are assumed to be generated continuously throughout the year except for the drywell, where a 30 day release period is used.

The basis for the selection and relative contributions of the major areas is EPRI report NP-495 (Reference 12.2-2). This report provides data on the important sources of iodine-131 at operating BWRs and uses measured data to determine the relative release rate from each source. The relative release rates for all airborne radionuclides are, except for reactor enclosures tritium, assumed to be directly proportional to the iodine-131 release rates. Since the spent fuel pool and the reactor vessel (when it is open during refueling) are the major sources of airborne tritium in the reactor enclosure, tritium releases for that enclosure are assigned entirely to the refueling area.

Table 12.2-94 lists the major airborne contributors in each enclosure and the percentage of the total enclosure release assigned to each. Tables 12.2-95 through 12.2-97 provide the specific equipment areas of the plant associated with the major contributors and the applicable exhaust air flow rates. Note that only those equipment areas that have a significant potential for airborne radioactive material releases were included in the
"other equipment areas" category.

12.2.2.8 Estimated Airborne Radioactive Material Concentrations Within the Plant

The airborne radionuclide concentrations for each equipment area were calculated using the following methodology. For a specific area, the appropriate enclosure release (Table 12.2-93) was multiplied by the applicable release percentage for the area (Table 12.2-94) and divided by the area's annual exhaust flow (Table 12.2-95, 12.2-96, or 12.2-97). The resultant concentrations are presented in Tables 12.2-98 through 12.2-100, which also include the fractions of the maximum permissible concentrations in air as defined in 10CFR20 Appendix B, Table I (pre-1994).

12.2.2.9 Changes to Source Data Since PSAR

Airborne radioactive material sources were not specified in the LGS PSAR. Section 12.2.2 has been added in compliance with the "Standard Format and Content of Safety Analysis Report for Nuclear Power Plants," Regulatory Guide 1.70.

Table 12.2-6

BASIC REACTOR DATA[1]

PARAMETER		VALUE USED IN MODEL
Reactor rated thermal power		3527 megawatts
Overall average core power density		53.8 watts/cc
Core power peaking factors:		
At core center		
$\frac{P_{max}}{P_{ave_Z}}$	(axial)	1.5
$\frac{P_{max}}{P_{ave_R}}$	(radial)	1.4
At core boundary		
$\frac{P_{max}}{P_{ave_Z}}$	(axial)	0.5
$\frac{P_{max}}{P_{ave_R}}$	(radial)	0.7

Core volume fractions:

Material	Density gm/cc	Volume Fraction
UO_2	10.4	0.254
Zr	6.4	0.140
H_2O	1.0	0.274
Void	0	0.332

Average water density between core and vessel and below the core	0.74 g/cc
Average water-steam density above core:	
In the plenum region	0.23 g/cc
Above the plenum (homogenized)	0.6 g/cc
Average steam density	0.036 g/cc

(1) This table represents the physical data required to form the reactor vessel model, which includes volume fractions, reactor power, and power distribution.

(1) "Effective Source Density" is density of radiation source or combination of sources used in shielding design analyses.
(2) These rooms contain components associated with the abandoned radwaste evaporator system. Installation of these components was not completed for plant operation (Section 11.2.2.1.3).

(1) Based on EOL assembly (1000 days irradiation).
(2) Assumes reactor to have been operating at 3323 MW_t. Expect shielding to be sufficient for approximate 6% power increase to 3515 MWt.
(3) Assumes 764 assemblies per core.
(4) Assumes 2 days decay, when earliest fuel transfer from core to storage pool is expected.
(5) Assumes 0.5 years decay, when earliest offsite transport is expected.
(6) Isotopes with specific activities less than 1.0×10^{-20} are not listed.
Note: This table applies to the assumed spent fuel shipping cask, and not to the Independent Spent Fuel Storage Installation (ISFSI) Transfer Cask or HI-TRAC VW cask which will have significantly lower activities due to increased decay period of the ISFSI fuel.

(1) Based on shielding design source terms given in Tables 12.2-2 through 12.2-5.
(2) Tube side is reactor water with 37.5 seconds decay accumulated for 6.98 seconds at 341.7 gpm at 0.757 g/cc; shell side is filtered and demineralized reactor water with 353.81 seconds decay accumulated for 14.7 seconds at 310 gpm at 0.834 g/cc.
(3) Shell side assumes a decontamination factor of 10 across the filter/demineralizer (except for Cs and Rb, which have a DF of 2, and gases, which have a DF of 1).
(4) Shell side includes noble gases generated by particulate parents accumulating on filter/demineralizer resins.
(5) Isotopes with activities less than 1.0×10^{-20} are not listed.

Pr-144	6.00×10^{-7}	6.49×10^{-7}	Ag-110m	7.98×10^{-6}	1.60×10^{-6}
La-142	5.36×10^{-4}	5.42×10^{-4}	W-187	3.99×10^{-4}	7.99×10^{-5}

(1) Based upon shielding design source terms given in Tables 12.2-2 through 12.2-5.
(2) The tube side is reactor water with 52.0 seconds decay accumulated for 8.15 seconds at 292.4 gpm at 0.885 g/cc; shell side is filtered and demineralized reactor water with 322.01 seconds decay accumulated for 16.4 seconds at 278 gpm at 0.929 g/cc.
(3) The shell side assumes a DF of 10 across the filter/demineralizer (except for Cs and Rb, which have a DF of 2, and gases, which have a DF of 1).
(4) The shell side includes noble gases generated by particulate parents accumulating on filter/demineralizer resins.
(5) Isotopes with activities less than 1.0×10^{-20} are not listed.

(1) Based on shielding design source terms given in Tables 12.2-2 through 12.2-5.
(2) Pumps are assumed to be 295.01 seconds downline from the reactor recirculation loop.
(3) A DF of 10 is assumed across the filter/demineralizer (except for Cs and Rb, which have a DF of 2, and gases, which have a DF of 1).
(4) Includes noble gases generated by particulate parents accumulating on filter/demineralizer resins.
(5) Isotopes with specific activities less than 1.0×10^{-20} are not listed.

Table 12.2-24

Ag-110m	6.75×10^{-4}
W-187	3.38×10^{-2}

(1) Corrosion (noncoolant activation) products in reactor water (given in Table 12.2-5) with no decay were normalized to yield a contact dose rate of 200 mR/hr for one fuel pool heat exchanger.

(2) Isotopes with activities less than 1.0×10^{-20} are not listed.

Table 12.2-30

REACTOR ENCLOSURE EQUIPMENT COMPARTMENT
EXHAUST AIR FILTERS SHIELDING DESIGN SOURCE TERMS[1][2]

ISOTOPE[3]	ACTIVITY (Ci)
I-131	1.90×10^{-2}
I-133	7.95×10^{-3}
Co-60	9.37×10^{-3}
Co-58	1.64×10^{-4}
Cr-51	3.29×10^{-5}
Mn-54	2.03×10^{-3}
Fe-59	7.18×10^{-5}
Zn-65	1.25×10^{-3}
Zr-95	3.55×10^{-4}
Sr-89	6.50×10^{-5}
Sr-90	1.73×10^{-5}
Sb-124	1.64×10^{-4}
Cs-134	1.19×10^{-2}
Cs-136	5.68×10^{-5}
Cs-137	1.90×10^{-2}
Ba-140	7.08×10^{-5}
Ce-141	4.49×10^{-5}
La-140	7.08×10^{-5}
Y-90	1.71×10^{-5}
Y-89m	6.50×10^{-9}
Nb-95	3.46×10^{-4}
Nb-95m	7.08×10^{-6}

(1) Based on NUREG-0016, Revision 0, table 1-1 (Reference 12.2-1) release rates, with fission products adjusted to 0.35 Ci/cc offgas release rate at 30 minutes decay.

(2) Assumes a one year accumulation of all these isotopes at 40,000 cfm.

(3) Isotopes with activities less than 1.0×10^{-20} are not listed.

Table 12.2-31

CONTROL ROD DRIVE MECHANISM SHIELDING DESIGN SOURCE TERMS[1]

CONTAMINATED CRD MECHANISM FILTER[2]		CONTAMINATED CRD MECHANISM BODY[3]		DECONTAMINATED CRD MECHANISM BODY[4]	
Isotope[5]	Activity (Ci)	Isotope[5]	Activity (Ci)	Isotope[5]	Activity (Ci)
Na-24	2.32×10^{-2}	Na-24	4.35×10^{-2}	Na-24	2.18×10^{-3}
P-32	2.32×10^{-4}	P-32	4.35×10^{-4}	Pa-32	2.18×10^{-5}
Cr-51	5.79×10^{-3}	Cr-51	1.09×10^{-2}	Cr-51	5.44×10^{-4}
Mn-54	4.63×10^{-4}	Mn-54	8.70×10^{-4}	Mn-54	4.35×10^{-5}
Mn-56	5.79×10^{-1}	Mn-56	1.09	Mn-56	5.44×10^{-2}
Co-58	5.79×10^{-2}	Co-58	1.09×10^{-1}	Co-58	5.44×10^{-3}
Co-60	5.79×10^{-3}	Co-60	1.09×10^{-2}	Co-60	5.44×10^{-4}
Fe-59	9.26×10^{-4}	Fe-59	1.74×10^{-3}	Fe-59	8.70×10^{-5}
Ni-65	3.47×10^{-3}	Ni-65	6.53×10^{-3}	Ni-65	3.26×10^{-4}
Zn-65	2.32×10^{-5}	Zn-65	4.35×10^{-5}	Zn-65	2.18×10^{-6}
Zn-69m	3.47×10^{-4}	Zn-69m	6.53×10^{-4}	Zn-69m	3.26×10^{-5}
Ag-110m	6.95×10^{-4}	Ag-110m	1.31×10^{-3}	Ag-110m	6.53×10^{-5}
W-187	3.47×10^{-2}	W-187	6.53×10^{-2}	W-187	3.26×10^{-3}

(1) Based on shielding design source terms given in Tables 12.2-1 through 12.2-5.
(2) Specific activity of corrosion products in the reactor coolant concentrated in the filter to yield a contact dose rate of 50 R/hr.
(3) Specific activity of corrosion products in the reactor coolant concentrated in the body to yield a contact dose rate of 10 R/hr.
(4) Specific activity of corrosion products in the reactor coolant concentrated in the body to yield a contact dose rate of 0.5 R/hr.
(5) Isotopes with specific activities less than 1.0×10^{-20} are not listed.

Table 12.2-32

TURBINE OPERATING DECK SHIELDING DESIGN SOURCE TERMS[1][2]

SOURCE	DECAY TIME IN TRANSIT (seconds)	AVERAGE DENSITY (g/cc)	AVERAGE N-16 SPECIFIC ACTIVITY (μCi/cc)
Main steam piping to high pressure turbine	3.27	3.78×10^{-2}	1.38
High pressure turbine exhaust piping	3.63	7.44×10^{-3}	2.61×10^{-1}
Cross-around piping to combined intercept valves	6.43	6.41×10^{-3}	1.71×10^{-1}

(1) Based on shielding design source terms given in Tables 12.2-1 through 12.2-5.
(2) Assumes a total rated flow of main steam from the RPV of 14,140,500 lb/hr.

(1) Based on shielding design source terms given in Tables 12.2-1 through 12.2-5.
(2) Main steam with 3.63 seconds decay accumulated for 2.185 seconds at rated flow per moisture separator.
(3) All particulates and 20% of N-16 that enter the moisture separator accumulated for 14.85 seconds at rated flow per moisture separator drain tank.
(4) Isotopes with activities less than 1.0×10^{-20} are not listed.

Table 12.2-34

FEEDWATER HEATERS AND DRAIN COOLER SHIELDING DESIGN SOURCE TERMS[1][2]

Equipment	N-16 ACTIVITY IN SHELL SIDE OF FEEDWATER HEATERS		
	Vapor Region (Ci)	Liquid Region [3] (Ci)	Total (Ci)
Feedwater Heater No. 106	5.54	3.71	9.25
Feedwater Heater No. 105	3.84	2.88	6.72
Feedwater Heater No. 104	1.41	5.31	6.72
Feedwater Heater No. 103	1.61	3.04	4.65
Feedwater Heater No. 102	5.89×10^{-1}	2.23	2.82
Feedwater Heater No. 101	3.45×10^{-1}	2.22	2.57
Feedwater Heater Drain cooler	--	5.41×10^{-1}	5.41×10^{-1}

(1) Based on shielding source terms given in Table 12.2-4.
(2) All data are based on "Valve Wide Open" flow conditions.
(3) Assumes 20% of N-16 in steam that condenses enters the liquid region.

Table 12.2-35

Cs-140	1.02×10^{-8}				

(1) Based on shielding design source terms given in Tables 12.2-1 through 12.2-5.
(2) Assumes 2 minutes decay in transit through the condenser hotwell.
(3) Reactor water activities with a water/steam carryover factor of 0.02 by weight for halogens and 0.001 for others (coolant activation gases and noble gas fission products are excluded).
(4) Noble gas daughters created during the 7 second transit time from the RPV steam nozzles to the condensers noncondensables exhaust.
(5) Isotopes with specific activities less than 1.0×10^{-20} are not listed.

Table 12.2-39

(1) Based on shielding design source terms given in Tables 12.2-1 through 12.2-5.
(2) Assumes 2.25 minutes decay in transit through condenser hotwell and piping to filter/demineralizer.
(3) Backwash volume for the receiving tank is assumed to be 9000 gallons.
(4) Carryover component of condensate accumulated for 10 days at 4314 gpm at 1.0 g/cc.
(5) Fallout component of condensate accumulated for 10 days at 4314 gpm at 1.0 g/cc.
(6) Isotopes with activities less than 1.0×10^{-20} are not listed.

				Xe-144	7.86×10^{-13}

(1) Based on shielding design source terms given in Tables 12.2-1 and 12.2-2.
(2) Assumes all fission gases and halogens in main steam at 100% reactor power.
(3) Assumes a transit time of 109 seconds from the RPV steam nozzles to the mechanical vacuum pump, at 3% reactor power.
(4) Isotopes with specific activities less than 1.0×10^{-20} are not listed.

Table 12.2-43

OFFGAS PIPING SHIELDING DESIGN SOURCE TERMS [1][2][3][4]

ISOTOPE[5]	SPECIFIC ACTIVITY (Ci/cc)	ISOTOPE	SPECIFIC ACTIVITY (Ci/cc)	ISOTOPE	SPECIFIC ACTIVITY (Ci/cc)
N-13	3.99×10^{-7}	Kr-89	1.45×10^{-5}	Xe-135m	2.91×10^{-6}
N-16	2.28×10^{-3}	Kr-90	3.13×10^{-5}	Xe-135	2.46×10^{-6}
N-17	1.14×10^{-6}	Kr-91	3.69×10^{-5}	Xe-137	1.68×10^{-5}
O-19	4.56×10^{-5}	Kr-92	3.69×10^{-5}	Xe-138	9.97×10^{-6}
F-18	2.28×10^{-7}	Kr-93	1.11×10^{-5}	Xe-139	3.13×10^{-5}
Kr-83m	3.81×10^{-7}	Kr-94	2.58×10^{-6}	Xe-140	3.36×10^{-5}
Kr-85m	6.84×10^{-7}	Kr-95	2.35×10^{-7}	Xe-141	2.68×10^{-5}
Kr-85	2.24×10^{-9}	Xe-131m	1.68×10^{-9}	Xe-142	8.15×10^{-6}
Kr-87	2.24×10^{-6}	Xe-133m	3.25×10^{-8}	Xe-143	1.34×10^{-6}
Kr-88	2.24×10^{-6}	Xe-133	9.18×10^{-7}	Xe-144	6.27×10^{-8}

(1) Based on shielding design source terms given in Tables 12.2-1 and 12.2-4.
(2) Main steam (activation and fission gases only) with no decay (at RPV nozzles).
(3) Assumes a 20% washout of N-16 in the main condensers.
(4) Credit for decay is taken for shielding various segments of the offgas piping.
(5) Isotopes with specific activities less than 1.0×10^{-20} are not listed.

Cs-139	2.13×10^{-2}	Y-90	7.16×10^{-4}	Xe-137	1.56×10^{-1}
Ba-139	2.07×10^{-2}	Rb-89	1.08×10^{-2}	Xe-138	9.45×10^{-2}
Cs-138	7.53×10^{-3}	Sr-89	1.06×10^{-2}	Xe-139	2.58×10^{-1}
Cs-137	4.15×10^{-4}	Y-89m	1.06×10^{-6}	Xe-140	2.14×10^{-1}
Cs-135	6.33×10^{-10}	Rb-88	1.71×10^{-3}	Xe-141	5.89×10^{-3}
Rb-95	4.25×10^{-6}	Rb-87	3.59×10^{-1}	Xe-142	1.08×10^{-3}
Sr-95	7.58×10^{-7}	N-13	3.01×10^{-3}	Xe-143	2.11×10^{-5}
Y-95	6.72×10^{-7}	N-16	8.86	Xe-144	2.93×10^{-4}

(1) Based on shielding design source terms given in Tables 12.2-1 and 12.2-4.

(2) Main steam (activation and fission gases only) with 9.1 seconds decay accumulated for 0.305 seconds at rated flow (includes an 18 month buildup of 1% of the particulate daughters of gases).

(3) Assumes a 20% washout of N-16 in the main condensers.

(4) Isotopes with activities less than 1.0×10^{-20} are not listed.

Note: Since the short term activity reaches equilibrium within a few days after startup, extending the refueling cycle to 24 months does not contribute a significant amount to the total dose from the system.

Y-89m	1.25×10^{-9}
Rb-88	2.24×10^{-6}
Rb-87	1.29×10^{-15}

(1) Based on shielding design source terms given in Tables 12.2-1 and 12.2-4.
(2) Assumes a 20% washout of N-16 in the main condensers.
(3) Based on activity at outlet of offgas recombiner aftercondenser.
(4) Assumes an 18.6 second holdup pipe between aftercondenser outlet and analyzer cells.
(5) Assumes a flow rate of 0.3 scfm of offgas through the analyzer tubing (includes a 40 year buildup of particulate daughters of gases).
(6) Isotopes with specific activities less than 1.0×10^{-20} are not listed.
(7) Based on sum of radiation sources in analyzer cells.

Cs-137	2.08×10^{-3}
Ba-140	1.95×10^{-3}
Ce-141	2.70×10^{-4}
La-140	1.95×10^{-3}
Y-90	6.85×10^{-5}
Y-89m	4.34×10^{-7}
Nb-95	8.66×10^{-5}
Nb-95m	1.77×10^{-6}

(1) Based on NUREG-0016, Revision 0, table 1-1 (Reference 12.2-1) release rates, with fission products adjusted to 0.35 Ci/sec offgas release rate at 30 minutes decay.

(2) Assumes a one year accumulation of all these isotopes at 63,000 cfm.

(3) Isotopes with activities less than 1.0×10^{-20} are not listed.

Table 12.2-50

SGTS AIR FILTERS SHIELDING DESIGN SOURCE TERMS[1][2]

ISOTOPE[3]	ACTIVITY (Ci)
I-131	4.66×10^{-3}
I-133	1.61×10^{-2}

(1) Based on shielding design source terms given in Tables 12.2-1 and 12.2-4.
(2) Isotopes with activities less than 1.0×10^{-20} are not listed.
(3) Based on 150 scfm main condenser air inleakage.

Table 12.2-81

CHARCOAL MAIN BED SHIELDING DESIGN SOURCE TERMS

This table lists the shielding design source terms for the various components that comprise the charcoal main bed. The table is divided into the following parts:

a. First Half of Adsorber Number 1 (Unit 1)

b. Second Half of Adsorber Number 1 (Unit 1)

c. Adsorber Number 2 (Unit 1)

d. Adsorber Number 3 (Unit 1)

e. Adsorber Number 4 (Unit 1)

f. Adsorber Number 1 (Unit 2)

g. Adsorber Number 2 (Unit 2)

h. Adsorber Number 3 (Unit 2)

i. Adsorber Number 4 (Unit 2)

j. Adsorber Number 5 (Unit 2)

Table 12.2-81(a)

FIRST HALF OF ADSORBER NUMBER 1 (UNIT 1)[1][3][4]

ISOTOPE[2]	ACTIVITY (Ci)	ISOTOPE	ACTIVITY (Ci)	ISOTOPE	ACTIVITY (Ci)
Xe-131m	$1.72 \times 10^{+1}$	Cs-135	3.21×10^{-2}	Rb-91	2.29×10^{-3}
Xe-133m	$2.06 \times 10^{+2}$	Kr-83m	$8.68 \times 10^{+1}$	Sr-91	9.87×10^{-3}
Xe-133	$8.12 \times 10^{+3}$	Kr-85m	$2.28 \times 10^{+2}$	Y-91	9.86×10^{-3}

(1) Assumes the reactor to have been operating for 1000 days at 3458 Mw(t) at time of LOCA.

(2) Assumes 100% of noble gases and 25% of halogens in core are released to primary containment atmosphere.

(3) Assumes 0.5% per day leak rate from primary to secondary containment.

(4) This activity is assumed to be uniformly distributed throughout the free air volume of primary containment, including the drywell and wetwell. This volume is 404,000 ft^3.

=_____

(1) Assumes the reactor to have been operating for 1000 days at 3458 Mw(t) at time of LOCA.

(2) Assumes 100% of noble gases and 25% of halogens in core are released to primary containment atmosphere.

(3) Assumes 0.5% per day leak rate from primary to secondary containment.

(4) Assumes a secondary containment recirculation system flow rate of 60,000 cfm with a charcoal filter efficiency of 0.95 for halogens.

(5) Assumes a SGTS flow rate of 2778 cfm with a charcoal filter efficiency of 0.99 for halogens.

(6) This activity is assumed to be uniformly distributed throughout the free air volume of the secondary containment. This volume is 4,000,000 ft^3, and includes the common refueling floor for both units.

(1) Assumes reactor to have been operating for 1000 days at 3458 Mw(t) at time of LOCA.
(2) Assumes 100% of noble gases and 25% of halogens in core are released to primary containment atmosphere.
(3) Assumes 0.5% per day leak rate from primary to secondary containment.
(4) Assumes a secondary containment recirculation system flow rate of 60,000 cfm with a charcoal filter efficiency of 0.95 for halogens.
(5) Assumes an SGTS flow rate of 2778 cfm with a charcoal filter efficiency of 0.99 for halogens.
(6) Assumes turbine enclosure and control structure intake environs cloud immediately, allowing only for atmospheric dispersion.
(7) Building wake atmospheric dispersion factors (X/Q) used are given by post-LOCA time period:
0 to 8 HRS 3.46×10^{-4} sec/m^3
8 to 24 HRS 2.04×10^{-4} sec/m^3
24 to 96 HRS 1.30×10^{-4} sec/m^3
96 to 720 HRS 5.71×10^{-5} sec/m^3

(1) Based on shielding design source terms given in Tables 12.2-2, 12.2-3, and 12.2-5.
(2) Filtered and demineralized fuel pool water (DF of 2 for Cs and Rb, DF of 10 for others) accumulated for 6.11 hours at 1500 gpm.
(3) This activity is in 550,000 gallons.
(4) Isotopes with activities less than 1.0×10^{-20} are not listed.

Table 12.2-89

TRAVERSING INCORE PROBE MATERIALS

DETECTOR REGION

Material	Weight (g)
304L stainless steel (Co ≤ 0.014%)	4.92
Commercially pure titanium	0.662
Alumina	0.885
Nickel/iron alloy	0.248
Copper	0.021

CABLE REGION

Material	Weight (g/inch)
AISI 304L stainless steel (Co ≤ 0.014%)	0.43
AISI 1070 carbon steel	2.16
Magnesium oxide (insulation)	0.0798

(1) BWR-GALE Computer Code (Reference 12.2-1).
(2) Includes control structure releases.
(3) Includes offgas enclosure releases.

Table 12.2-94

ESTIMATED IN-PLANT DISTRIBUTION OF AIRBORNE RADIOACTIVITY RELEASES[1]

RELEASES	AIRBORNE RELEASE FRACTION (%)
Turbine Enclosure[2]	
Condenser areas	60.30
SJAE areas	7.00
Mechanical vacuum pump areas	3.50
Turbine hall areas	9.20
Other equipment areas[3]	20.00
	100.00
Reactor Enclosure	
RWCU pump areas	23.65
RWCU filter/demineralizer areas	9.80
Refueling areas[4]	9.15
ECCS areas (RHR, HPCI, etc.)	7.40
Drywell areas	30.00
Other equipment areas[3]	20.00
	100.00
Radwaste Enclosure[5]	
Solids handling areas	8.40
Liquid waste handling areas	71.60
Other equipment areas[3]	20.00
	100.00

(1) Based on report for EPRI Research Project 274-1 (Reference 12.2-2).
(2) Includes control structure equipment areas.
(3) Assumes 80% of enclosure release by major areas listed and 20% by all other equipment areas within the enclosure.
(4) All of reactor enclosure tritium is assumed to be released in the refueling area.
(5) Includes offgas enclosure equipment areas.

(1) Based on 3 years of simulated use consisting of 1 hour of detector exposure in core semimonthly.
(2) At 1 meter.
(3) At 1 meter from the midpoint of the 12 foot length of irradiated cable adjacent to the detector.

12.3 RADIATION PROTECTION DESIGN FEATURES

12.3.1 FACILITY DESIGN FEATURES

Specific design features for maintaining personnel exposures ALARA are discussed in this section. These are used in addition to, and in conjunction with, the more generalized design features described in Section 12.1.2.

12.3.1.1 Common Equipment and Component Designs for ALARA

This section describes the design features used for several general classes of equipment and components. Since these classes of equipment are common to many of the plant systems, the features employed in each system to minimize exposures are similar and can be discussed generically by equipment type.

Filters: Filters that accumulate radioactivity are supplied with the means either to backflush/recharge the filter remotely or to perform cartridge replacement with semiremote tools (i.e., long-handled tools). For cartridge filters, adequate space is provided to allow removing, loading, and transporting the cartridge to the solid radwaste storage area.

Demineralizers: Demineralizers in radioactive systems are designed so that spent resin can be remotely transferred to spent resin tanks and fresh resin can be remotely loaded into the demineralizers. The demineralizers and piping can be flushed with condensate or demineralized water to remove any accumulations of resin. The equipment and floor drain demineralizers are typical examples; these are shown on drawings M-62 and M-63, respectively.

Evaporators: System abandoned (Section 11.2.2.1.3).

Pumps: Wherever practicable, pumps in radioactive areas are provided with mechanical seals to reduce seal servicing time. Pumps and associated piping are arranged to provide adequate space and access for maintenance. Small pumps are installed in a manner that allows easy removal if necessary. All pumps in radioactive waste systems are provided with flanged connections for ease of removal. Pump casings have connections for draining the pump prior to maintenance. The use of base plates with drains connected to the floor drain system minimizes the spread of contamination resulting from leakage of continuously operating pumps.

Tanks: Whenever practicable, tanks are provided with sloped bottoms and bottom outlet connections. Overflow lines are lower than vent lines and are directed to the waste collection system to prevent an overflow from spreading contamination within plant structures. For tanks containing radioactive material, the tank and associated discharge piping can be flushed to reduce radiation levels if required for entry into the tank cells. Access is provided for removal, maintenance, or inspection of tank motor agitators and also for cleaning operations involving tank internals. The solid radwaste collection system (drawing M-66 and Figure 12.3-2) provides examples of these features.

Heat Exchangers: Heat exchangers are provided with corrosion-resistant tubes of stainless steel or other suitable materials with tube-to-tube sheet joints usually welded to minimize leakage. Impact baffles are provided and tube side and shell side velocities are limited to minimize erosive effects. Space is reserved for tube bundle removal, and provisions for flushing are supplied.

Instruments: Instrument devices are located in low radiation zones and away from radiation sources whenever practicable to reduce personnel exposure during maintenance. Primary instrument devices, which for functional reasons are located in high radiation zones, are designed for easy removal to a lower radiation zone for maintenance and calibration. Some instruments located in high radiation zones, such as thermocouples, are provided in duplicate to preclude the need for immediate entry in case of instrument failure and allow maintenance to be performed at a later time when radiation levels may be lower. Transmitters and readout devices are located in low radiation zones. Instrument and sensing lines are provided with flushing capability and are routed to minimize radioactive gas buildup. Backflushing capability exists for reactor vessel sensing lines. Tanks containing two-phase fluids are fitted with probe-type instruments.

Whenever practicable, diaphragm seals are provided on instrument sensing lines on process piping that contains highly radioactive solids to reduce radiation exposures during servicing of the instrument. Instrument and sensing line connections are typically located in or above the piping midplane to avoid corrosion product buildup.

Valves: To minimize personnel exposures from valve operations and maintenance, motor-operated, air-operated, or other remotely actuated valves are used to the maximum extent practicable where the reduction in operational exposure is greater than the expected increase in maintenance exposure associated with the remote operator.

Whenever practicable, valves are located in valve galleries and are shielded separately from the major components that accumulate radioactivity. Long runs of exposed radioactive piping are minimized in valve galleries. In areas where manual valves are used on frequently operated radioactive process lines, either reach rods or radiation shielding is provided to minimize personnel exposure.

For equipment located in high radiation zones, remote actuators are provided for frequently operated valves associated with system operation. Examples of remote actuators can be seen on drawing M-66. All other valve operations are either infrequent or performed when the equipment is not operating. To the maximum extent practicable, these valves are provided with straight reach rods to allow operators to feel whether or not the valves are tightly closed. Valves with reach rods are installed with their stems located in a horizontal position wherever possible, so that the reach rods are also horizontal but above head level to prevent restriction of access during maintenance.

Provisions are made in many radiation areas to drain adjacent radioactive components when maintenance is required on valves.

Wherever practicable, valves for clean, nonradioactive systems are separated from radioactive sources and are located in readily accessible areas. Vent, drain, and instrument root isolation valves on radioactive systems are located close to the process piping or equipment with which they are associated. This minimizes the lengths of piping carrying process fluids when these valves are closed.

Manually operated valves required for normal operation and shutdown are not located in filter and demineralizer valve compartments.

For large valves (2½ inches and larger) originally supplied and installed in lines carrying radioactive fluids, a double set of packing with a lantern ring is usually provided. Such valves, except those having a packing gland which constitutes a direct communication path between primary containment atmosphere and the reactor building, are being systematically provided with an

improved packing arrangement that eliminates use of the second packing set. Power-actuated valves so changed are also being fitted with automatic gland adjustment capability. A stuffing box is also provided with a leak-off connection that may be piped to a drain header. Flow from the leak-off is stopped by a plug or a manual stop valve. Full ported valves are used in systems containing radioactive solids.

Valve designs with minimum internal crevices are used where crud trapping could become a problem, such as in piping carrying spent resin. Globe valves two inches and smaller in radioactive systems are Y-pattern-type to facilitate rodding if plugged.

Piping: The piping in pipe chases is designed for the lifetime of the unit. The number of valves or instruments in the pipe chases has been reduced to the maximum extent practicable. Piping layout is discussed in Section 12.3.1.2.

Floor Drains: Floor drains and sloped floors are provided for each room or cubicle that has serviceable components containing radioactive liquids. Whenever practicable, drain lines are embedded in concrete floors which provide shielding. If a radioactive drain line must pass through a radiation zone lower than that at which it will terminate, proper shielding is provided. Local gas traps or porous seals are not used on radwaste floor drains. Gas traps are provided at the common sump or tank. Wherever practicable, provisions exist for removing plugging in drain piping. Floor drains are designed to handle potential backflooding.

Lighting: Multiple electric lights are provided for each cell or room containing highly radioactive components so that the burnout of a single lamp does not require entry and immediate replacement of the defective lamp; sufficient illumination still remains available. Lighting in a radioactive area is actuated from outside the area and long-life bulbs are used. Section 9.5.3 describes the lighting system.

HVAC: The HVAC system is designed to minimize radioactive buildup and provides for easy access and fast replacement of the filter elements. Filter banks and components are separated from adjacent banks and components. Section 12.3.3 provides additional description of the HVAC radiation protection design features.

Sample Stations: Sample stations for routine sampling of process fluids are located in accessible areas. Shielding is provided at the local sample stations as required to maintain radiation zoning in proximate areas and minimize personnel exposure during sampling. The counting room and laboratory facilities are described in Section 12.5.

Clean Services: Wherever practicable, clean services such as compressed air piping, clean water piping, ventilation ducts, and cable trays are not routed through radioactive pipe-ways. In addition, active components of these clean services are located outside high radiation areas wherever possible to minimize any radiation exposure associated with maintenance of clean systems.

12.3.1.2 Common Facility and Layout Designs for ALARA

This section describes the design features used for standard-type plant processes and layout situations for radioactive systems and for potentially radioactive systems. These features are used in conjunction with the general equipment designs described in Section 12.3.1.1 and include the details discussed in the following paragraphs:

Valve Galleries: Valve galleries are provided with shielded entrances for personnel protection. In many cases, the valve galleries are divided by shielding or distance into subcompartments that service only two or three components so that personnel are only exposed to the valves and piping associated with a few components at any given location. Process isolation valves are located close to wall penetrations. Floor drains are provided to control radioactive leakage, and curbs are supplied as necessary. To facilitate decontamination in valve galleries, concrete surfaces are covered with a smooth surfaced coating that allows easy decontamination.

Piping: Each piping run is analyzed to determine the potential radioactivity level and maximum expected surface dose rate. Radioactive pipes are routed separately from nonradioactive pipes to minimize personnel exposure. Pipes carrying radioactive materials are routed through controlled access areas zoned for a corresponding level of activity. Where radioactive piping must be routed through corridors or other low radiation areas, shielded pipe-ways are provided. Valves and instruments are not normally placed in radioactive pipe-ways. Wherever practicable, each equipment compartment is used as a pipe-way only for those pipes associated with equipment in the compartment. Doing so minimizes exposure due to the operation of one system while maintenance is being performed on another system that is shut down.

Piping is designed to minimize low points and dead legs. Drains are provided on piping where low points and dead legs cannot be eliminated. Where possible, thermal expansion loops are raised rather than dropped. In radioactive systems, the use of nonremovable backing rings in the piping joints is minimized to eliminate a potential crud trap for radioactive materials. Wherever possible, branch lines having little or no flow during normal operation are connected above the horizontal midplane of the main pipe. Line size changes are typically made by eccentric reducers. Orifices are placed in vertical lines wherever possible.

Piping carrying resin slurries is run with large radius bends wherever possible instead of elbows, and horizontal runs are minimized. To prevent possible crud buildup, flow control valves and orifices are not normally used unless they are required for system operation. Large diameter piping is typically used with a minimum number of pipe fittings to reduce crud accumulation.

Field Run Piping: All routing of radioactive process piping, large and small, is reviewed by the engineering office to ensure that the radiation zone routing is proper and that the above principles are being employed.

Penetrations: Penetrations are normally located with an offset between the source and the accessible areas to minimize radiation streaming. If offsets are not practicable, penetrations are located as far as possible above the floor elevation to reduce the exposure to personnel. If neither of these two methods is used, then alternative means are employed, such as using baffle shield walls or radiation shielding in the area around the penetration.

Contamination Control: Access control and traffic patterns are considered in the basic plant layout to minimize the spread of contamination. Equipment vents and drains from radioactive systems are normally piped directly to the collection system instead of allowing any contaminated fluid to flow across to the floor drain. All-welded piping systems are used for radioactive systems to the maximum extent practicable to reduce system leakage and crud buildup at joints. The valves in some radioactive systems are provided with leak-off connections piped directly to the collection system.

Decontamination of potentially contaminated areas within the plant is facilitated by the application of suitable smooth surfaced coatings to the concrete floors and walls.

Floor drains and sloping floors are provided in all potentially radioactive areas of the plant. In addition, radioactive and potentially radioactive drains are separated from nonradioactive drains.

Systems that become highly radioactive, such as the radwaste slurry transport system, are provided with flush and drain connections. Certain systems have provisions for chemical cleaning prior to maintenance.

Equipment Layout: In systems where process equipment is a major radiation source (such as fuel pool cleanup, radwaste, condensate demineralizer, etc.), pumps, valves, and instruments are separated from the process component. This allows servicing and maintenance of items in reduced radiation zones. Control panels are located in the lowest dose radiation zones. Redundant equipment can be separated from each other, and shielding is provided between the equipment to allow maintenance concurrent with system operation.

Except for HVAC components, major components (such as tanks, demineralizers, and filters) in radioactive systems are located in individual shielded compartments. For highly radioactive components (such as filters and demineralizers), completely enclosed shielded compartments with hatch openings are provided. Provision is made for some major plant components for removal to lower dose radiation zones for maintenance. Large HVAC filter plenums with multiple filter cartridges are individually shielded.

Labyrinth entrance-way shields or shielding doors are provided for each compartment or plenum from which radiation could stream to access areas and exceed the radiation dose limits for those areas. Adequate space for removal of components is provided.

Wherever practicable, lubrication of equipment in radiation areas is achieved with the use of tube-type extensions to reduce exposure during maintenance.

Figures 12.3-1 to 12.3-7 provide typical layout arrangements for demineralizers, liquid and particulate filters, waste sludge tanks, offgas recombiners, sample stations, charcoal beds, and their associated valve compartments or galleries.

Exposure from routine in-plant inspection is controlled by locating inspection points in shielded low background radiation areas wherever possible. Radioactive and nonradioactive systems are normally separated to limit radiation exposure from routine inspection of nonradioactive systems. For radioactive systems, emphasis is placed on adequate space and ease of motion in a shielded inspection area. Where longer times for routine inspection are required and permanent shielding is not feasible, sufficient space for portable shielding is normally provided. In high radiation areas where routine surveillance is required, remote viewing devices are provided as needed. Typically, equipment and valves in high radiation areas are made easily accessible by providing permanent access platforms, easily removable insulation, etc. Equipment man-ways are readily accessible. Equipment lay-down area requirements are considered in the layout, and adequate space is provided where necessary.

Facilities for Handling Sealed and Unsealed Radioactive Material: As discussed in Section 12.2.1.8, special materials used in the radiochemistry laboratory require the design of special handling equipment. For unsealed materials, the following are provided:

a. Exhaust hoods that exhaust to the ventilation system are located in areas such as sample stations and the radiochemistry laboratory.

b. Decontamination facilities, the radiochemical laboratory, controlled zone shop, and instrument repair shops are situated at various locations in the plant and are described in Section 12.5.

c. An area for the repair and maintenance of removed CRDs is provided in the reactor enclosure in close proximity to the CRD removal hatch.

12.3.1.3 Radiation Zoning and Access Control

Access to areas inside the plant structures and plant yards is regulated and controlled. Each high radiation area (as defined in 10CFR20) is provided with a personnel alert barrier. Each high radiation area with a dose rate greater than 1 Rem/hour and very high radiation areas (as defined in 10CFR20) require additional controls per Health Physics Supervision. Section 12.5 describes the control of ingress and egress of plant operating personnel to controlled access areas and the procedures employed to ensure that personnel exposure is within the limits prescribed by 10CFR20.

All plant areas are categorized into radiation zones according to expected radiation levels. Each radiation zone defines either the highest component dose rate in the area or the radiation level to which the aggregate of all contributing sources must be attenuated by shielding, whichever is higher. Each room, corridor, and pipe-way of every plant structure is evaluated for potential radiation sources during normal operation, including anticipated operational occurrences and shutdown. The radiation zone categories used, and their descriptions, are given in Table 12.3-1, and the specific zoning for each plant area is shown in drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130 N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-139, N-140, N-141, N-142, and N-143. All frequently used areas such as corridors are shielded for Zone I or Zone II access.

The locations of airborne radioactivity and area radiation monitors are described in Section 12.3.4. Unit 1 and common area radiation monitors are shown on drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130 N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-139, N-140, N-141, N-142, and N-143, and Table 12.3-7. Unit 2 area radiation monitors are shown on Table 12.3-7.

12.3.1.4 Control of Activated Corrosion Products

To minimize the radiation exposure associated with the deposition of activated corrosion products in reactor coolant and auxiliary systems, the following steps have been taken:

a. The reactor coolant system consists mainly of austenitic stainless steel, carbon steel, and low alloy steel components. The nickel content of these materials is low, and it is controlled in accordance with applicable ASME material specifications. A small amount of nickel base material (Inconel 600) is employed in the reactor vessel internal components. Inconel 600 is required where components are attached to the reactor vessel shell, and the coefficient of expansion must match the thermal expansion characteristics of the low alloy vessel steel. Inconel 600 is selected because it provides the proper thermal expansion characteristics and adequate corrosion resistance, and it can be readily fabricated and welded.

b. Materials employed in the reactor coolant system are purchased to ASME material specification requirements. No special controls on levels of cobalt impurities are specified.

c. Hard-facing and wear materials having a high percentage of cobalt are restricted to applications where no satisfactory alternative materials are available.

d. A high temperature filtration system is not employed in the RWCU. The reasons for this decision include:

   1. Lack of quantitative data on the removal efficiency for insoluble cobalt by the high temperature filter.

   2. Uncertainty in the deposition model, including the relative effectiveness of cobalt removal on deposition rate.

   3. Doubtful cost-effectiveness in an area where other methods under study (such as decontamination) may prove better at reducing dose rates while also being more cost-effective.

e. Items a, b, and c above also apply to valve materials in contact with reactor coolant. Valve packing materials are selected primarily for their properties in the particular environment.

f. Sections 12.1.2.2, 12.3.1.1, and 12.3.1.2 describe the various flushing, draining, testing, and chemical addition connections that have been incorporated into the design of piping and equipment that handle radioactive materials. If decontamination is to be performed, these connections are used for that purpose.

g. The plant is designed with a powdered resin, pressure precoat cleanup system for the primary coolant in the reactor, and a full flow condensate cleanup system for the feedwater. These systems are described in Sections 5.4.8 and 10.4.6, respectively.

h. A chemistry control program to reduce crud buildup has been developed based upon studies performed by GE. This program will be implemented at LGS.

12.3.2 SHIELDING

In this section the bases for radiation shielding and shielding configurations are discussed.

12.3.2.1 Design Objectives

The basic objective of the plant radiation shielding is to reduce personnel exposures, in conjunction with a program of controlled personnel access to and occupancy of radiation areas, to levels that are within the dose regulations of 10CFR50 and are ALARA within the dose regulations of 10CFR20. Shielding and equipment layout and design are considered in ensuring that exposures are kept ALARA during all anticipated personnel activities in all areas of the plant containing radioactive materials.

The plant conditions considered in radiation shielding design are normal operation including anticipated operational occurrences at full power, and plant shutdown. The shielding design objectives are as follows:

a. To ensure that radiation exposure to plant operating personnel, contractors, administrators, visitors, and proximate exclusion area boundary occupants are ALARA and within the limits of 10CFR20.

b. To ensure sufficient personnel access and occupancy time to allow normal anticipated maintenance, inspection, and safety-related operations required for each plant equipment and instrumentation area.

c. To reduce potential equipment neutron activation and mitigate radiation damage to materials.

The control room is sufficiently shielded so that the direct dose plus the inhalation dose (calculated in Chapter 15) in the event of DBAs does not exceed the limits of GDC 19.

12.3.2.2 General Shielding Design

Shielding is provided to attenuate direct radiation through walls and penetrations, and to attenuate scattered radiation to less than the upper limit of the radiation zone for each area shown in drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130 N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-140, N-141, N-142, and N-143, which show the minimum shielding requirements for all plant areas. Shielding design criteria and shielding design source terms for specific plant equipment are presented in Section 12.2.

The material used for most of the plant shielding is ordinary concrete with a minimum bulk density of 140 lb/ft^3. Whenever poured-in-place concrete has been replaced by concrete blocks or other material, design ensures protection on an equivalent shielding basis as determined by the shielding characteristics of the concrete block and associated grout fill material selected. As discussed in Section 1.8, Regulatory Guide 1.69 is not employed for LGS. Further discussion of concrete standards is contained in Section 3.8. Water is used as the primary shield material for areas above the spent fuel transfer and storage areas.

The guidance provided in Regulatory Guide 8.8 was followed for LGS. ALARA design features are discussed in Sections 12.1.2 and 12.3.1. Specific features pertaining to shielding are described below.

12.3.2.3 Shielding Calculational Methods

The shielding thicknesses provided to ensure compliance with plant radiation zoning and to minimize plant personnel exposure are based on maximum equipment activities under the plant operating conditions, as described in Section 12.2. The thickness of each shield wall surrounding radioactive equipment is determined by approximating the actual geometry and physical condition of the source or sources. The isotopic concentrations are converted to gamma ray sources using data from standard References 12.3-1 through 12.3-5.

The geometric model assumed for shielding evaluation of pipes, tanks, heat exchangers, filters, demineralizers, and evaporators (abandoned) is a finite cylindrical volume source. In cases where

radioactivity is deposited on surfaces, such as inside pipe, the source is treated as a cylindrical annulus. Typical computer codes that are used for original design shielding analysis are listed in Table 12.3-2, which includes References 12.3-6 through 12.3-15. Shielding attenuation data used in those codes include gamma mass attenuation coefficients (Reference 12.3-16), gamma buildup factors (Reference 12.3-17), neutron/gamma multigroup cross-sections (Reference 12.3-18), and albedos (Reference 12.3-19). Additional sources of information pertaining to shielding techniques include References 12.3-20 through 12.3-27. This list of publications and computer programs are as applied in the original plant design and are not meant to be all-inclusive.

Shielding design for plant changes use programs and references which are industry standards at the time of the change. Examples of standards include those developed by the American Nuclear Society's ANS-6 Radiation Protection and Shielding Division, and the International Commission on Radiological Protection.

Computer programs used include those distributed by the Oak Ridge National Radiation Safety Information Computational Center, or commercially developed programs implementing established methods and parameters in industry standards.

The shielding thicknesses are selected to reduce the aggregate computed radiation level from all contributing sources below the upper limit of the radiation zone specified for each plant area. Shielding requirements are evaluated at the point of maximum radiation dose through any wall. Therefore, the actual anticipated radiation levels in the greater region of each plant area are below this maximum dose and therefore below the radiation zone upper limit.

Where shielded entry-ways to compartments containing high radiation sources are necessary, labyrinths or mazes are designed so that the scattered dose rate plus the direct dose rate through the shield wall from all contributing sources is below the upper limit of the radiation zone specified for each plant area.

12.3.2.4 Turbine Enclosure Shielding Design

Radiation shielding is provided as necessary for the following systems in the turbine enclosure and control structure, excluding the control room, to ensure that zone access requirements (drawings N-110, N-111, N-112, N-113, N-115, N-125, N-126, N-127, N-128, and N-130) are met for the surrounding areas:

a. Main steam system

b. Condensate system

c. Feedwater system

d. Air removal system

e. Sealing steam system

f. Condensate cleanup system

g. Gaseous radwaste recombiner system

h. Turbine enclosure HVAC system

i. Control room HVAC system.

12.3.2.5 Control Room Shielding Design

Drawings N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-128, N-130 N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-139, N-140, N-141, N-142, N-143 and Figure 12.3-26 represent layout and isometric drawings of the control room, showing its relationship to the reactor enclosure.

The design basis LOCA dictates the shielding requirements for the control room. Shielding is provided to permit access and occupancy of the control room under LOCA conditions with radiation doses limited to 5 rem whole body from all contributing modes of exposure for the duration of the accident, in accordance with GDC 19.

The design basis LOCA is described in Section 15.6.5. The direct radiation from airborne fission products inside the reactor enclosure contributes less than 50 mRem to personnel inside the control room for the 30 day period following a LOCA, based on the radioactivity sources described in Section 12.2.

The assumptions used to determine control room habitability are listed in Regulatory Guide 1.3 and are discussed in Section 15.0.

For isotopes that escape from the drywell to the reactor enclosure, credit is taken for shielding by the internal structures in the reactor enclosure. Shielding credit is taken for the reactor enclosure and control structure walls. For all isotopes that remain within the drywell, shielding credit is taken for the drywell wall.

12.3.2.6 Reactor Enclosure and Refueling Area Shielding Design

During reactor operation, the steel-lined, reinforced concrete drywell wall and the reactor enclosure walls protect personnel occupying adjacent plant structures and yard areas from radiation originating in the reactor vessel and in associated equipment within the reactor enclosure. The reactor vessel shield wall, drywell wall, and various equipment compartment walls, together with the reactor enclosure walls, reduce the radiation levels in the yard area outside the reactor enclosure to less than Zone I maximum dose rates, for those areas that are normally accessible.

Where personnel and equipment removal hatch openings or penetrations pass through the drywell wall, additional shielding, such as labyrinths or doors, is provided to attenuate the radiation to below the required level defined by the radiation zone outside the drywell wall.

Inside Drywell Structure: Areas within the drywell are Zone V and are normally inaccessible during plant operation. The reactor vessel shield provides shielding for access in the drywell during shutdown and reduces the activation of and radiation damage to drywell equipment and materials.

Outside Drywell Structure: The drywell wall reduces radiation levels in accessible areas of the reactor enclosure from sources within the drywell to below the maximum level for Zone II. Shielding requirements for the personnel access and equipment removal and CRD removal hatch openings are shown on drawings N-119 and N-134 in the areas numbered 401, 405, and 409, respectively. Shielding for these areas includes high density concrete, because neutron shielding must be considered for these large openings in the drywell wall. Drywell piping and electrical penetrations are shielded by providing either lock shields within the penetration assembly or a shielded penetration room. Shielded piping penetration room locations and bulk shielding requirements are

shown on drawings N-118, N-119, N-120, N-133, N-134, and N-135. These rooms, numbered 306, 307, 309, 501, 510, 522, 523, and 599 are designated radiation Zone V during reactor power operation and are provided with personnel access controls.

Radiation shielding is provided as necessary for the following systems in the reactor enclosure and refueling area to ensure that the radiation zone and access requirements (drawings N-116, N-122, N-131, N-137, and N-139) are met for surrounding areas:

a. RWCU system

b. FPCC system

c. Neutron monitoring system

d. HPCI system

e. RCIC system

f. RHR system

g. Core spray system

h. Reactor enclosure and refueling area HVAC systems.

Main steam lines are located within shielded structures from the drywell wall to the reactor enclosure wall.

Spent fuel is a primary source of radiation during refueling. Because of the extremely high activity of the fission products contained in the spent fuel assemblies and the proximity of Zone II areas, extensive shielding is provided for areas surrounding the fuel transfer canal and pool to ensure that radiation levels remain below zone levels specified for adjacent areas.

After reactor shutdown, RHR system pumps and heat exchangers are in operation to remove heat from the reactor water. The radiation levels in the vicinity of this equipment will temporarily reach Zone V levels due to corrosion and fission products in the reactor water. Shielding is provided to attenuate radiation from RHR equipment during shutdown cooling operations to levels consistent with the radiation zoning requirements of adjacent areas. Adequate shielding is also provided to maintain radiation zoning requirements during the hot standby operation of the RHR system.

The concrete shield walls surrounding the spent fuel cask loading, storage, and transfer areas, as well as the shield walls surrounding the fuel transfer and storage areas, are sufficient to limit radiation levels outside the shield walls in all accessible areas to below Zone II maximum dose rates.

Water in the spent fuel pool provides shielding above the spent fuel transfer and storage areas. Radiation levels at the fuel handling equipment are calculated to be below Zone II maximum dose rates during normal operations.

Water is also used as shielding material above the steam dryer and separator storage area. Concrete walls and water in the pool are designed to provide Zone II dose rates in adjacent accessible areas during storage of the dryer and separator.

A portable refueling shield is provided to reduce radiation dose rates in the drywell that are due to the transfer of spent fuel assemblies from the reactor vessel to the spent fuel pool. During refueling, the lead and steel shield is located in the reactor well, between the reactor vessel and the spent fuel pool, which permits continuous personnel occupancy of the drywell.

In addition, a temporary local personnel alarming rate meter is expected to be used in the drywell, with local alarms. Access controls to the upper reaches of the drywell aid in ensuring satisfactory protection for personnel.

12.3.2.7 Radwaste Enclosure Shielding Design

Radiation shielding is provided as necessary for the following systems in the radwaste enclosure to ensure that the radiation zone and access requirements (drawings N-140 through N-143) are met for surrounding areas:

a. Liquid radwaste equipment drain subsystem

b. Liquid radwaste floor drain subsystem

c. Liquid radwaste chemical waste subsystem

d. Liquid radwaste laundry drain subsystem

e. Solid radwaste system

12.3.2.8 Offgas Enclosure Shielding Design

Radiation shielding is provided as necessary for the gaseous radwaste system in the offgas enclosure to ensure that zone access requirements (drawings N-140 through N-142) are met for surrounding areas.

12.3.2.9 Diesel Generator Enclosure Shielding Design

There are no radiation sources in the diesel generator enclosure; therefore, no radiation shielding is required for the enclosure.

12.3.2.10 Miscellaneous Plant Areas and Plant Yard Areas

Radiation shielding is provided for all radiation sources located in plant enclosures so that radiation levels at accessible areas outside are maintained below Zone I levels. Plant yard areas that are frequently occupied by plant personnel are accessible during normal operation and shutdown. These areas are surrounded by a security fence and closed off from areas accessible to the general public.

12.3.3 VENTILATION

The plant ventilation system provides a suitable environment for personnel and equipment during normal operation and anticipated operational occurrences. Detailed HVAC system descriptions are provided in Section 9.4. Control room habitability is discussed in Section 6.4.

12.3.3.1 Design Objectives

The systems are designed to operate so that the in-plant airborne activity levels for normal operation (including anticipated operational occurrences) in the general personnel access areas are within the limits of 10CFR20. The systems operate to reduce the spread of airborne radioactivity during normal and anticipated abnormal operating conditions.

During postaccident conditions, the ventilation system for the plant control room provides a suitable environment for personnel and equipment and ensures continuous occupancy in this area. The plant ventilation systems are designed to comply with the airborne radioactivity release limits for offsite areas during normal operation.

12.3.3.2 Design Criteria

Design criteria for the plant HVAC systems include the following:

a. During normal operation and anticipated operational occurrences, the average and maximum airborne radioactivity levels to which plant personnel are exposed in restricted areas (as defined in pre-1994 10CFR20) of the plant are ALARA and within the limits specified in 10CFR20. The average and maximum airborne radioactivity levels in unrestricted areas (as defined in pre-1994 10CFR20) of the plant during normal operation and anticipated operational occurrences will be ALARA and within the limits of 10CFR20.

b. During normal operation and anticipated operational occurrences, the dose from concentrations of airborne radioactive material in unrestricted areas beyond the exclusion area boundary will be ALARA and within the limits specified in 10CFR20 and 10CFR50.

c. The dose limits of 10CFR50.67 will be satisfied following those hypothetical accidents, described in Chapter 15, that involve a release of radioactivity from the plant.

d. The dose to control room personnel shall not exceed the limits specified in GDC 19 and 10CFR50.67 following those hypothetical accidents, described in Chapter 15, that involve a release of radioactivity from the plant.

12.3.3.3 Design Guidelines

To accomplish the design objectives, the following guidelines are followed whenever practicable.

12.3.3.3.1 Guidelines to Minimize Airborne Radioactivity

The following design guidelines describe equipment and layout features that minimize the formation of airborne radioactivity:

a. Equipment vents and drains are piped directly to a collection device connected to the collection system instead of allowing any radioactive fluid to flow across the floor to the floor drain.

b. All-welded piping systems are used on radioactive systems to the maximum extent practicable to reduce system leakage.

c. Decontaminatable coatings are applied to the concrete floors and walls of potentially radioactive areas to facilitate decontamination.

d. Radioactive equipment has design features that minimize the potential for airborne radioactive contamination during maintenance operations. These features include flush connections on pump casings for draining and flushing the pump before maintenance and flush connections on piping systems that could handle radioactive fluids.

e. Exhaust hoods are used in the laboratories, work areas, and sample stations to facilitate processing of radioactive samples by forcing contaminants away from the personnel breathing areas and into the ventilation and filtering systems.

f. Equipment decontamination facilities are ventilated to ensure control of released radioactivity and prevent the spread of radioactive contamination.

g. The valves in some systems are provided with leak-off connections piped directly to the collection system.

h. To minimize the amount of airborne radioactivity that results from valve packing leakage, most larger valves (2½ inches and larger) are supplied and installed with a double set of packing and lantern ring in lines carrying radioactive fluids. The stuffing box is provided with a leak-off connection which is usually plugged, but may be piped through a manual stop valve to a drain header. An improved packing arrangement is being systematically provided for such valves and eliminates use of the second packing set. The exceptions for those valves that have a packing gland, which constitutes a direct communication path between primary containment atmosphere and the reactor building. These valves are being fitted with an improved packing arrangement that uses two packing sets and a lantern ring to maintain packing gland testability. Power-actuated valves, as part of the improved packing arrangement, are fitted with automatic gland adjustment capability.

12.3.3.3.2 Guidelines to Control Airborne Radioactivity

a. The airflow is directed from areas with lesser potential for radioactive contamination to areas with greater potential for radioactive contamination.

b. In building compartments with a potential for radioactive contamination, a greater volumetric flow is exhausted from the area than is supplied to the area to minimize the amount of uncontrolled exfiltration from the area, or makeup air for the exhaust from the area is infiltrated from surrounding less contaminated areas with no direct supply to the area provided.

c. Floor and equipment drain collection tank vents are piped to a collection header and processed by the ventilation system.

d. Air is supplied to each principal enclosure via separate supply intakes and duct systems.

e. Air being discharged from potentially contaminated areas of the reactor and turbine enclosures is passed through prefilters, HEPA filters, and charcoal filters before release (drawings M-75 and M-76). Air being discharged from the radwaste enclosure is passed through prefilters and HEPA filters as shown in Figure 9.4-3. In addition, to aid in minimizing the quantity of radioactive material discharged, means are provided to isolate the reactor enclosure and the control room upon indication of high airborne activity levels.

f. Suitable primary containment isolation valves are installed in accordance with GDC 54 and GDC 56, including valve controls, to ensure that the containment integrity is maintained.

g. Only exhaust duct-work serves potentially contaminated equipment rooms. The duct-work is at negative pressure so that any leakage is directed into the duct.

12.3.3.3.3 Guidelines to Minimize Personnel Exposure from HVAC Equipment

a. Ventilation ducts are designed to minimize the leakage of radioactive contamination into or out of ducts (as applicable) and the buildup of radioactive contamination within the ducts. Internal obstructions are avoided wherever practicable. Within the reactor enclosure and control structure, welded construction of duct sections is used, and flanged and gasketed joints are used to join duct-work segments. Seismic class II duct-work in the turbine and radwaste enclosures is constructed to Sheet Metal and Air Conditioning Contractors National Association standards modified to allow no more than 4% leakage. All duct-work is 100% leak tested after installation.

b. Access and service of ventilation systems in potentially radioactive areas are improved by component location to minimize operator exposure during maintenance, inspection, and testing, as follows:

    1. The outside air supply units and building exhaust system components are enclosed in ventilation equipment rooms. These equipment rooms are located in radiation Zone II areas and are accessible to the operators. Work space is provided around each unit for anticipated maintenance, testing, and inspection. Filter adsorber units comply with the access and service requirements of Regulatory Guide 1.52 and Regulatory Guide 1.140, to the extent discussed in Sections 6.5.1 and 9.4, respectively.

    2. Local cooling equipment servicing the normal building requirements is located in low radiation areas whenever practicable.

c. All filter systems in which radioactive materials could accumulate to produce significant radiation fields external to the duct-work are appropriately located and shielded to reduce exposure to personnel.

d. The HVAC system is designed to allow fast replacement of components. To simplify element handling, access to active elements is direct from working platforms. Space is provided on the platforms for accommodating safe personnel

movement during replacement of components, including the use of necessary material handling facilities, and during any inplace testing operations.

e. The prefilters and HEPA filters are designed with replaceable 2 foot by 2 foot units that are clamped in place against compression seals. The filter housings are designed, tested, and proven to be airtight with bulkhead-type doors that are closed against compression seals. There are two types of charcoal filters: tray-type and rechargeable-type. The tray-type charcoal filter units are designed with replaceable trays clamped in place against compression seals. There are three trays for each 2 foot by 2 foot unit. The rechargeable charcoal filter units are designed with perforated metal beds filled with bulk charcoal. The bulk charcoal in the beds can be drained and refilled.

f. While most of the activity in the filter train is eliminated by simply removing the contaminated filters, further decontamination of the internal structure is facilitated by the proximity of electrical outlets for operation of decontamination equipment, and water supply for washdown of the interior, if necessary. Drains are provided on the filter housing for removal of contaminated water.

g. Filters in all systems are changed based on the airflow and the pressure drop across the filter bank. Charcoal adsorbers are changed based on the residual adsorption capacity of the bed as measured by the testing of carbon samples taken from the removable canisters located in the carbon bed. The testing of the carbon adsorbers and all other components is described in Sections 6.5 and 9.4.

12.3.3.4 Design Description

Portions of the ventilation systems serving the following enclosures are assumed to be potentially radioactive and are discussed in detail in Section 9.4.

a. Turbine enclosure

b. Control structure

c. Secondary containment

d. Radwaste enclosure

e. Chemistry Laboratory Expansion

f. Offgas enclosure

Although the control room is considered a nonradioactive area, radiation protection is provided to ensure habitability (Section 6.4).

Ventilation system design parameters are given in Tables 12.3-3 through 12.3-6.

A typical layout of a potentially radioactive filter unit is given on Figure 12.3-7.

12.3.4 AREA RADIATION AND AIRBORNE RADIOACTIVITY MONITORING INSTRUMENTATION

12.3.4.1 Area Radiation Monitors

Fixed area radiation monitors are mounted throughout the plant at selected locations. Each location contains a gamma-sensitive detector, local indicator, and local alarm (visual and audio). Indicators, alarms, and recorders are located in the control room, except for the nine local area monitors (Section 12.3.4.1.3). Alarm setpoints are adjusted from the auxiliary equipment room/control room except for local area monitors.

The location and range for each monitor are given in Table 12.3-7. Ranges specified are consistent with the potential dose rates for a given area. Selection of location is based on the equipment in the area and the need for personnel access. In some locations, the detector is mounted immediately inside a cavity while associated local indicators and alarms are mounted just outside the access door. Personnel are thereby alerted to unusual radiation levels within the cavity before initiating access. Experience at PBAPS Units 2 and 3 was used in determining locations.

Area monitors located at fuel storage areas comply with the requirements of 10CFR70.24. These and area monitors in the radwaste enclosure comply with requirements of GDC 63. The area radiation monitors, with associated alarms, indicators and recorders in the main control room provide the capability to alert supervisors and personnel in that area of abnormally high and unexpected radiation levels. Subsequent notification to appropriate plant personnel could avoid inadvertent unnecessary exposure. Unexpected increases in radiation levels may be due to changes in operations, deposition of crud, or transport of radioactive material (e.g., sources) within the plant. Recorded area radiation monitor readings serve to define trends that may result from build-up, spills, or contamination of a process fluid.

Control and calibration of radiation monitoring (fixed and portable) are provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program described in Section 17.2.

12.3.4.1.1 Design Bases

The purpose of the area radiation monitoring system is to provide personnel protection in accordance with the guidelines of 10CFR20, 10CFR50, 10CFR70, and Regulatory Guide 8.8. The area radiation monitoring system has no function related to the safe shutdown of the plant or to the quantitative monitoring of the release of radioactive material to the environment. Consistent with this purpose, the area radiation monitoring system is designed to provide the following functions:

a. Warn of excessive gamma radiation levels in areas where nuclear fuel is stored or handled, in accordance with 10CFR70.24(a)(2).

b. Provide operating personnel with a record and indication in the control room of gamma radiation levels at selected locations within the various plant structures, in accordance with Regulatory Guide 8.8.

c. Supplement other systems in detecting abnormal migrations of radioactive material in or from process streams.

d. Provide local alarms at strategic locations throughout the plant, in accordance with Regulatory Guide 8.8, where a substantial change in radiation levels or loss of sensing capability might be of immediate danger to personnel in the area.

e. Contribute supervisory information to the control room so that correct decisions can be made with respect to deployment of personnel in the event of a radiation accident.

f. Assist in the detection of unauthorized or inadvertent movement of radioactive material in the plant including the radwaste enclosure.

g. Furnish information for conducting radiation surveys.

h. Area Radiation Monitors may be removed from service for maintenance, testing, or known evolutions which would cause an ARM to alarm. Additionally an ARM may be removed from service to clear control room annunciators so other ARM alarms will not be masked. ARM's may be removed from service if the appropriate compensatory actions, if required, are taken (i.e. HP surveys, access control) when the ARM is removed from service.

The above functions are performed under the following design conditions:

h. Environmental parameters shown in Table 12.3-8 are applicable to the design of the area radiation monitoring equipment except for the monitors located inside primary containment, where the detectors are designed for a normal operating temperature range of 64°F to 151°F (up to 340°F for accident conditions) and a pressure range of atmospheric to 2 psig.

i. Noise from any source in the operating environment should not disturb the meter indication by more than ±2% of equivalent full-scale.

j. The detector/indicator and trip unit should be responsive to gamma radiation over an energy range of 0.08 MeV to 7 MeV. The energy dependence should not exceed ±20% of the indicated scale reading for a dose rate of approximately 50 mRem/hr resulting from 0.1 MeV to 3 MeV gammas.

k. At the control room, the reading should be reproducible within ±10% of the local indicated point, and drift should not exceed ±0.2% of equivalent linear full-scale for a 24 hour period or ±2% for a 30 day period.

l. The range of the monitors is shown in Table 12.3-7. The ranges selected ensure readout of both the highest and lowest anticipated radiation levels, in accordance with Regulatory Guide 8.8.

m. Operate without effective change in performance when the ac supply voltage changes over a range of ±10% from nominal value or has a frequency variation of ±5% from nominal value.

n. Operate so that interruption or failure of the ac power supply will result in actuation of the trip circuit to produce an alarm, in accordance with Regulatory Guide 8.8.

12.3.4.1.2 Design Details

The area radiation monitoring system is shown in the typical functional block diagram of Figure 12.3-27. Each channel consists of a combined sensor/converter unit, a local auxiliary unit (readout with visual and audible alarm), a combined indicator/trip unit, a shared power supply, and a shared

multipoint recorder. The locations of the radiation sensors are indicated in Table 12.3-7. Further design details of the area radiation monitoring system are as follows:

a. Each indicator and trip unit is provided with one upscale trip continuously adjustable over the entire scale and one downscale trip adjustable over the lower decade. Provision is made to permit the upscale trip to be set and checked for accuracy with respect to the indicator.

b. Detectors are wall-mounted and suitable for operation in the anticipated plant environment with no additional protection.

c. Panel locations of the remote equipment are shown in Table 12.3-9.

d. The following features are provided for components located in the auxiliary equipment room:

   1. Radiation level indicator (meter)

   2. High radiation alarm light (amber)

   3. Downscale alarm light (white)

   4. Alarm reset (push button)

   5. Meter zero adjust (on the amplifier)

   6. Alarm level adjust

   7. Trip check push button

   8. Power supply switch and "power-on" light (clear lens)

   9. Indicators to show power supply voltages

   10. Annunciator outputs

   11. Recorder outputs

e. The radiation monitors are calibrated at regular time intervals in accordance with station procedures. Calibration methods are covered in detail in the equipment procedures manual.

f. The following annunciators are located in the control room to alert the operator:

   1. Reactor enclosure area, high radiation (Units 1 and 2)

   2. Refueling floor area, high radiation (Units 1 and 2)

   3. Turbine enclosure area, high radiation (Units 1 and 2)

   4. Turbine enclosure common area, high radiation

   5. Radwaste enclosure common area, high radiation

6. Reactor enclosure common area, high radiation
7. Admin. bldg. area, high radiation
8. Unitized area, Rad monitors downscale
9. Common area, Rad monitors downscale

12.3.4.1.3 Local Area Monitors

In addition to the area radiation monitors described above, ten local area monitors are provided, located on each of the two refueling bridges, the three turbine enclosure crane cabs, the east and west unit 1 and 2 turbine enclosure deep bed vessel areas, and the health physics and chemistry source storage and calibration room. The essential differences between these monitors and those area monitors described above are as follows:

a. No outputs to the control room are provided.

b. Alarms are local only.

c. No recorders are provided.

d. Local power (battery) packs are provided in the event of external power cutoff, except for the local area radiation monitors in the health physics and chemistry source storage and calibration room, and east and west Unit 1 and 2 turbine enclosure deep bed vessel areas.

The power for the turbine enclosure cranes is turned off except when the cranes are being used or tested. The battery backup for the crane monitors is not available when the crane power is off.

A portable alarming rate meter will be used in the drywell to warn plant personnel if a core component is dropped during fuel transfer operations. The meter will have local alarms to ensure adequate personnel warning. Administrative controls will be used to prevent access to the upper drywell and unnecessary high exposures to personnel.

12.3.4.1.4 Postaccident Area Radiation Monitors

In the event of an accident, access will be required to certain locations outside secondary containment to perform sampling, analysis, and monitoring tasks. The identified areas include the counting room and chemistry laboratory, the main control room, the turbine enclosure near the control room exit, the north stack instrument room, the postaccident sampling station. The operational support center utilizes a portable arm. The area monitors associated with these locations have been designated as postaccident area radiation monitors. In addition to having dose rates available through the shared multipoint recorder in the control room, instantaneous and stored data are available on demand for display and trending in the control room, TSC via the RMMS computer system. Data from PMS is transmitted to the EOF via the emergency plan display system (EPDS). The ranges of these area monitors are specified in Table 12.3-7 and incorporate the highest anticipated postaccident dose rates for these locations. The design details and operating conditions are as described in Sections 12.3.4.1 and 12.3.4.2. Compliance with Regulatory Guide 1.97 (Rev 2) is discussed in Section 7.5.

12.3.4.2 Airborne Monitoring

Airborne radioactivity monitoring is accomplished by use of the following:

a. Monitoring ventilation ducts in key locations throughout the plant.

b. Continuous air monitors which are portable, cart-mounted, and monitor particulate activity.

c. High and low volume portable samplers capable of attaching filters and charcoal cartridges for particulate and iodine monitoring.

The ventilation system monitors are located at positions which provide representative air concentrations and a rapid indication of abnormal conditions. Those systems which require HEPA filtration have monitors upstream of the filters. Both the in-line GM tube and beta scintillator, and off-line particulate, iodine, and noble gas monitoring configurations can be utilized. Readout and annunciation are provided in the main control room. The off-line monitors provide the capability to obtain particulate and iodine samples for isotopic analysis. Emergency dc power is provided in the event of a LOOP. The detectors are calibrated routinely and after any maintenance work is performed on the detector.

CAMs are located in freely accessible areas where airborne radioactivity is most likely to exist. These CAMs are mobile and can be moved from area to area as deemed necessary by plant conditions or maintenance operations. CAMs incorporate either fixed or movable filters for the collection of particulate activity, which is monitored directly by a detector. Readout is recorded in counts per minute. The filters can be removed for further analysis using counting room instrumentation. Audible and visual alarms indicate when setpoint levels have been exceeded. The detectors are calibrated routinely and after any maintenance work is performed on the detector.

The CAM's primary function is to indicate trends and sudden changes in airborne activity. Typical locations are solid waste handling areas, spent fuel pool areas, and the reactor operating floor and turbine building. The monitoring system is capable of detecting particulate, iodine and noble gas radioactivity. A flexible hose can be attached to the monitor intake and inserted into a cavity or work area to detect the presence of localized airborne activity. Conformance to Regulatory Guide 8.2 is discussed in Section 12.5.1.

Ventilation monitors and CAMs are used as trending devices and will indicate areas and times needing special samples taken.

Alarm setpoints are set at low levels to ensure close respiratory controls. CAMs, however, cannot account for inversion conditions or properly identify isotopic content of the air. When a setpoint is reached, the monitor alarms. The reason for the alarm is evaluated and when necessary, grab air samples are taken and analyzed in the counting lab. The DAC hours are isotopically calculated by the computer program or are done manually. Appropriate actions can then be taken based on accurate data.

Potentially airborne accessible areas are air sampled at regular intervals. The survey/sampling frequency is designed for that area by the routine survey program.

Low and high volume samples with filter paper or charcoal cartridges are used. These are described in more detail in Section 12.5.3.1.3.

Airborne monitoring provides the information necessary to determine stay times in given areas and applicable respiratory equipment. The information is also of value in identifying process system leakage. Such monitoring is conducted in accordance with the guidelines of Regulatory Guide 1.21.

Control and calibration of radioactivity monitoring (fixed and portable) are provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program described in Section 17.2.

Qualification and training of health physics and chemistry personnel will follow ANSI/ANS 3.1- 2014 guidance.

Table 12.3-1

PLANT RADIATION ZONE DESCRIPTION

DESIGNATION	MAXIMUM DESIGN DOSE RATE (mRem/hr)	DESCRIPTION
I	≤ 0.5	No radiation sources, no radiological control required
II	≤ 2.5	Low radiation sources, radiological control required
III	≤ 15	Low to moderate radiation sources, radiological control required
IV	< 100	Moderate radiation sources, radiological control required
V	≥ 100	High radiation sources, radiological control required

Table 12.3-2

LIST OF COMPUTER CODES USED IN SHIELDING DESIGN CALCULATIONS

GRACE 1	Multigroup, multiregion, gamma ray attenuation code used to compute gamma heating and gamma dose rates in slab geometry (Reference 12.3-6).
GRACE 2	Multigroup, multiregion, gamma ray attenuation code used to compute the dose rate or heat generation rate for a spherical or a cylindrical source with slab or concentric shields (Reference 12.3-7).
ANISN	Multigroup, multiregion code solving the Boltzmann transport equation for neutrons and gamma rays in one-dimensional slab, cylindrical, or spherical geometry (Reference 12.3-8).
SDC	Multigroup, multiregion, gamma ray attenuation code that calculates dose rates for 13 geometry options (Reference 12.3-9).
QAD	Multigroup, multiregion, three-dimensional, point kernel code that calculates fast neutron and gamma ray dose and heat generation rates (Reference 12.3-10).
NAP	Determines neutron activation and gamma emission source strengths as a function of neutron exposure and decay time (Reference 12.3-11).
MORSE-CG	Three-dimensional Monte Carlo neutron and gamma ray general transport code (Reference 12.3-12).
DOT 3	Two-dimensional neutron, gamma ray, discrete ordinate, transport code (Reference 12.3-13).
ORIGEN	Isotopic generation and depletion code that solves equations of radioactive growth and decay for isotopes of arbitrary coupling (Reference 12.3-14).
G-33	A general purpose gamma ray scattering code (Reference 12.3-15).

These programs are as used in original plant design. Updated versions or alternative programs applying the same basic industry standard analysis methodology may be used in evaluation of plant design changes.

Table 12.3-3

TURBINE ENCLOSURE VENTILATION SYSTEM DESIGN FEATURES

AREA	RADIOLOGICAL SAFETY FEATURES	SUPPLY/EXHAUST AIR FLOW RATE (cfm)
General Personnel Access Areas	Three 50% supply fans, three 50% exhaust fans	250,000/200,000
Equipment Areas	Two 100% exhaust fans, continuously filtered	0/63,000

Table 12.3-4

CONTROL STRUCTURE VENTILATION SYSTEM DESIGN FEATURES

OPERATION MODE	RADIOLOGICAL SAFETY FEATURES	AIR FLOW RATE (cfm)	EXPOSURE TO AIRBORNE CONCENTRATIONS
Normal	Two 100% supply and return fans	26,200	Background
Accident	Two 100% supply fans. Automatic/ manual switch to emergency intake and filtering and recirculation system on high activity signal; recirculation and filtering	3,000 maximum	Less than allowable limits set in 10CFR20

Table 12.3-5

REACTOR ENCLOSURE AND REFUELING AREA VENTILATION SYSTEMS
DESIGN FEATURES

AREA	RADIOLOGICAL SAFETY FEATURES	SUPPLY/EXHAUST AIR FLOW RATE (cfm)
Reactor Enclosure General Personnel Access Areas	Three 50% supply fans, three 50% exhaust fans. No or low activity exhaust is not filtered; enclosure isolation on high activity signal. Automatic switch to recirculation and SGTS.	180,000/140,000 Emergency: 60,000 recirculation 3,000 maximum SGTS
Reactor Enclosure Equipment Areas	Two 100% exhaust fans, two 100% filters. Automatic switch to recirculation and SGTS.	0/40,000(1)
Refueling Area General Personnel Access Areas	Three 50% supply fans, three 50% exhaust fans. No or low activity exhaust is not filtered; area isolation on high activity signal. Automatic switch to SGTS.	54,000/54,000 3,000 maximum SGTS

(1) Transfer air flow from personnel access areas

12.4 DOSE ASSESSMENT

This section discusses the estimated radiation exposures both in-plant and at locations outside the plant structures. Sections 12.4.1 and 12.4.2 discuss direct radiation and airborne radiation exposures within the plant; Section 12.4.3 is concerned with exposures outside the plant structures; and Section 12.4.4 estimates the exposure to Unit 2 construction workers during the operation of Unit 1. The ISFSI radiation exposures are not considered here, as they are addressed in separate 10CFR72.212 document(s).

Not all the methods for occupational radiation dose assessment discussed in Regulatory Guide 8.19 are employed for LGS. Alternative methods are described in Section 12.4.1.

12.4.1 Direct Radiation Dose Estimates For Exposures Within The Plant

To estimate the total annual man-rem dose from direct radiation to personnel within the plant, seven broad categories or job functions were defined, and the annual man-rem dose for each category was evaluated. Where the functions and expected radiation levels are predictable or clearly defined, analytical methods were employed for the man-rem estimates. In other cases, the estimate basis is historical exposure data from operating BWR power plants. Section 12.4.1.1 provides the definitions and components of each of the seven broad categories, and Section 12.4.1.2 describes briefly the estimation techniques used.

The resultant dose estimates are contained in Section 12.4.1.3, along with further discussion of the factors involved and the methodology used for each category and its related components.

12.4.1.1 Definition of Categories Used in Exposure Estimates

Seven broad categories were used in estimating the total annual man-rem dose. These categories are:

Routine Operations: This category is composed of the following three components or subcategories:

a. Routine patrols and surveillances of the reactor enclosure, turbine enclosure, control structure, and radwaste and offgas enclosures.

b. Periodic tests and checks in the reactor enclosure, turbine enclosure, control structure, and radwaste and offgas enclosures.

c. Control room operations; specifically, the dose received by operators in the control room and radwaste control room.

Routine Maintenance: This includes all scheduled maintenance. This does not imply that a particular date has been established, but rather that the maintenance is planned and occurs at least annually. This category also includes the preventative maintenance performed in the radiation areas of the reactor, turbine, radwaste, and offgas enclosures.

Inservice Inspections: These are inspections normally performed by NDT personnel and outside contractors. Such inspections normally occur during outages on piping and systems that cannot be checked while at power.

Special Maintenance: All maintenance that is not scheduled. This maintenance is not planned in advance and normally cannot be predicted.

Radwaste Processing: This includes any work with solid or liquid radwaste: movement of casks and liners; radwaste, condensate system, or fuel pool filter changes; resin moving; baling of low level trash, etc. Maintenance of radwaste equipment is covered by the maintenance categories and is not included in this job function.

Refueling: This is all work with fuel or reactor components performed in the reactor and pool area.

Health Physics: This covers all health physics activities and includes chemistry operations and sample collection.

12.4.1.2 Exposure Estimate Methodology

Analytical Method: The analytical method used for man-rem estimation is based upon the product of estimated exposure time and estimated ambient dose rate. Estimates of the occupancy time requirements for operations associated with equipment in plant radiation areas (e.g., maintenance time or surveillance time) are first developed. An applicable frequency of occurrence is then factored in to determine the annual exposure time for each operation. Areas with no significant radiation sources are not included in the exposure estimate. Where radiation sources are present, the design maximum dose rate of 2.5 mRem/hr is assumed for some Zone II areas (radiation zones are defined in Table 12.3-1). Similarly, 15.0 mRem/hr is assumed for some Zone III areas. All other estimated dose rates are based on either calculations or actual radiation levels encountered at operating plants. Radiation levels encountered or estimated are adjusted in proportion to power. The analytical method was used in determining the exposure estimates for the routine maintenance and routine operations categories.

Historical Method: In the historical method, the annual man-rem is estimated from the exposures received at operating BWR power plants. This method was used for all the remaining categories (special maintenance, inservice inspection, radwaste processing, refueling, and health physics). The data sources are the annual and semiannual BWR operating reports and plant correspondence with regulatory agencies. Included are a total of 61 reactor years of operation for 16 nuclear units, which are listed in Table 12.4-1. The average licensed power level of these units is 747 MWe with the smallest rated at 514 Mwe. The data were
collected and assembled using the following guidelines:

a. No data before the first calendar year which contained at least nine months of commercial operation are used.

b. In multiple unit plants, each unit is assumed to contribute equally to the annual exposures.

c. If exposure contributions from two or more job functions cannot be separated, a conservative approach is taken by assigning all the exposure to one function and by making no entry in the data base for the other.

Table 12.4-2 contains the results of the historical data compilation and includes both the number of reactor years contributing to and the standard deviations associated with each job function. The large standard deviations, which range from about 60% to 160% of the mean values, are indicative of the wide spread of data that have been reported within each exposure category.

12.4.1.3 Results of Annual Direct Radiation Dose Estimates

The annual man-rem estimates for each category and subcategory are detailed below in Sections 12.4.1.3.1 through 12.4.1.3.7. The methods used in their determination are as described previously, with any additional assumptions or required information included below.

In each of the following sections, the annual exposure estimates are reported for two plant configurations: single-unit operational, and two units operational. In general, the "two-unit dose" is twice the "single-unit dose"; however, the exposures associated with certain job functions are assumed to be independent of the number of units in operation since the functions are performed regardless of whether one or two units are operational. These specific job functions are:

a. Control room operations

b. Radwaste control room operations

c. Radwaste and offgas enclosure routine surveillances

d. Radwaste and offgas enclosure periodic testing

e. Radwaste and offgas enclosure routine maintenance

For these estimates, the single-unit dose is assumed to be the same as the two-unit dose.

A summary of the direct radiation dose estimates is given in Section 12.4.1.3.8.

12.4.1.3.1 Routine Operations Dose Estimate

During normal operations, routine patrols and surveillances are performed by plant operators. The majority of items checked are rotating equipment (pumps, fans, etc), and each is viewed to verify the absence of leaks, excessive vibrations, or other abnormal conditions. For the surveillance man-rem exposure estimation, the following assumptions were made:

a. Dose rates are estimated as outlined in Section 12.4.1.2. Additionally, because of the high potential dose rates associated with certain equipment, routine surveillances of such equipment are performed from a remote location (such as the equipment cell doorway) and credit is taken for the lower ambient radiation level at that point.

b. Each patrol consists of only one person.

The results of the routine surveillance exposure estimate are contained in Tables 12.4-3 through 12.4-5.

Similarly, the details and results of the exposure estimate for the periodic testing subcategory are also contained in Tables 12.4-3 through 12.4-5. Since periodic testing is assumed to occur during equipment shutdown, the estimated shutdown dose rates are therefore used for determining the associated exposures.

The remaining subcategory is control room operations exposures. Exposures have been estimated from the anticipated control room radiation levels and the staffing requirements for the main and radwaste control rooms. It is assumed that the staffing levels of both control rooms are identical for either one or two units operational. Table 12.4-6 contains the details of the control room operations exposure estimate.

The total annual exposure estimate for the routine operations category is the sum of the three subcategory annual exposures as shown in Table 12.4-7 and summarized below:

Annual Exposure Estimate: Routine Operations

42.6 man-rem (single-unit operational)

68.9 man-rem (two units operational)

12.4.1.3.2 Routine Maintenance Dose Estimate

A detailed review of plant radiation areas was performed to produce a listing of the types and quantities of selected equipment present in each area. Next, total annual maintenance man-hours were estimated for each equipment type identified based on a combination of operating experience and engineering judgement. Total estimated man-hours are shown in Table 12.4-8 and are intended to include all expected routine activities for each equipment type such as valve repacking, valve relapping, pump seal replacement, fan overhaul, etc.

In any area, the total annual man-hours for routine maintenance is then the summation of the quantity-man-hour products for all equipment types found in the area. Multiplying the area's annual maintenance man-hours by the anticipated area dose rate produces the estimated man-rem by area. As with periodic testing, the estimated shutdown dose rate was used for estimating maintenance exposures.

A "total annual" maintenance approach was used for each component since currently available data generally does not contain sufficient information to provide a basis for man-hour breakdowns by maintenance activity. In addition, the area-by-area methodology employed makes estimate compilations by system unnecessary, since locations where high man-rem expenditures are expected are clearly indicated. Tables 12.4-3 through 12.4-5 contain the details of the routine maintenance exposure estimate for each enclosure. The sum from the three enclosures is presented below:

Annual Exposure Estimate: Routine Maintenance

232.5 man-rem (single-unit operational)

427.7 man-rem (two units operational)

12.4.1.3.3 Inservice Inspection Dose Estimate

The annual exposure estimate for inservice inspection is based upon the data from operating BWRs given in Table 12.4-2, and is:

Annual Exposure Estimate: Inservice Inspection

27.5 man-rem (single-unit operational)

55.0 man-rem (two units operational)

12.4.1.3.4 Special Maintenance Dose Estimate

The annual exposure estimate for special maintenance is based upon the data from operating BWRs given in Table 12.4-2, and is:

Annual Exposure Estimate: Special Maintenance

273.1 man-rem (single-unit operational)

546.2 man-rem (two units operational)

12.4.1.3.5 Radwaste Processing Dose Estimate

Most of the operations in the plant associated with the radwaste processing category are performed remotely and are therefore not suitable for evaluation by the analytical estimation technique. Consequently, the annual man-rem estimate for radwaste processing is more properly taken from the historical BWR operating data of Table 12.4-2, since this provides a conservative estimate of the anticipated exposure.

Annual Exposure Estimate: Radwaste Processing

37.0 man-rem (single-unit operational)

74.0 man-rem (two units operational)

12.4.1.3.6 Refueling Dose Estimate

The annual exposure estimate for refueling is based upon the data from operating BWRs given in Table 12.4-2, and is:

Annual Exposure Estimate: Refueling

19.2 man-rem (single-unit operational)

38.4 man-rem (two units operational)

12.4.1.3.7 Health Physics Dose Estimate

The annual exposure estimate for health physics monitoring is based upon the data from operating BWRs given in Table 12.4-2, and is:

Annual Exposure Estimate: Health Physics

29.3 man-rem (single-unit operational)

58.6 man-rem (two units operational)

12.4.1.3.8 Summary of Direct Radiation Dose Estimates

The annual dose estimates in the preceding seven sections are summarized and totaled in Table 12.4-9. As shown in this table, the estimate of total annual in-plant exposure from direct radiation is:

Annual Exposure Estimate: Total

661.2 man-rem (single-unit operational)

1,268.7 man-rem (two units operational)

Dose estimates for inservice inspection, special maintenance, radwaste processing, refueling, and health physics are based on historical data from operating facilities. Any further breakdown of the dose estimate (such as was made for routine operations and routine maintenance) for these types of activities would still rely primarily on the historical information available. The resultant dose estimate would therefore not be any more precise than an estimate based solely on reported radiation exposures.

In all five areas where historical data is used in the dose estimate, the LGS design includes design features which will reduce actual exposures received by plant personnel. However, due to the lack of sufficiently detailed information to allow the precise quantification of the dose reduction, the calculation of the reduction was not attempted.

As an example of design features which will result in dose reduction, the following design features have been incorporated to facilitate inservice inspection:

a. Quick removal insulation around the RPV nozzles

b. Access panels in the shield wall to the RPV bottom head welds

c. The use of a remote, trackless vehicle for RPV weld inspection

d. The use of remote automatic weld inspection of the RPV nozzle welds

12.4.2 AIRBORNE RADIOACTIVITY DOSE ESTIMATES FOR EXPOSURES WITHIN THE PLANT

The estimated exposures to plant personnel from airborne radioactivity are based upon the source distributions and radionuclide concentrations presented in Section 12.2.2 and Tables 12.2-93 through 12.2-101. Because of the limited geometry afforded by the finite compartment sizes within the plant, personnel exposures due to noble gas immersion are expected to be insignificant when compared to inhalation exposures and therefore have not been estimated.

In order to determine whether exposure contributions from airborne radioactive particulates are significant, an evaluation was made in each area of the ratio of total particulate maximum permissible concentration fractions to total radioiodine MPC fractions (which is equivalent to the ratio of particulate MPC-hours to iodine MPC-hours). For the turbine and reactor enclosure areas, the particulate-to-iodine ratios are approximately 0.02 and 0.05, respectively, indicating that the particulate inhalation exposures are not significant in those areas. In the radwaste enclosure areas, however, the particulate-to-iodine ratio is approximately 1.11. Since over 75% of the total particulate MPC fraction is attributable to Co-60, both the thyroid inhalation dose due to

radioiodines and the lung inhalation dose due to Co-60 were estimated for the radwaste enclosure (the thyroid and the lung are the critical organs for iodines and Co-60, respectively).

In addition to the inhalation exposures due to radioiodines (all enclosures) and to Co-60 (radwaste enclosure), whole body exposures due to airborne tritium were also estimated for those areas where tritium is assumed to be present (turbine and reactor enclosures).

Tables 12.4-10 through 12.4-12 contain the compilations of the estimated annual occupancy times and the estimated annual exposures for each of the areas identified in Section 12.2.2 as potential sources of airborne radioactivity. The occupancy times are based upon detailed reviews of each area and the determination of the operations which might occur in those areas. The exposures are based upon the estimated airborne concentrations in Tables 12.2-98 through 12.2-100, dose factors from table C-1 of Regulatory Guide 1.109, and an assumed breathing rate of 3.47×10^{-4} m^3/sec.

12.4.3 Exposures At Locations Outside Plant Structures

The radiation exposures at locations outside the plant structures were estimated for two areas: the site boundary and the visitor's center. Section 12.4.3.1 discusses direct radiation exposure at these locations, and Section 12.4.3.2 deals with airborne exposures.

12.4.3.1 Direct Radiation Dose Estimates Outside Plant Enclosures

At locations outside plant enclosures, the direct radiation exposure has two principal components:

a. Sources of activity stored outside the enclosures, specifically, the refueling water storage tanks and the CST.

b. Turbine shine due to the N-16 present in the reactor steam.

Based on the calculated surface dose rates for the refueling water storage tanks and CST given in Section 12.2.1.7, the dose contribution at locations outside the plant enclosures due to these tanks is considered negligible.

The N-16 present in the reactor steam in the primary steam lines, turbines, and moisture separators provides a dose contribution to locations outside the plant enclosure as a result of the high energy gamma rays that it emits as it decays. To reduce the turbine shine doses, radiation shielding is provided around each turbine train.

Hydrogen injection by the HWC system causes the reactor water chemistry to become less oxidizing which results in a re-distribution of the N-16 normally produced by radiolysis in the reactor core. Under HWC conditions, more of the N-16 is carried over into the steam and less remains in the reactor water. Thus, areas where steam piping exists will experience a greater level of radiation due to the increased N-16. The increased exposure is within the estimates provided in Chapter 11 and 12.

Exposure at locations outside plant structures will also increase due to direct radiation and turbine shine from the N-16, which is a high energy gamma emitter. In order to minimize these effects, additional radiation shielding has been installed around the high pressure turbine and combined intermediate valves.

The resultant annual exposure due to turbine shine was calculated with the SKYSHINE computer program (Reference 12.4-1). Point sources are used to represent the components on the turbine deck and the source strengths are given in Table 12.4-13.

With an assumed 100% occupancy factor and an 80% capacity factor, the maximum calculated dose rate occurs at the northeast site boundary (Figure 12.4-1 and Table 12.4-14) and is 5.5 mRem/year.

The dose rate in the visitor's center is calculated by the SKYSHINE program to be 1.53×10^{-3} mRem/hr with two units operational. Assuming a visitor stays at the visitor's center one day a year for eight hours, the estimated dose for the visitor is 1.2×10^{-2} mRem/year, as shown in Table 12.4-14.

12.4.3.2 Airborne Radioactivity Dose Estimates Outside Plant Enclosures

Doses at the site boundary due to released radioactivity are given in Section 11.3.

12.4.4 EXPOSURES TO CONSTRUCTION WORKERS

12.4.4.1 Direct Radiation Dose Estimates

The estimated dose rates from direct radiation and turbine shine received by construction workers on Unit 2 due to the operation of Unit 1 are well within the limits of 10CFR20 for exposure to individuals in unrestricted areas. Access to Unit 1 for Unit 2 workers is restricted by permanent concrete walls, security fences or chains, etc.

The estimated dose rates are the sums of the direct radiation from the Unit 1 reactor enclosure, turbine enclosure, radwaste enclosure, and offgas enclosure; and the turbine shine doses resulting from the decay of N-16 in the steam lines and turbine equipment of Unit 1. As discussed in Section 12.4.3.1, dose contributions from outside storage tanks are considered negligible and are not included in the exposure estimate.

The annual dose from Unit 1 operation has been estimated for various points in the Unit 2 construction area. The results of this estimate are listed in Table 12.4-15, and their corresponding points are shown on Figure 12.4-1.

The doses from turbine shine were calculated with the SKYSHINE computer program in the manner described in Section 12.4.3.1. The resultant dose includes the direct as well as air-scattered contribution. Credit is taken for the shielding which is afforded by the Unit 2 walls and floor slabs. The radioactive wastes are processed and stored in the radwaste enclosure, where shielding is provided to ensure that the dose outside the enclosure is less than 0.5 mRem/hr. With an allowance for distance between the radwaste enclosure and the Unit 2 construction area, the estimated direct shine dose is less than 0.01 mrem/hr under normal operating conditions.

The exposure for Unit 2 construction workers has been estimated based on the following assumptions:

a. The current construction schedule is met.

b. Personnel assigned to the control structure or Unit 2 turbine enclosure are assumed to work in the turbine enclosure only. Personnel assigned to the Unit 2 reactor enclosure or drywell are assumed to work in the reactor enclosure only.

c. The average dose rate in the yard areas is the average of the dose rates at points 1 through 5 of Figure 12.4-1, 0.0335 mRem/hr. The average dose rate in the field office is 0.0215 mRem/hr. Each of these dose rates includes 0.01 mRem/hr for the direct shine contribution and is for 100% plant capacity.

d. The capacity factor for Unit 1 in determining total estimated exposure is 80%.

e. 40 hours per week per person at the work site, 50 weeks per year.

Exposure to personnel in various categories and locations is summarized in Table 12.4-15, which gives the total estimated exposure to Unit 2 construction workers as 41.16 man-rem.

10CFR20.202 specifies that personnel monitoring equipment is required if the maximum expected dose per calendar quarter for workers in an area exceeds one-fourth of the 1250 mRem/quarter limit. It is determined that, even in areas with the highest radiation levels (the turbine deck), no construction worker would receive a dose greater than this, so personnel monitoring equipment is not necessary. However, periodic radiation surveys are to be made by the radiation protection staff.

12.4.4.2 Exposures Due to Airborne Radioactivity

Based on expected annual releases of gaseous effluents (Table 11.3-1), a worst location annual average atmospheric dispersion factor of 1.48×10^{-5} sec/m^3, and an annual occupancy of 2000 hr (40 hr/week for 50 weeks/year) the total body gamma, beta skin, and thyroid gamma dose rates from airborne radionuclides to a construction worker are estimated to be 2.47 mRem/year, 4.77 mRem/year and 0.57 mRem/year, respectively, during the construction stage. Dose rates at specific receptor points are presented in Table 12.4-16. A comparison of these values with those in Table 12.4-14 shows that doses to construction workers resulting from direct shine are dominant.

(1) All values are on a per unit basis.

(2) The estimated exposures assume all man-hours are expended in the area in which they appear. Portions of these man-hours may actually be spent at lower radiation levels within the area. Components may also be removed to a lower background area for maintenance.

(3) Estimated dose rate is based upon surveillance being performed from a remote location such as the equipment cell doorway. Estimated and measured dose rates will increase approximately in proportion to power.

(4) Room numbers are shown on drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130, N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-140, N-141, N-142, and N-143.

		TOTALS:	515	2.508	893	9.607	12,176	123.395

(1) All values are on a per unit basis.

(2) The estimated exposures assume all man-hours are expended in the area in which they appear. Portions of these man-hours may actually be spent at lower radiation levels within the area. Components may also be removed to a lower background area for maintenance.

(3) Estimated dose rate is based upon surveillance being performed from a remote location such as the equipment cell doorway. Estimated and measured dose rates will increase approximately in proportion to power.

(4) Control rod drive rebuild, repair, and testing.

(5) Room numbers are shown on drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130, N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-140, N-141, N-142, and N-143.

616,617	13	0	40	53	2.8×10^{-2}	-
618	13	3	40	56	2.9×10^{-2}	
TOTALS	515	893	14,341	15,749	$5.8 \times 10^{+1}$(3)	3.8×10^{-2}

(1) All values in the table are on a per unit basis.

(2) Maintenance man-hours include 2,165 man-hours for refueling operations.

(3) The total thyroid dose of 58 man-rem takes no credit for respiratory protection. If a protection factor as low as 5 is assumed in the drywell (which is estimated to produce over 80% of the reactor enclosure thyroid exposures), the total thyroid dose is reduced to below 20 man-rem per year.

(4) Thyroid dose attributable only to inhalation of radioiodines.

(5) Uniform dose to the total body from uptake of tritium.

(6) Room numbers are shown on drawings N-110, N-111, N-112, N-113, N-115, N-116, N-117, N-118, N-119, N-120, N-121, N-122, N-124, N-125, N-126, N-127, N-128, N-130, N-131, N-132, N-133, N-134, N-135, N-136, N-137, N-140, N-141, N-142, and N-143.

12.5 HEALTH PHYSICS PROGRAM

12.5.1 ORGANIZATION

The organizational structure, including the responsibilities of those charged with performance of health physics duties, is described in Section 13.1. Health physics operations are made effective and ALARA goals are achieved through the cooperation and active participation of the various group represented in this structure.

The objectives of health physics operations are to:

a. Detect, identify and define radiation hazards.

b. Provide protection for personnel against radiation hazards.

c. Monitor and measure radioactive effluents from the plant.

d. Control plant-related radiation exposures (occupational and general public) to levels ALARA.

e. Control plant radioactive effluents to levels ALARA.

f. Conduct plant activities in conformance with authorized procedures and applicable regulations.

These objectives are accomplished or enhanced by the various training programs, by the use of prepared procedures, by performance of area surveys and monitoring of personnel, by record keeping, by applying good health physics practices, by periodic review and revision of procedures, by evaluation of activities for ALARA purposes, and by the control of plant operations to minimize occupational exposures and releases to the environment. Health physics operations include the posting, notification, and reporting provisions of 10CFR19 and General Employee Training (Section 13.2) provides the requisite instruction to workers.

Health physics operations conform with the guidelines of Regulatory Guide 8.2 (Rev 0) and of ANSI N13.2 (1969), Guide for Administrative Practices in Radiation Monitoring, with the clarification that controlled areas which are locked or otherwise prevent personnel access are not required to be surveyed at a specific periodicity. In addition to this section, Sections 13.1, 13.2, 13.5, and 12.1 describe the management commitment, organization, responsibilities, authority, training, procedures, and review techniques which implement Regulatory Guide 8.8 (Rev 3), as it applies to the operating phase and Regulatory Guide 1.8 (Rev 1-R). As described in Section 12.1, a formal ALARA review program, which is consistent with the guidelines given in Regulatory Guide 8.8, was implemented during the design and construction phase. The qualification requirements for the Radiation Protection Manager are described in Section 13.1.3. Chapter 17 addresses implementation of other applicable regulatory guides. Implementation of Regulatory Guide 1.16 is addressed in the Technical Specifications.

12.5.2 FACILITIES, EQUIPMENT, AND INSTRUMENTS

This section describes the basic facilities, equipment, and instruments directly related to the health physics operations.

12.5.2.1 Health Physics and Chemistry Facilities

12.5.2.1.1 Supervisory Offices and Field Offices

Health Physics and Chemistry supervisory offices are located outside the RCA. Field offices and work areas for technicians are located adjacent to the RCA.

12.5.2.1.2 Chemical Laboratories

Chemical laboratories are located in the Chemistry Laboratory Expansion including the Hot Lab, the Instrumentation Lab (within the bounds of the RCA) and the Cold Lab (beyond the bounds of the RCA). A conventional chemistry section and radiochemistry section are provided. These sections are segregated so that noncontaminated samples (such as river water) can be prepared and analyzed without having to work under radiologically controlled conditions. The laboratories are accessible to the counting room for convenience in transporting prepared samples for counting. Sample stations are located near their respective systems for sampling condensate, feedwater, reactor water, and radwaste. The laboratories are designed to support routine chemical analysis, as well as, developmental work for emergent issues and appropriate emergency response functions as described in the Emergency Plan.

12.5.2.1.3 Counting Room

The counting room is located in the Chemistry Laboratory Expansion in a low background area. The room is designed with thick shield walls to further reduce background radiation, thus improving instrumentation sensitivity.

12.5.2.1.4 Control Points

Control points and change areas are located throughout the plant near the various job sites. These facilities are for the most part temporary. They are set up during outages and special jobs. They are staffed and stocked to provide health physics monitoring and protective equipment on an as-needed basis.

12.5.2.1.5 Testing and Laboratory Facilities

Calibration and instrument repair facilities are provided. Licensed sources are stored in this facility under approval of the Manager Radiation Protection. Sources are used to calibrate portable radiation survey meters, direct reading dosimeters, certain process and effluent radiation instruments, and area monitors.

12.5.2.1.6 Medical Support

Arrangements with local physicians and hospitals provide offsite support for continued medical treatment of traumas involving radioactive contamination.

A contract is maintained with a primary health physics-medical consultant. The consultant retains a qualified staff that provides expertise in the long-term treatment of patients exposed to excessive external radiation or internal contamination.

12.5.2.1.7 Personnel Decontamination Facility

A personnel decontamination facility located in the radwaste enclosure at el 217' is provided with a sink, shower, change area, and contamination monitoring devices. Personnel decontamination is performed in accordance with Health Physics procedures. Control of personnel decontamination is provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program.

No male/female discrimination has been made in the design for the decontamination facilities. Adequate showers and sinks are available for personnel decontamination. Procedures will be implemented to provide the appropriate privacy. Additional male and female facilities are provided in the administration building but are not intended for contamination removal.

12.5.2.1.8 Laundry and Respirator Facility

A laundry and respirator facility is located adjacent to the Unit 1 turbine enclosure at el 217'. The facility includes space for sorting anticontamination clothing, and for receiving clothing from an offsite laundry. The facility includes space for inspecting, surveying, bagging, and repairing respirators. Procedures are established for inspection, cleaning and maintenance of such protective equipment.

12.5.2.2 Instruments and Equipment

Instrumentation design and capabilities improve as the state of the art changes. Normally, the instrumentation listed in Table 12.5-1 or instruments of similar capabilities will be provided. Any instrumentation or equipment described in these sections may be replaced by items providing similar or improved capabilities.

Instrumentation for detecting and measuring radiation consists of counting room equipment, portable instrumentation, and air samplers. Capabilities for detecting alpha, beta, gamma, and neutron radiation are provided. Sufficient inventory is provided to accommodate use, repairs and calibration. The equipment is described later in this section and is listed in Table 12.5-1. Sufficient chemical equipment and analytical instruments are provided to perform the required sample preparations and analyses.

LGS will equip the counting room and provide the portable instruments, personnel monitoring instruments, and protective equipment with the capabilities as described in Regulatory Guide 8.8, section 4. Support facilities at LGS will also follow the guidance of Regulatory Guide 8.8.

LGS is in compliance with Regulatory Guide 1.97 (Rev 2) in regard to Health Physics and Chemistry Laboratory and survey equipment.

Control of instrument storage, calibration and maintenance is provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program.

Operability of personnel monitors, radiation survey instruments, and laboratory equipment is verified periodically in accordance with plant procedures and work processes.

12.5.2.2.1 Chemical Laboratories

The chemical laboratories are segregated so that one section handles only low level or background samples and the remaining section handles contaminated samples.

Grab samples are transported to the appropriate section of the laboratories. The laboratories, are equipped with constant air flow fume hoods. The fume hoods permit safe preparation and processing of samples under controlled conditions. Effluent of fume hoods within the RCA are filtered through HEPA filters. The laboratories are stocked with chemical reagents and equipment to provide for sample preparation and analysis.

The laboratories contain conventional analytical instruments, equipment and chemicals. Samples intended for activity analysis and isotopic identification are prepared for transport to the counting room. A frisking station is located in the Chemistry Laboratory Expansion.

12.5.2.2.2 Counting Room

Samples processed in the chemical laboratories for activity analysis and isotopic identification, and samples direct from the plant (such as air samples and smears) are transported to the counting room located in the Chemistry Lab Expansion. Equipment is available for gross alpha, gross beta, and gross gamma activity measurements and for determination of the activity levels of specific isotopes. Proportional counters and gamma spectrometers are provided. The room itself has thick shield walls to reduce instrument background radiation. The room is temperature controlled and the voltage supply is regulated for instrument stability.

Major instrumentation includes a Gamma Spectrometer for specific isotopic identification; alpha and beta counters; a scintillation detector; and a liquid scintillation analyzer for low energy emitters such as tritium.

Background and efficiency checks are performed routinely. Alpha and beta plateaus are established to determine operating voltages for proportional counters. Calibrations are based on NIST related standards for the isotopes of interest. Conventional reference standards such as Sr, C, and Ra in equilibrium with daughter activity, Cs, and Co are used for calibration when gross counting is the objective.

12.5.2.2.3 Portable Survey Instruments and Equipment

Portable survey instruments and equipment are used primarily for conducting area surveys and for monitoring personnel throughout the plant. Some portable instruments and equipment are designated for emergency use and will be stored at the Technical Support Center, readily accessible to personnel responding to an emergency.

Portable instruments and equipment for routine plant use are provided to permit alpha, beta, gamma, and neutron radiation measurements, and for obtaining samples of surface and airborne contamination. The inventory includes ion chambers, GM probes, neutron rem counters or equivalent, alpha probes, alpha and beta counters, scintillation detectors, high and low volume air samplers, filters, charcoal cartridges, and smears. Portable instruments and equipment available for emergency use include air sampling equipment with particulate filters and silver zeolite cartridges, portable ion chambers, alpha scintillation probes, energy compensated beta/gamma GM probes (for low energy photons), and portable beta/gamma geiger counters.

At least some of the ion chambers and GM probes have movable beta shields to enable distinguishing between beta and gamma radiation. The ion chambers are the prime devices for dose rate determinations and have beta factors specified as appropriate for the type of meter and its use.

GM probes may be used for dose rate determinations. Their application for this purpose is of value when the ability of an ion chamber to respond reliably is impaired by high humidity, high or low temperature, or very low dose rates. Certain instrument designs with GM probes have extendable arms. This feature allows the user to remain in a relatively lower radiation area while measuring high dose rates at the point of interest. This application is a good example of an effective ALARA policy.

The ranges and numbers of instruments are adequate for their intended use whether routine or emergency.

12.5.2.2.4 Personnel Dosimeters

Personnel monitoring is provided by the use of such devices as optically stimulated luminescent, direct reading dosimeters (electronic dosimeters or pocket ion chambers), or calculations from area survey data and exposure times. Personnel monitoring is provided per 10CFR20. The form of personnel monitoring depends on the type of radiation and the expected radiation level. Types of dosimetry devices change as the state of the art improves.

Devices are available and used appropriately for determining whole body or equivalent exposure, extremities exposure and skin exposure. Health Physics practices include the use of multiple badges in addition to the whole body badge as required by procedures.

A direct reading dosimeter will be used by all personnel entering the RCA who are required to be monitored for exposure per 10CFR20. The DRD is used to provide real time indications of dose received by an individual and provides estimated exposure data. As required, these dosimeters are calibrated and/or drift checked on a routine basis per procedures.

Dosimetry devices used for determining the official exposure doses are subject to extensive quality control programs. This is true whether the processing is by a contractor or onsite. Currently, DLRs are used for penetrating (gamma, neutron) and nonpenetrating (beta) radiation. Whenever neutron exposure is of concern, the current technique is to use neutron survey instruments to determine a rem dose rate, then to multiply by the stay time or a monitoring device/DLR which has been accredited for neutron monitoring through NAVLAP N13.11 criteria.

The personnel dosimetry program is conducted by qualified personnel under the direction of the Radiation Protection Manager.

Control of personnel monitoring (e.g., whole body counter) and external (e.g., DLR system) is provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program.

12.5.2.2.5 Miscellaneous Instruments and Equipment

Other monitoring devices are available and may be assigned to personnel or located in work areas for the purpose of alerting personnel to changes in radiation condition.

Radiation monitors that "chirp" at a rate proportional to gamma dose rate or contain an audible alarming feature are assigned to personnel as deemed necessary. These devices are of particular value when worn by individuals whose duties routinely involve entering various areas of the plant. Changing operating conditions or the progression of the individual into the area could cause sudden changes in radiation levels. These devices alarm at preset values to alert personnel of the changed conditions as the individual walks into the area.

Alarming rate meters may be positioned in a given work area. They serve the purpose of alerting individuals working in that area of increases in radiation level above a preset value.

Friskers, personnel contamination monitors, or portal monitors are positioned at or near various change areas and plant exit points. The purpose of these devices is to control the spread of radioactive contamination. Friskers are generally used within the plant for personnel to monitor themselves at any time, especially when leaving a controlled area. Personnel contamination monitors or friskers are generally used at all primary exits from the radiologically controlled area and at the access points to approved eating, drinking, and smoking areas within the radiological controlled area. The placement of these devices may vary in support of the station's contamination control program, and other devices with the required sensitivity may be considered for use if the situation warrants. Instrumentation, such as small article monitors or friskers, is used to monitor tools, equipment and personal items. The instruments are used to ensure that items exiting the RCA are within procedurally defined limits.

Continuous air monitors are used to monitor airborne concentration at specific work locations. These CAMs provide the means to observe trends or sudden changes in the airborne concentrations. They are not intended for quantitative analysis. The fixed filter-type can be used as a low volume grab air sample in that the filter medium can be removed and analyzed in more detail in the counting room.

Fixed area radiation monitors are mounted in selected locations. Each contains a gamma-sensitive detector, local indicator and local alarm, as well as indicators, alarms, and recorders in the control room. These monitors will alert personnel to unexpected or abnormally high radiation levels in these areas.

12.5.2.2.6 Bioassay

Internally deposited radioactive material is evaluated by use of whole body counting or in-vitro analysis. The whole body counter sensitivity for gamma emitting isotopes of interest will be equivalent to small fractions of isotopic organ burdens.

The bioassay program will incorporate features of Regulatory Guide 8.9 and Regulatory Guide 8.26. Conservative investigation levels are established. When investigation levels are exceeded, an investigation will be performed and, as necessary, will include consultation with independent experts for further evaluation of internal exposure consistent with Regulatory Guide 8.9 and International Commission on Radiological Protection criteria.

12.5.2.2.7 Personnel Protective Equipment

Special protective equipment such as coveralls, plastic suits, shoe covers, gloves, head covers, and respirators are available, and are stored in various plant locations and clothing change areas. This equipment is used to prevent deposition of radioactive material internally or on body surfaces. Most of the plant will be kept free of contamination so that no special protective equipment will be needed. Contaminated areas are identified with posted signs. Radiological postings, work orders or RWPs (or equivalent) are the primary mechanisms for defining the equipment required to enter these contaminated areas.

A variety of combinations of protective equipment may be prescribed depending on the nature and level of the contamination. The use of engineering controls will be considered to minimize the need for protective equipment and clothing as practical. Cotton clothes may be adequate normally; but in wet areas plastic rain suits or bubble suits may be prescribed. Respirators may be required if airborne hazards exist or if surface contamination could cause an airborne hazard as defined in the implementing procedures. Sufficient quantities of NIOSH approved respiratory equipment will be provided to adequately protect workers in general and emergency conditions. This will include SCBAs, respirators (general use or welding), and all the necessary supplementary equipment required (hoses, regulators, etc.).

The guidance of Regulatory Guide 8.15 will be followed to ensure the proper selection, care, fitting, and use of respiratory protective equipment. Regular sampling and survey programs will be provided to determine the need for the appropriate respiratory protective devices. Bioassays, record keeping, and medical evaluations will be incorporated into the LGS respiratory protection program. Written procedures will be developed with the help of the operating experience at PBAPS to provide an effective and acceptable respiratory protection program. Section 12.5.3.5.3 also addresses compliance with Regulatory Guide 8.15.

Control of respiratory protection, including testing, is provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program.

12.5.3 PROCEDURES AND PRACTICES

Health physics procedures are classified according to specific concerns. Thus, there are operating procedures, analytical procedures, emergency procedures, and surveillance test procedures. Health physics is a consideration in other plant procedures as well. This section describes the fundamental procedures applicable to health physics operations. The procedures and methods of operation which, in combination with licensee policy and training, ensure that radiation exposures will be ALARA are those which implement the controls and prescribe the use of equipment described in this section and in Section 12.5.1.

12.5.3.1 Radiation Surveys (Area Surveys)

Area survey procedures describe the purpose and techniques of detecting the presence of and measuring the level of radiation and contamination. Contamination may be on surfaces or airborne. Area surveys are conducted throughout the plant. Such surveys may be routine or may be related to specific jobs upon request. An area survey may be performed before, during, and after various work activities. Area surveys are performed by health physics technicians or other trained and qualified personnel (i.e. Advanced Radiation Workers). Control of radioactivity sampling (air, surface, liquids) is provided by procedures that are responsive to the appropriate portions in the Quality Assurance Program.

12.5.3.1.1 Radiation Detection

The primary instrument for beta/gamma dose rate measurements is an ion chamber. Circumstances may require the use of other instruments to determine dose rates. GM probes may be used for low radiation levels or where environmental conditions (temperatures, humidity) cause erratic responses from ion chambers.

Surveys for neutrons are performed by instruments designed for that purpose. A rem counter or equivalent that has the ability to measure neutron dose rate in rem per hour is the preferred neutron measurement instrument. However, other instruments or devices for determining neutron energies may also be used. For example, moderated and unmoderated boron triflouride (BF_3) probes may be used to detect the presence of low and high energy neutrons. Some instruments are designed with extension arms. These types of instruments may be used in high dose rate areas to provide distance from the source to the technician, thus reducing personnel dose.

12.5.3.1.2 Surface Contamination Detection

A variety of techniques are necessary to detect and measure radioactive contamination. Procedures describe the use of smears (e.g., small paper discs) and swipes (e.g., large area survey) to wipe a surface to pick up removable contamination. Smears and swipes are analyzed using portable survey meters and/or counting room equipment. Fixed contamination is determined by scanning a surface with portable survey meters. Equipment is available for alpha and beta/gamma activity measurements.

12.5.3.1.3 Airborne Contamination

Airborne contamination is determined by using air samplers to draw a known volume of air through a filter paper or charcoal cartridge. A charcoal cartridge is used with the filter paper where iodine is of concern. The filter paper is analyzed by gross beta/gamma count and/or gamma spectrometry. Gamma spectroscopy is also performed on the charcoal cartridges. The gamma spectrometry identifies the particulate and iodine isotopic activity. DAC-hours shall be tracked in accordance with Heath Physics procedures. Gross beta/gamma count data is used to judge the need for filter paper gamma spectrometry. High volume air samplers and low volume air samplers having nominal sample rates of 25 scfm and 1 scfm, respectively, are available. The high volume air sampler is used primarily to obtain grab samples rapidly before, during, and after work activities. The low volume air sampler is used primarily to obtain the average air concentration for the work period.

12.5.3.1.4 Survey Frequency and Techniques

The frequency and extent (scope) of area surveys is a function of dose rate in the area, accessibility to the area, and nature of the area in plant operations. For example, contamination checks in control rooms and eating areas are performed nominally on a daily basis; seldom entered high radiation areas are surveyed as infrequently as monthly, or only as needed for entries. As part of the ALARA program, the performance of area surveys are coordinated so that, wherever feasible, routine area survey data is used to perform RWP work. This practice avoids duplication and reduces exposure to technicians.

Area survey data are usually obtained or known before work starts in an area. Resurveys may be performed in the area during the job if the work activity is prolonged. Other conditions for

resurveys would be if the work activity or other plant operation caused changed conditions. Surveys may also be performed at the completion of the work activity.

Depending on the survey results, the area surveyed is roped off and posted appropriately to alert personnel to the radiation conditions and requirements for entry.

Procedures for area surveys describe the use of instruments, effective survey techniques, and documentation of data. The specifications for clean, radiation and high radiation areas are defined. Various levels of surface and airborne contamination are established as guidelines for prescribing protective equipment such as clothing and respirators. Procedures include consideration for potential as well as actual radiation hazards.

12.5.3.2 Radiation Work Permits (or Equivalent)

Where radiation dose rates, airborne concentrations, or surface contamination levels exceed procedural limits, an RWP (or equivalent) is required for work. Health Physics will evaluate the radiological conditions associated with the work to be performed. Health Physics will specify the appropriate protective clothing, equipment, and monitoring required including dosimetry by use of radiological postings, work orders, or RWPs. Area survey frequency is established by Health Physics. All personnel performing work under a particular RWP (or equivalent) must be familiar with the permit conditions and must sign a RWP (or equivalent) compliance sheet. Information documented from RWP (or equivalent) entries include name, time in and out, and estimated exposure for entry. The RWP (or equivalent) computer may be used in lieu of a compliance sheet to document this information. Health Physics may terminate an RWP (or equivalent) if radiation conditions change.

Health Physics supervision selectively reviews RWPs and survey documentation which are then filed. RWPs (or equivalent) serve as a source of data for dose comparison on repeat jobs. They can be used to determine the effectiveness of ALARA efforts.

12.5.3.3 Handling and Storage of Radioactive Material

Health Physics personnel are notified of the receipt of radioactive material, and of intended shipment of radioactive material. This is done so that required surveys can be performed and to verify that correct labeling and placarding has been accomplished.

Calibration sources for radiation instrumentation and sources used to prepare secondary standards are stored in a source vault. This vault is capable of being locked. The lock is under the control of the Radiation Protection Manager.

Small quantities of sealed or unsealed sources may be stored for convenience in shielded cabinets, caves, or safes. Such sources are used locally in the chemical laboratories, counting room, or when response-checking instruments throughout the plant.

Spare instruments containing built-in sources and slightly contaminated equipment intended for reuse may be stored at times in the warehouse. Such items are clearly identified as containing radioactive material.

12.5.3.4 Controlling Access and Stay Time

The plant is surrounded by security fencing. Entrance must be via the guardhouse. Security procedures are applied by the guards at this point to identify each individual and to determine

their purpose for entry. Security and dosimetry badges are assigned. Escorts are provided to satisfy procedural requirements. Entrance to the RCA is via the Health Physics Access Point. Health Physics procedures are applied at this point to set exposure limits and ensure Health Physics Training of each individual prior to entry.

12.5.3.4.1 Access to Radiation and High Radiation Areas

Radiation areas are identified by posted radiation signs. Signs are used to define requirements for entry. Where appropriate, yellow and magenta or black rope or tape is used as a barrier to prevent access or to divert personnel to a specific control point for access. RWPs are used to define the exposure limits, document entry and exit, and record estimated exposure for each individual. Procedures describe the purpose and application of the RWPs. Administrative guides for personnel exposure are established by procedure. These guides are set at values less than the exposure dose limits in 10CFR20. Variations from these guides must be requested. Procedures describe the steps for approval of dose extensions. Additionally, positive control is exercised over each high radiation area by use of barricades, conspicuously posting the area, and requiring an RWP for entrance. Areas greater than 1000 mR/hr are controlled by using lock doors or gates. Exceptions to this practice are permitted per Technical Specification 6.12. Issuance of the keys are controlled by Health Physics. Each key used and the individual using the key are recorded. Certain work activities having high dose rates and short stay time may be monitored directly by Health Physics Technicians to prevent personnel from inadvertently exceeding the prescribed dose for the work. Personnel are advised to observe the reading on their direct reading dosimeter frequently.

12.5.3.4.2 Contamination Control

Contaminated areas are conspicuously identified to prevent inadvertent access. Floor coverings, called step off pads, typically are used to access these areas. Appropriate procedures give guidance for the selection and application of protective clothing and respirators under various specific conditions. Personnel requiring access to contaminated areas must determine the radiological controls and requirements via Health Physics briefings, radiological postings, work orders or RWPs.

As personnel leave the work area, they remove the protective clothing and respirators before stepping across the step-off-pad. Personnel must monitor themselves to assure that no contamination has been transferred to their bodies or clothing.

Tools or equipment to be removed from a contaminated area are surveyed or contained prior to removal from the area. Items suspected of or having loose surface contamination must be placed in a container (e.g., a plastic bag), surveyed, and tagged at the step-off-pad. The tools may be placed in storage, may be taken to another contaminated area for reuse, or they may be designated for appropriate storage, disposal, or decontamination. Tools, equipment and personal items are surveyed prior to removal from the RCA. Health Physics procedures describe the survey techniques and limits.

The presence of radioactive contamination, whether surface or airborne, inhibits mobility of personnel around the plant. Protective equipment that must be worn creates inconveniences and introduces other factors that affect performance. For these reasons, plus the obvious external and internal radiation hazards, decontamination is initiated judiciously to confine the contamination to as small an area as practicable and/or to reduce the contamination levels to minimize protective requirements. Special coatings that aid in decontamination are applied to walls and floors. The ventilation flow pattern is from clean areas to contaminated areas. Process equipment is isolated in various cavities or cells. These cells are vented in a controlled manner, usually through filters to

effluent stacks that monitor flow rate and radioactivity. Highly contaminated equipment drains are piped to sumps to avoid the use of floor drains and attendant spillage of fluids on the floor.

Control of radioactive contamination measurement and analysis and radioactive contamination control are provided by procedures that are responsive to the appropriate portions of the Quality Assurance Program.

12.5.3.5 Training

See Section 13.2.

12.5.3.5.1 Respiratory Fit Test

A functioning Respiratory Protection Program, which meets the requirements of 10CFR20. and Regulatory Guide 8.15 (October 1976), permits the application of protection factors to select the appropriate type of respirators. This can only be done for individuals who have received training in the use of the respirators, have been tested for the validity of fit for the type of respirators intended for their use, and who have been medically certified. Procedures are established that describe the technique, fit test frequency, and define acceptance criteria.

12.5.3.5.2 Compliance with Regulatory Guides

Regulatory Guide 8.2 - Section 12.1 describes the general ALARA program and policies. As specific procedures and the LGS ALARA plan are developed, Regulatory Guide 8.2 will be used for guidance.

Regulatory Guide 8.7 - Exposure records will be kept in accordance with 10CFR20 and maintained until the NRC authorizes their disposition. As the procedures are developed, the guidance of ANSI N13.6 (1969) as endorsed by Regulatory Guide 8.7 will be followed.

Regulatory Guide 8.8 - Sections 13.1, 13.2, 13.5, 12.1, and 12.5 address the management commitment, organization responsibilities, authority, training, procedures, and review techniques which implement Regulatory Guide 8.8 for LGS operation.

Regulatory Guide 8.9 - As stated in Section 12.5.2.2.6, the bioassay program will incorporate features of Regulatory Guide 8.9. When conservative investigative levels are exceeded, a consultant will assist in a more detailed evaluation of internal exposure. These procedures and practices will follow the guidance of International Committee of Radiation Protection publications and Regulatory Guide 8.9.

Regulatory Guide 8.10 - The development and implementation of a formal ALARA program will follow the guidance of Regulatory Guide 8.8 which is a nuclear power plant specific reference of Regulatory Guide 8.10.

Regulatory Guide 8.13 - Instruction to workers concerning prenatal radiation exposure will be given as part of the General Employee Training Program. This program will provide all employees with the information that is identified in Regulatory Guide 8.13.

Regulatory Guide 8.15 - The development and implementation of a respiratory protective equipment program will follow the guidance of Regulatory Guide 8.15.

Regulatory Guide 8.26 - The bioassay program will incorporate features of Regulatory Guide 8.26.

Regulatory Guide 1.8 - LGS is in compliance with this guide to the extent discussed in Sections 13.1 and 13.2. The licensee has implemented ANSI/ANS 3.1-2014, section 5, which is endorsed by Regulatory Guide 1.8.

Regulatory Guide 1.16 - LGS Technical Specifications were based on NUREG-0123, Revision 4, "Standard Technical Specifications for General Electric BWRs," as described in Chapter 16. Reporting of operating information will be in accordance with the Technical Specifications,

Regulatory Guide 1.33 - LGS will follow the guidance of Regulatory Guide 1.33 which endorses/modifies ANSI N18.7 (1976) with certain alternate approaches which are addressed in detail in Section 17.2.

Regulatory Guide 1.39 - LGS is in general conformance to the guidance of Regulatory Guide 1.39, which endorses/modifies ANSI N45.2.3 (1973). LGS will comply with Regulatory Guide 1.39 with certain alternate approaches which are outlined in detail in Section 17.2.

Regulatory Guide 1.97 - LGS is in compliance with Regulatory Guide 1.97 in regard to Health Physics and Chemistry Laboratory and Survey Equipment.

CHAPTER 13 - CONDUCT OF OPERATIONS

13.1 ORGANIZATIONAL STRUCTURE

The Exelon Generation Company, LLC (EGC) corporate organization and its functions and responsibilities are described in Chapter 1 of the Quality Assurance Topical Report (QATR) designated as NO-AA-10, as revised.

13.1.2 OPERATING ORGANIZATION

The organizational structure and reporting relationships are described in the Quality Assurance Topical Report, NO-AA-10 and Nuclear Organization charts, HR-AA-2009.

Table 13.1-2, shows the title of each position and the positions for which reactor operator and senior reactor operator licenses are required.

SHIFT CREW COMPOSITION - MINIMUM REQUIREMENTS[1,2,3,4]

		ONE UNIT FUELED		TWO UNITS FUELED		
POSITION	LICENSE REQUIRED	Operating	Cold Shutdown	Two Units Operating	One-Unit Operating and One-Unit Shutdown	Two Units Cold Shutdown
Shift Manager	SRO	1	1	1 per 2 units	1 per 2 units	1 per 2 units
Shift supervisor	SRO	2	2	2 per 2 units	2 per 2 units	2 per 2 units
Plant Reactor operator	RO	1	The Plant Reactor operator position or the assistant position will be manned.	1 per 2 units	1 per 2 units	-
Reactor operator	RO	1	-	1 per unit	1 per unit	1 per unit
Equipment operator	-	2	The equipment operator position will be manned	3 per 2 units	3 per 2 units	3 per 2 units

.

(1) At least one licensed RO shall be present in the control room and assigned to each reactor that contains fuel.

(2) At least 2 licensed ROs, excluding the operator of the second unit, shall be present in the control room during reactor startup, scheduled reactor shutdown, and recovery from reactor trips.

(3) All core alterations shall be directly supervised by either a licensed SRO or SRO Limited to Fuel Handling, who has no other concurrent responsibility during this operation.

(4) A health physics technician shall be onsite at all times when fuel is in a reactor to ensure implementation of the radiation protection program.

13.2 TRAINING

13.2.1 PLANT PERSONNEL TRAINING PROGRAM

The Limerick Generating Station (LGS) training program incorporates the requirements specified in 10CFR55, 10CFR50 as promulgated in the NRC Final Rule 10CFR50.120 - "Training and Qualification of Nuclear Power Plant Personnel," which became effective May 26, 1993 and the applicable provisions of the Operating Licenses, including the Technical Specifications. The LGS training program is based on a Systems Approach to Training (SAT). The training program provides qualified personnel to operate and maintain the facility in a safe manner in all modes of operation. The training program will be periodically reviewed by management for effectiveness, and will be periodically evaluated and revised, as appropriate, to reflect industry experience as well as changes to the facility, procedures, regulations, and quality assurance requirements. Achievement of this goal is based on a philosophy of providing training developed from a systematic analysis of job requirements using job and task analysis where available. This philosophy is consistent with both Nuclear Regulatory Commission (NRC) requirements and Institute of Nuclear Power Operations (INPO) recommendations necessary for accreditation of training programs.

13.2.1.1 INPO Accredited Training Programs

The following training programs have been accredited by INPO and are continually maintained based on Systems Approach to Training (SAT).

	Program	Date Originally Accredited
1.	Non-Licensed Operator	10/30/86
2.	Reactor Operator	10/30/86
3.	Senior Reactor Operator	10/30/86
4.	Shift Manager (formerly Shift Supervisor)	10/30/86
5.	Shift Technical Advisor	10/30/86
6.	Engineering Support Personnel	10/30/86
7.	Licensed Operator Requalification	10/30/86
8.	Maintenance Technician - Mechanical and Supervisor	10/30/86
9.	Maintenance Technician - Electrical and Supervisor	10/30/86
10.	Instrument and Control Technician and Supervisor	10/30/86
11.	Chemistry Technician	10/30/86
12.	Health Physics Technician	10/30/86

Program/Course plans describing the content and details of these programs are maintained by the Nuclear Training Section.

13.2.1.2 Access Training

Persons employed at LGS, including temporary maintenance and service personnel, are required to successfully complete General Employee Training (GET) and Fitness for Duty Training (FFD) prior to being granted unescorted site protected area access. The frequency of retraining for GET and continuing training programs are determined by following the SAT-based training process. Retraining for FFD is required on a nominal annual basis. Training content is commensurate with job responsibilities, and complies with the requirements of:

10CFR19.12	(GET),
10CFR26	(FFD),

and the guidance specified in:

ANSI/ANS 3.1-2014	(GET),
Regulatory Guide 8.13	(GET),
Regulatory Guide 8.29	(GET).

General Respiratory Training (GRT) is required for personnel who may wear respiratory protective equipment as part of normal work requirements or as emergency response team members. Re-training in GRT is required on a nominal annual basis. The content and conduct of GRT complies with the recommendations specified in NUREG-0041, "Manual of Respiratory Protection Against Airborne Radio-Materials," and Regulatory Guide 1.78, Position C-13, and the criteria of ANSI Z88.2.

Program/Course Plans for GET, GRT, and FFD are maintained by the Nuclear Training Section. These plans provide a detailed description of the Program/Course, in accordance with the provisions of Regulatory Guide 1.70.

13.2.1.3 Emergency Preparedness Training

See the Emergency Plan (Ref: UFSAR 13.3)

13.2.1.4 Radwaste Shipping Training

Training of personnel involved in Radwaste packing, shipping, handling, or minimization receive training appropriate to the level of the task they perform. This training complies with the guidance in NRC I.E. Bulletin 79-19. A Program/Course Plan for Radwaste Shipping Training is maintained by the Nuclear Training Section. These plans provide a detailed description of the Program/Course, in accordance with the provisions of Regulatory Guide 1.70.

13.2.1.5 Fire Protection Training

The objective of fire protection training is to ensure that the shift and plant staff Fire and Damage Teams are prepared and capable of responding to fire emergencies. Leaders and members of the Fire Brigade receive initial training at the West Conshohocken Fire School. Site specific fire training is administered on a 2 year cycle. Each fire brigade member participates in at least two drills per year. Also see Section 9.5.1.5.

The fire brigade training program will consist of an initial classroom instruction program followed by periodic classroom instruction, fire fighting practice, and fire drills as follows:

a. Instruction

1. The initial classroom instruction will include:

(a) Indoctrination of the plant fire fighting plan with specific identification of each individual's responsibilities.

(b) Identification of the type and location of fire hazards and associated types of fires that could occur in the plant.

(c) Toxic and corrosive characteristics of expected products of combustion.

(d) Identification of the location of fire fighting equipment for each fire area and familiarization with the layout of the plant, including access and egress routes to each area.

(e) Proper use of available fire fighting equipment and the correct method of fighting each type of fire. The types of fires covered should include fires in energized electrical equipment, fires in cables and cable trays, hydrogen fires, fires involving flammable and combustible liquids or hazardous process chemicals, fires resulting from construction or modifications (welding), and record file fires.

(f) Proper use of communication, lighting, ventilation, and emergency breathing equipment.

(g) Proper method for fighting fires inside buildings and confined spaces.

(h) Direction and coordination of the fire fighting activities (fire brigade leaders only).

(i) Detailed review of fire fighting strategies and procedures.

(j) Review of the latest plant modifications that affect the fire fighting equipment or the fire fighting plans.

Items (i) and (j) may be deleted from training of no more than two of the non-operations personnel who may be assigned to the fire brigade

2. Instruction will be provided by qualified individuals who are knowledgeable, experienced, and suitably trained in fighting the types of fires that could occur in the plant and in using the types of equipment available in the plant.

3. Instruction will be provided to all fire brigade members and fire brigade leaders.

4. Regular planned meetings will be held at least every 3 months for all brigade members to review changes in the fire protection program and other subjects as necessary.

5. Periodic refresher training sessions will be held to repeat the classroom instruction program for all brigade members over a 2 year period. These sessions may be concurrent with the regular planned meetings.

b. Practice

Practice sessions will be held on the proper method of fighting the various types of fires that could occur in a nuclear power plant. These sessions will provide brigade members with experience in actual fire extinguishment and the use of emergency breathing apparatus under strenuous conditions encountered in fire fighting. These practice sessions will be provided at least once per year for each fire brigade member.

c. Drills

1. Fire brigade drills will be performed in the plant so that the fire brigade can practice as a team. In addition to in-plant drills, an offsite facility enables drills to include the use of the live fire conditions. These elements plus the use of breathing apparatus and full protective clothing create actual conditions that would be encountered during a real plant fire emergency. Additional drills, including backshift unannounced drills are conducted in plant areas throughout the year.

2. Drills will be performed at regular intervals not to exceed 3 months. Each fire brigade member should participate in each drill, but must participate in at least two drills per year.

   A sufficient number of these drills, but not less than one for each shift fire brigade per year, will be unannounced to determine the fire fighting readiness of the plant fire brigade, brigade leader, and fire protection systems and equipment. Persons planning and authorizing an unannounced drill will ensure that the responding shift fire brigade members are not aware that a drill is being planned until it is begun. Unannounced drills will not be scheduled closer than 4 weeks.

   At least one drill per year will be performed on a "back shift" for each shift fire brigade.

3. The drills will be preplanned to establish the training objectives of the drill and will be critiqued to determine how well the training objectives have been met.

   Unannounced drills will be planned and critiqued by members of the management staff responsible for plant safety and fire protection. Performance deficiencies of a fire brigade or of individual fire brigade members will be remedied by scheduling additional training for the brigade

or members. Unsatisfactory drill performance will be followed by a repeat drill within 30 days.

4. At 3 year intervals, a randomly selected unannounced drill will be critiqued by qualified individuals independent of the plant staff. A copy of the written report from such individuals will be available for NRC review.

5. Drills will, as a minimum, include the following:

   (a) Assessment of fire alarm effectiveness, time required to notify and assemble the fire brigade, and selection, placement, and use of equipment and fire fighting strategies.

   (b) Assessment of each brigade member's knowledge of their role in the fire fighting strategy for the area assumed to contain the fire. Assessment of the brigade member's conformance with established plant fire fighting procedures and use of fire fighting equipment, including self-contained emergency breathing apparatus, communication equipment, and ventilation equipment, to the extent practicable.

   (c) Simulated use of fire fighting equipment required to cope with the situation and type of fire selected for the drill. The area and type of fire chosen for the drill should differ from those used in the previous drill so that brigade members are trained in fighting fires in various plant areas. The situation selected should simulate the size and arrangement of a fire that could reasonably occur in the area selected, allowing for fire development due to the time required to respond, to obtain equipment, and organize for the fire, assuming the loss of automatic suppression capability.

   (d) Assessment of the brigade leader's direction of the fire fighting effort as to thoroughness, accuracy, and effectiveness.

d. Records

Individual records of training provided to each fire brigade member, including drill critiques, will be maintained for at least 3 years to ensure that each member receives training in all parts of the training program. These records of training will be available for NRC review. Retraining or broadened training for fire fighting within buildings will be scheduled for all those brigade members whose performance records show deficiencies.

13.2.1.6 Fire Protection Requalification Training

Leaders and members of the Fire Brigade receive annual refresher training at the West Conshohocken Fire School. Site specific fire training is administered on a 2 year cycle. Each fire brigade member participates in at least two drills per year.

All diesel operations and operational maintenance activities at LGS are performed by operations personnel as described in Section 13.1.2. The licensee includes diesel generator training in the

INPO accredited programs for operations personnel and supervision, tailored to the specific job classifications, based upon task analyses. This training, originally drawn from manufacturer's recommendations, is equivalent to vendor training. Operations personnel perform diesel generator activities in accordance with approved operating and test procedures.

Activities beyond the responsibilities assigned to operating personnel are referred to plant technical personnel and/or maintenance personnel. Maintenance personnel may be members of the onsite or offsite organization. The licensee provides a variety of INPO accredited maintenance training classes to ensure the availability of qualified maintenance technicians and supervisors. Maintenance activities are performed under supervision appropriately qualified and experienced on the type of diesel generators at Limerick. Maintenance supervision is responsible for the assignment of personnel properly qualified for the task. Qualified personnel, qualified and experienced Maintenance supervision, use of approved procedures, and technical expertise of manufacturer's service representatives provides competency equivalent to vendor training so that diesel generator reliability is maintained.

13.2.2 Records

The plant training organization is responsible for maintaining training records for the plant staff. Records for the plant staff shall be sufficient to show qualification for the position held. As applicable for the training course, records include copies of written examinations and answers, lecture attendance records, results of evaluations, and records of additional remedial training. All quality records indicating pertinent, formalized training of the plant staff shall be entered into the Nuclear Records Management System for proper maintenance and recall, by the plant nuclear training section.

13.2.3 Training Organization

13.2.3.1 See Figure 13.2-1

Table 13.2-1

Matrix of LGS Training Program Guidelines

Intentionally Left Blank
(See Section 13.2.1)

13.3 EMERGENCY PLANNING

The Exelon Standardized Radiological Emergency Plan (EP-AA-1000) for the LGS has been submitted as a separate document.

13.4 REVIEW AND AUDIT

13.4.1 GENERAL

The licensee shall establish and implement review and audit functions to ensure that activities important to safety are properly accomplished in accordance with company policies and rules, approved operating procedures, and operating license provisions during the operations phase. As fully described below, these functions are as provided in ANSI N18.7 (1976)/ANS 3.2, paragraphs 4.1 through 4.5, as modified by Regulatory Guide 1.33 (Rev 2), positions C.3, C.4, and C.5.a, and ensure implementation of 10CFR50.59 with regard to proposed changes, tests, and experiments. The review and audit functions will be implemented in accordance with the provisions of the Quality Assurance Topical Report (QATR) and are described in the QATR.

13.4.2 ONSITE REVIEW

The Plant Operations Review Committee (PORC) satisfies a portion of the independent review program requirement described in ANSI N187 (1976) / ANS 3.2, Section 4.3, "Independent Review Program". A comprehensive description of the PORC function is located in Exelon Procedure LS-AA-106, "Plant Operations Review Committee". Exelon process description NO-AA-10, "Standard Quality Assurance Topical Report (QATR)," also includes a description of PORC functions. PORC performs independent reviews of activities that have the potential to affect nuclear safety and advises the plant manager regarding approval or disapproval of these activities.

13.4.3 INDEPENDENT REVIEW

The information from this section has been relocated to the Quality Assurance Topical Report (QATR).

13.4.4 ASSESSMENT PROGRAM

The information from this section has been relocated to the Quality Assurance Topical Report (QATR).

The QATR describes how the Quality Assurance Program is to be functionally implemented with due regard to the safety and health of the public and the personnel on site. The LGS Quality Assurance Program as described by the QATR is incorporated herein by reference.

13.4.5 INDEPENDENT TECHNICAL REVIEW FUNCTION

The information from this section has been relocated to the Quality Assurance Topical Report (QATR).

13.5 PLANT PROCEDURES

Safety-related activities performed by the plant staff shall be governed by written and approved procedures of a type appropriate to the circumstances and activity, and shall be carried out in accordance with those procedures. Where appropriate for determining that important activities have been satisfactorily accomplished, quantitative or qualitative acceptance criteria shall be included. The licensee utilizes the operating experience gained at PBAPS Units 2 & 3 (BWR units similar to LGS) in the development of the procedures.

As fully described below, the licensee has implemented ANSI N18.7 (1976)/ ANS 3.2, Section 5 as modified by NRC Regulatory Guide 1.33 (Rev 2), paragraphs C.1 and C.5.b through C.5.j, as these documents apply to operating staff activities, in the preparation, content, and control of procedures. Programmatic controls are in place to assure that procedures are maintained current. These controls take the place of, and eliminate the need for, scheduled periodic reviews and revisions.

Sections 13.5.1.1 through 13.5.1.27 describe administrative procedures. Many of these sections describe how various procedure types (such as maintenance procedures or preventive maintenance procedures) are developed and controlled, whereas other sections describe an administrative process (such as purchasing).

It is planned that most administrative and operating procedures will be in effect at least six months prior to fuel loading of Unit 1. The procedures will be implemented with sufficient lead time to ensure that operating personnel can become familiar with them. The licensee recognizes the benefits of using the preoperational testing phase to demonstrate the adequacy of operating procedures and, where practicable, this will be accomplished.

The following paragraphs describe the types of procedures to be employed by station operating personnel in the conduct of safety-related activities. These procedures are normally prepared by the station operating staff. However, organizations providing technical support and consultants may assist in procedure development. The procedures and revisions thereto are reviewed by Station Qualified Reviewers (SQRs) who are approved and designated as such by the PORC Chairman to perform such reviews for specific classes of procedures. The SQRs determine in writing if a cross-disciplinary review is required by the appropriate personnel prior to approval. Procedures or revisions thereto are approved by responsible Superintendents who are designated as such for specific classes of procedures by administrative procedures. PORC reviews administrative procedures and those procedures or revisions thereto requiring a 10 CFR 50.59 evaluation be performed. The Plant Manager or his designated alternate approves administrative procedures, emergency plan implementing procedures, security plan implementing procedures, and any procedure or revision thereto requiring a 10 CFR 50.59 evaluation be performed.

13.5.1 ADMINISTRATIVE PROCEDURES

Administrative procedures generally include those that establish station management policy, those that control activities that involve interfaces among disciplines or groups supporting plant operations, and those that establish criteria for procedures and activities implemented by the plant staff and support organizations. Administrative procedures shall be prepared in sufficient detail so that tasks are performed in a consistent, efficient manner and to ensure that the necessary reviews and approvals are performed.

The following paragraphs describe the administrative procedures expected to be employed. The numbers of procedures and their specific content may be altered as the procedures are developed and experience is gained in their implementation.

13.5.1.1 Procedure for Preparation and Control of Administrative Procedures

This procedure shall provide the measures to control and coordinate the preparation, review, approval, and issuance of administrative procedures. This procedure shall require that administrative procedures be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used. The format and content of administrative procedures shall be defined as:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References, including technical specifications or procedures as applicable.

d. Prerequisites when there are independent actions or procedures that must be completed prior to using the procedure.

e. Procedure section. The procedure shall provide the steps needed to perform the task in the degree of detail necessary to ensure correct, efficient performance without direct supervision or undue reliance on memory. This section may also provide criteria statements to be implemented by other procedures.

Administrative procedures are written to provide direction for the efficient administration of plant business and reflect the station management philosophy and to implement corporate policies regarding these functions.

13.5.1.2 Procedure for Plant Operations Review Committee

This procedure shall define the requirements of membership, meeting frequency, quorum, responsibilities, authority, and records for the PORC in implementation of technical specification provisions. The PORC shall review significant conditions adverse to plant safety to ensure that the cause of the condition is identified, that corrective action is taken and documented, and that appropriate subjects are referred to the Nuclear Review Board.

13.5.1.3 Procedure for Plant and Shift Operations

This procedure shall define the responsibilities and authority of plant operating personnel, including:

a. Prohibition against manipulation of the reactor controls by personnel who are not licensed reactor operators or senior reactor operators. Trainees may manipulate controls under the direct supervision of a licensed operator.

b. Requirement that apparatus and mechanisms that may affect the reactivity or power level of the reactor only be manipulated with the knowledge and consent of the licensed reactor operator or senior reactor operator present at the controls.

c. Requirement for a licensed reactor operator or senior reactor operator to be present at the controls at all times when fuel is in the reactor.

d. Reactor operator's responsibility and authority for shutting down the reactor when he determines that the safety of the reactor is in jeopardy, when operating parameters exceed reactor protection setpoints and automatic shutdown does not occur, or when there is doubt as to whether safe conditions exist.

e. Responsibility to determine the circumstances, analyze the cause, and determine that operations can proceed safely before the reactor is returned to power after a trip or unscheduled or unexplained power change.

f. Senior reactor operator's responsibility for directing the licensed activities of the reactor operator and to be present at the plant and to provide direction for returning the reactor to power following a trip or an unscheduled or unexplained power change.

g. Responsibility to respond conservatively to instrument indications including the case in which the credibility of the indication is in doubt.

h. Responsibility to adhere to the technical specifications and the provisions of the operating license.

i. Responsibility to review routine operating information to ensure safe operation.

j. Functional relationship of the STA to the operating shift.

This procedure shall also provide instructions to plant staff and operating personnel in areas of general and continuing applicability to plant management such as:

a. The necessity to adhere to plant procedures and to refer directly to procedures for complex or extensive jobs where reliance on memory cannot be trusted, such as reactor startup, tasks that are infrequently performed, and complex tasks that must be performed in a specific order.

b. The responsibility of plant personnel to take action, in the event of an emergency not covered by approved procedures, so as to minimize personnel injury and damage to the facility, and to protect public health and safety.

c. Personnel conduct.

d. Availability on call of plant staff and operating personnel.

e. Preparation of plant logs and records.

f. Requirements for shift turnover.

g. Definition of "at the controls" (Figure 13.5-1).

h. Recording data or completing documentation as tasks are performed when such data or documentation of tasks is required.

i. Definition of SRO control room boundaries (Figure 13.5-2).

13.5.1.4 Procedure for Release of Safety-Related Equipment

This procedure shall implement the licensee's standard requirements for blocking and tagging equipment and shall establish criteria for this function such as:

a. Designation of personnel authorized to release equipment or systems for maintenance and the method of documenting such authorization.

b. Aspects to be considered in releasing equipment such as: how long equipment may be out of service; potential for degradation of protection when one subsystem of a redundant safety system has been removed from service; equipment and personnel safety.

c. Aspects to be considered in returning equipment to service such as removal of jumpers and test signals and return of valves, breakers, or switches to proper positions.

This procedure shall provide for identification of released equipment and for controls, such as blocking/locking or tagging, to maintain personnel and reactor safety and to avoid unauthorized operation of the equipment. The procedure shall provide for independent verification, where appropriate, to ensure that the blocking and tagging methods have been implemented correctly. The functional acceptability of equipment shall be verified and documented as equipment is returned to service.

Operating personnel will ensure that when any part of a redundant safety system is removed from service, the portion remaining in service is operable and in surveillance as required in the Technical Specifications. An administrative procedure, which governs when equipment is returned to service, requires Shift Management to review all Work Orders and testing pertaining to the safety system being returned to service. Shift Management will ascertain if additional testing is required and consider the consequences of returning equipment to service.

13.5.1.5 Procedure for Temporary Modifications

This procedure shall provide controls for temporary modifications such as electrical jumpers, lifted electrical leads, and bypass lines. The requirements shall include independent verification of the intent/need for the installation, consideration of the need to revise applicable procedures, and a logging system to indicate current status of the temporary modification.

13.5.1.6 Procedure for Control of Plant Modifications

This procedure shall provide the controls for administration, design and design review, and preplanning of plant modifications so that modifications are performed in a manner to ensure quality as specified in the original or approved modification design. The procedure shall provide for consideration and specification of appropriate inspections and tests to develop a suitable level of confidence that the modification has been properly installed. Activities that ensure the quality of the modification shall be performed in accordance with documented drawings or instructions appropriate to the circumstances, that conform to the specified design requirements, and that provide for documentation of activities where appropriate. Skills normally possessed by trained

craft personnel may not require detailed step-by-step delineations in a written procedure. As part of the modification process, consideration shall be given to the need for revising applicable procedures.

The procedure for control of plant modifications shall require that the status of inspections and tests performed on items be indicated by use of stamps, tags, labels, routing cards, procedural sign-offs, or other suitable means that provide traceability between the record and the item(s). Also, where necessary to preclude inadvertent bypassing of inspections and tests, the procedure shall require that the item(s) that have satisfactorily passed required inspections and tests be identified. This procedure shall require that the following aspects of housekeeping and cleanliness control be considered in the development of instructions for the modification:

a. Housekeeping provisions shall recognize the special requirements involved with radiation zones and control areas.

b. Only proper materials, equipment, processes, and procedures may be used to ensure that the quality of plant equipment is not degraded.

c. Where necessary, special instructions for housekeeping and cleaning operations shall be provided and used.

d. Where needed to prevent contamination of safety systems with foreign materials, personnel and/or materials access control shall be established and a cleanliness inspection shall be performed immediately prior to closure. The inspection results shall be documented.

The procedure for control of plant modification shall require that appropriate inspections be established and implemented for modifications in accordance with the following criteria:

a. Inspections, examinations, measurements, or tests shall be specified and performed for each work activity where necessary to ensure quality.

b. Inspections shall be performed by qualified individuals other than those who performed or directly supervised the activity being inspected. Inspection of certain activities (such as work functions associated with normal plant operations, routine maintenance, and certain technical services routinely assigned to the onsite operating organization) may be conducted by shift or plant staff supervisory personnel or by other qualified personnel not assigned first-line supervisory responsibility for conduct of the work.

c. Modification work similar to construction phase work shall be subject to inspections similar to those performed in the construction phase.

d. Inspections shall be performed in accordance with approved written instructions or procedures that contain or reference the requirements, acceptance limits, and responsibilities for the inspection.

e. When specific hold points are required, they shall be indicated in appropriate documents.

f. When inspection techniques require specialized qualifications, inspection personnel shall meet the specified requirements for the technique involved.

g. If inspection is impossible or disadvantageous, indirect control by monitoring process methods, equipment, and personnel shall be provided. Both inspection and process monitoring shall be provided when control is inadequate without both.

h. Inspection instructions or procedures shall include or reference requirements for evaluation of inspection results when the nature of the results indicates that such an evaluation is needed to determine if the plant can be operated safely. Evaluation beyond that given by inspection-level personnel shall not normally be required for go/no-go and pass/fail type inspections.

i. Inspectors, data recorders, and those evaluating inspection results shall be identified and the records shall reflect implementation of the inspections and actions completed or planned to correct noted deficiencies.

The procedure for control of plant modifications shall require that special processes be identified and accomplished under controlled conditions in accordance with applicable codes, standards, specifications, criteria, or other special requirements. The procedure shall require that special processes be accomplished by qualified personnel using qualified procedures and equipment as provided in the specified requirements for the activity.

The procedure for control of plant modifications shall require that modifications be tested to demonstrate that they will perform satisfactorily in service and that such testing be performed in accordance with written test procedures or instructions that incorporate or reference the requirements and acceptance limits contained in the applicable design documents. Such testing shall confirm that modifications and associated procedure changes, if any, produce expected results.

13.5.1.7 Procedure for Control of In-plant Work

This procedure shall provide the controls needed to coordinate, approve, and implement in-plant work. The controls provided shall include:

a. Planning and coordination of maintenance and modification work so as not to compromise plant safety, including the consequences of concurrent or sequential maintenance and modification activities, the need to provide operable equipment to support the operating mode of the plant, and the need to remain within license limits. Such planning shall also include evaluation of use of special processes, equipment, and materials in regard to potential hazards to personnel and equipment.

b. A method to ensure that conditions adverse to plant safety (such as failures, malfunctions, deficiencies, deviations, defective plant equipment, abnormal occurrences and nonconformances related to plant equipment) shall be identified and corrected through corrective maintenance.

c. A method to maintain or coordinate maintenance of the identification and traceability of materials, parts, and components as it is established in the storeroom to provide insurance that only correct and accepted items are used and installed.

d. Obtaining the necessary permits, such as blocking and tagging of equipment and radiation work permits that specify radiation protection measures, monitoring, and protective clothing.

e. Review of repetitive malfunctions to determine the cause and corrective measures. This activity can include referral to Engineering for evaluation, determination of repair or replacement parts, and associated design, testing, and installation requirements.

13.5.1.8 Procedure for Administration of the Preventive Maintenance Program

This procedure shall establish the administrative requirements for the preventive maintenance program so that preventive maintenance is preplanned and performed in accordance with written procedures, documented instructions, or drawings appropriate to the circumstances. Preventive maintenance shall include those routine actions needed to ensure that plant equipment (including special tools) continues to operate properly by detection or prevention of actual or impending failures or substandard performance. The aspects of preventive maintenance that shall be addressed in this procedure include:

a. Establishment of the frequency and schedule for preventive maintenance actions.

b. Records of completion of preventive maintenance actions.

c. Preparation, approval, and control of written procedures, documented instructions, or drawings that are appropriate to the circumstances for the performance of preventive maintenance actions. The written procedures, documented instructions or drawings shall conform to the design requirements, and provide for documentation of activities where appropriate. Skills normally possessed by trained craft personnel may not require detailed step-by-step delineations in a written procedure. Preventive maintenance procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

This procedure shall establish the format and content of preventive maintenance procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References, including technical specifications, vendor documents, and drawings as appropriate to ensure the required quality of the work.

d. Prerequisites, including those independent actions or procedures that must exist prior to use of the preventive maintenance procedure. Prerequisites applicable only to certain sections of the procedure shall be so identified.

e. Precautions to alert the individual performing the task to those important measures that should be used to protect equipment and personnel, including the public, or to avoid an abnormal or emergency situation. Routine precautions that a trained craftsman is expected to take, such as normal electrical safety methods, shall not be required to be stated.

f. Procedure section. The procedure shall provide the steps needed to perform the task in the degree of detail necessary to ensure safety and correct performance without undue reliance on memory or direct supervision and in consideration of the skills normally possessed by trained craft personnel. Precautions and reference documents important to specific steps in the procedure shall be identified or included at those steps. This section shall also provide instructions for performing and documenting the results of required inspections and tests and provides the necessary acceptance criteria. When appropriate, checkoff lists shall be included in or appended to preventive maintenance procedures.

g. Return-to-normal. This section shall contain instructions as to the mode or condition in which the equipment is to be placed after completion of the preventive maintenance action.

Maintenance and preventive maintenance procedures are proven to be correct through their use. Because they are written for specific equipment, they are not subject to intersystem changes that may affect other procedure types, such as general plant procedures.

Maintenance and preventive maintenance procedures are reviewed when equipment modifications are made through the controlled modification program at the station. In addition, when indicated by the review of NRC Bulletins, Circulars and Notices, INPO documents and industry documents, the procedures are revised if necessary on a case-by-case basis.

To ensure feedback, preventive maintenance procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures.

13.5.1.9 Procedure for Administration of the Surveillance Testing Program

This procedure shall establish the administrative requirements and responsibilities for the surveillance testing program so that such testing is preplanned and performed in accordance with written procedures and drawings appropriate to the circumstances, and in accordance with the technical specification requirements. Included in this program shall be the safety-related instruments and control devices and special equipment as defined in the technical specifications. The aspects of surveillance testing that shall be addressed in this procedure include:

a. Establishment of calibration intervals and methods for installed safety-related instruments and control devices as defined in the technical specifications.

b. Requirements for the calibration of measuring and test equipment at specified intervals or prior to use to ensure the necessary accuracy of equipment and requirements for use of measuring and test equipment of the proper type and range.

c. Requirements for performing a documented evaluation of the validity and acceptability of previous calibration activities when measuring and test equipment are found to be out of calibration. The evaluation shall cover the applicable surveillance tests from the time of the previous calibration.

d. Requirements for performing special calibrations of installed safety-related instruments and control devices when the accuracy of the equipment is questionable.

e. Requirements for recording calibration activities and suitably marking equipment to indicate calibration status.

f. Establishment of a master surveillance test schedule reflecting the status of all planned surveillance tests.

g. Responsibilities for timely performance of surveillance tests, evaluation of results, reporting completion, and maintenance of appropriate records.

h. Planning for performance of required tests so as not to compromise plant safety including the possible consequences of concurrent or sequential testing, the need to provide operable equipment to support the operating mode of the plant, and the need to remain within license limits.

i. Preparation, approval, and control of written procedures for the performance of individual surveillance tests. Surveillance test procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

This procedure shall establish the format and content of surveillance test procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability and objectives(s) of the test.

c. References, including technical specifications, drawings, and vendor documents as appropriate to ensure the required quality of the work.

d. Prerequisites including those independent actions or procedures that must be completed and plant conditions that must exist prior to use of the surveillance test procedure, and including any special conditions to be used to simulate normal or abnormal operating conditions. Prerequisites applicable to only certain sections of the procedure shall be so identified. Special equipment or calibrations required to conduct the test shall be listed.

e. Precautions to alert the individual performing the task to those important measures that should be used to protect equipment and personnel, including the public; or to avoid an abnormal or emergency situation. Applicable limiting conditions shall be included.

   Routine precautions that trained craftsmen or test personnel are expected to take, such as normal electrical safety methods, need not be stated.

f. Procedure section. The procedure shall provide the steps needed to perform the test in the degree of detail necessary to ensure safety and correct performance without direct supervision and in consideration of the skills normally possessed by trained craft and testing personnel. Precautions and reference documents

important to specific steps in the procedure shall be identified or included at those steps. Where test steps are to be witnessed, the test sequence shall identify the hold points and shall require appropriate approval for the test to continue beyond the designated hold point. The procedure requires recording of test results, including data such as as-found and as-left information where appropriate. Acceptance criteria for the tests shall be specified. When appropriate, checkoff lists shall be included in or appended to the surveillance test procedures.

g. Return-to-normal. This section shall contain instructions as to the mode or condition in which the equipment is to be placed after completion of the surveillance test.

This procedure shall require recording the test date, corrective actions taken (if any), identification of those performing the test, and identification of those evaluating the test results to ensure that requirements have been met.

Surveillance tests and routine tests are performed on a periodic basis; this step-by-step use of the procedure demonstrates the adequacy of the procedures. In addition, when changes in the plant Technical Specifications are received, the appropriate procedures are identified and revised. Plant modifications, NRC Bulletins, and Information Notices also initiate procedure review and revision, if needed.

To ensure feedback, surveillance test procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures.

The surveillance test program shall include procedures for monitoring performance of plant systems to ensure that engineered safety features and emergency equipment are in the required state of readiness and that operating systems are performing properly.

The limits for significant parameters shall be identified as well as the nature and frequency of monitoring.

13.5.1.10 Procedure for Administration of Plant Records

This procedure shall establish the provisions and responsibilities for retention of plant records. Preparation of records is discussed in procedures that cover the specific activities. The responsibility for maintaining and storing records at specified location(s) shall be assigned. This procedure shall ensure that retention times are established so that applicable statutory requirements are satisfied. The significance of the event covered by the record-type and the contribution of the record to the ability to reconstruct significant events shall also be considered in establishing retention periods.

13.5.1.11 Procedure for Procurement

This procedure shall establish the controls for activities performed by the plant operating staff in regard to procurement of safety-related equipment. This procedure shall require that procurement of safety-related equipment (including spares and replacements) be purchased to specifications and codes equivalent to those specified for original equipment or to approved alternate requirements that have been evaluated to ensure that interfaces, interchangeability, safety, fit, and function are not adversely affected or contrary to applicable regulatory or code requirements. The

results of this evaluation shall be documented. The procedure shall define the requirements for preparation, review, and approval of procurement requirements and changes thereto to ensure that applicable regulatory requirements, design bases, and other requirements necessary to ensure adequate quality are included or referenced.

The procedure for procurement shall define the content of procurement documents as follows:

a. To the extent necessary, the procurement document shall require suppliers of Q-listed items to provide a quality assurance program consistent with original requirements, ANSI/ASME NQA-1-1994, 10CFR50, Appendix B, or approved alternate requirements as described above. When applicable, suppliers shall be required to extend applicable requirements of the procurement documents to their suppliers and subcontractors.

b. Basic technical requirements. Required drawings, specifications, and industrial codes and standards shall be identified by titles and dates of issue in such a way as to clearly set forth the applicable documents for fabrication. Where procedural requirements apply, they shall be identified clearly and in such a way as to avoid uncertainty as to source and need. Packaging and transportation shall be required to be accomplished in a manner that will ensure that quality is not degraded and that applicable regulatory requirements are met.

c. Source inspection and audit. Provisions for access to suppliers' facilities and records for source inspection and audit shall be specified when the need for such inspection or audit is determined.

d. Documentation requirements. Necessary records to show compliance with specifications, codes, standards, and fabrication requirements shall be specified as to preparation, retention, and submittal. In addition, applicable vendor documents such as drawings, specifications, procedures, qualification records, material analyses, and inspection and test records shall be specified as to preparation, retention, and submittal.

The procedure for procurement shall contain the provisions and responsibility for receipt inspection to determine the acceptability of purchased items in regard to the procurement documents and/or receipt inspection instructions. The procedure shall provide that, where required by contract requirements, codes, or regulations, documentary evidence that items conform to procurement requirements shall be available at the plant site prior to installation or use of such items, shall be retrievable, and shall be sufficient to identify the specific requirements such as codes, standards, or specifications met by the purchased item. The documentary evidence may be records as specified in the procurement documents, or results of tests and inspections such as material analyses, source inspection, performance data, in-depth sampling, and receipt.

This procedure provides that items not passing receipt inspection (including incomplete or incorrect documentation) shall not be considered acceptable. Affected items shall be considered inoperable and reliance shall not be placed on such items to fulfill their intended safety functions until such discrepancies are dispositioned by proper authority. The controls specified for such nonconforming items shall include:

a. Identification of nonconforming items by tagging and, where practicable, segregation.

b. Control of further processing or installation until the disposition is determined and approved.

c. Disposition of the nonconforming item as "use-as-is," repair, rework to complete or correct the item to the specified requirements, or reject (scrap). The responsibility and authority for the disposition shall be defined. Repaired and reworked items shall be reinspected in accordance with applicable procedures or instructions.

d. Documentation of the satisfactory completion of the disposition. This includes documentation verifying the acceptability of nonconforming items that are dispositioned "use-as-is" or repair, and describing the deviation and as-built condition.

e. Notification to appropriate organizations to ensure that effected drawings or records reflect as-built conditions.

The procedure for procurement shall establish requirements for identification and control of received materials, parts, and components (including partially fabricated subassemblies) to ensure that only correct and acceptable items are used and installed. The procedure shall provide for:

a. Use of physical identification (such as marking or tagging) to the maximum extent practicable. Physical separation, procedural control, or other appropriate means shall be used when physical identification is not used or not sufficient. Identification can be on the item or on records traceable to the item.

b. Identification marking shall be clear and unambiguous, and shall employ methods and materials that will remain legible considering the handling, storage, and installation conditions expected. The marking must not affect the function of the item.

c. Markings shall be transferred to subdivided parts and shall not be obliterated or hidden by surface treatment or coatings unless other identification means are instituted.

d. When applicable codes, standards, or specifications require traceability of materials, parts, or components to specific inspection or test records, such traceability shall be provided.

e. Identification shall relate the item to applicable drawings, specifications, procurement documents, or other pertinent technical documents.

13.5.1.12 Procedure for Administration of the Plant Security Program

This procedure shall establish the administrative requirements and responsibilities for the plant security program that is developed to implement the industrial security plan and to supplement features and physical barriers designed to control access to the plant and, as appropriate, to vital areas within the plant. This procedure shall require that security procedures be distributed to appropriate personnel in accordance with current distribution lists, which reflect the confidentiality of security provisions, to ensure that outdated or inappropriate procedures are not used.

This procedure shall define the format and content of security procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose of the procedure.

c. Prerequisites, when needed, including those independent actions or procedures that must be completed prior to use of the security procedure.

d. References, when needed.

e. Precautions to alert the individual performing the task to those important measures that should be used to protect equipment and personnel, including the public, or to avoid abnormal or emergency conditions.

f. Procedure section. The procedure shall provide the steps needed to perform the task in the degree of detail necessary to ensure safety and correct performance without undue reliance on memory or direct supervision. Precautions and reference documents important to specific steps in the procedure shall be identified or included at those steps. Acceptance criteria, where appropriate, shall be specified. When appropriate, checkoff lists shall be included in or appended to the procedure.

To ensure feedback, security procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures.

13.5.1.13 Procedure for Preparation of Maintenance Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation and control of maintenance procedures that are developed to maintain safety-related equipment. Actual coordination and planning for maintenance actions shall be accomplished through the procedure for controlling in-plant work. The following aspects of maintenance work shall be addressed in this procedure:

a. The need to perform maintenance activities in a manner to ensure quality as specified in the original or approved modification design.

b. Specification and performance of appropriate inspections and tests to attain a suitable level of confidence that the maintenance has been properly performed.

c. Activities that ensure the quality of maintenance shall be performed in accordance with documented drawings or instructions that are appropriate to the circumstances, that conform to the design requirements, and which provide for documentation of activities where appropriate. Skills normally possessed by trained craft personnel may not require detailed step-by-step delineations in a written procedure.

d. The status of inspections and tests performed on items shall be indicated by the use of stamps, tags, labels, routing cards, procedural sign-offs, or other methods that provide traceability between the record and the item(s). Also, where necessary to preclude inadvertent bypassing of inspections and tests, items that have satisfactorily passed required inspections and tests shall be identified.

e. Special control requirements for emergency maintenance that must proceed immediately to correct a degraded safety condition and for which a procedure does not exist.

This procedure shall require that the following aspects of housekeeping and cleanliness control be considered in development of maintenance procedures:

a. Housekeeping provisions must recognize the special requirements involved with radiation zones and control areas.

b. Only proper materials, equipment, processes, and procedures may be used to ensure that the quality of plant equipment is not degraded.

c. Where necessary, special instructions for housekeeping and cleaning operations shall be provided and used.

d. Where needed to prevent contamination of safety systems with foreign materials, personnel and/or materials access control shall be established and a cleanliness inspection shall be performed immediately before closure. The Inspection results shall be documented.

This procedure shall require that appropriate inspections be established and implemented for maintenance actions in accordance with the following criteria:

a. Inspections, examinations, measurements, or tests shall be specified and performed for each work activity where necessary to ensure quality.

b. Inspections shall be performed by qualified individuals other than those who performed or directly supervised the activity being inspected. Inspection of certain activities (such as work functions associated with normal plant operations, routine maintenance, and certain technical services routinely assigned to the onsite operating organization) may be conducted by shift or plant staff supervisory personnel or by other qualified personnel not assigned first-line supervisory responsibility for conduct of the work.

c. Inspections shall be performed in accordance with written approved instructions, drawings or procedures that contain or reference the requirements, acceptance limits, and responsibilities for the inspection.

d. When specific hold points are required, they shall be indicated in appropriate documents.

e. When inspection techniques require specialized qualifications, inspection personnel shall meet the specified requirements for the technique involved.

f. If inspection is impossible or disadvantageous, indirect control by monitoring process methods, equipment, and personnel shall be provided. Both inspection and process monitoring shall be provided when control is inadequate without both.

g. Inspection instructions or procedures shall include or reference requirements for evaluation of inspection results when the nature of the results indicates that such an evaluation is needed to determine if the plant can be operated safely. Evaluation beyond that given by inspection-level personnel is not normally required for go/no-go and pass/fail type inspections.

h. Inspectors, data recorders, and those evaluating inspection results shall be identified and the records shall reflect implementation of the inspections and actions completed or planned to correct noted deficiencies.

This procedure shall require that special processes be identified and accomplished under controlled conditions in accordance with applicable codes, standards, specifications, criteria, or other special requirements. The procedure shall require that special processes be accomplished by qualified personnel using qualified procedures and equipment as provided in the specified requirements for the activity.

This procedure shall require testing to be performed as necessary to demonstrate that the item performs satisfactorily in service.

The testing shall be performed in accordance with written approved procedures or instructions that include or reference requirements and acceptance criteria defined in appropriate design documents.

This procedure shall define the format and content of maintenance procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References, including technical specifications, vendor documents, and drawings as appropriate to ensure the required quality of the work.

d. Prerequisites, including those independent actions or procedures that must be completed and plant conditions that must exist prior to use of the maintenance procedure. Prerequisites applicable to only certain sections of the procedure shall be so identified.

e. Precautions to alert the individual performing the task to those important measures that should be used to protect equipment and personnel, including the public, or to avoid an abnormal or emergency situation. Routine precautions that a trained craftsman is expected to take, such as normal electrical safety methods, do not need to be stated.

f. Procedure section. The procedure shall provide the steps needed to perform the task in the degree of detail necessary to ensure safety and correct performance without undue reliance on memory or direct supervision, and in consideration of the skills normally possessed by trained craft personnel. Precautions and reference documents important to specific steps in the procedure shall be identified or included at those steps. This section shall also provide instructions for performing and documenting the results of required inspections and tests and provides the

necessary acceptance criteria. When appropriate, checkoff lists shall be included in or appended to maintenance procedures.

g. Return-to-normal. This section shall contain instructions as to the mode or condition in which the equipment is placed after completion of the maintenance action.

Maintenance procedures will normally be prepared by members of the Nuclear Maintenance Division staff, knowledgeable in the areas which the procedures address; however, members of the station operating staff and organizations providing technical support, including consultants, may assist in procedure development.

Maintenance and preventive maintenance procedures are proven to be correct through their use. Because they are written for specific equipment, they are not subject to intersystem changes that may affect other procedure types, such as general plant procedures.

Maintenance and preventive maintenance procedures are reviewed when equipment modifications are made through the controlled modification program at the station. In addition, when indicated by the review of NRC IE Bulletins, Circulars and Notices, INPO documents and industry documents, the procedures are revised if necessary on a case-by-case basis.

To ensure feedback, maintenance procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. Procedures shall also require that maintenance procedures be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.14 Procedure for Preparation of Transient Response Implementation Plan Procedures and Severe Accident Management Plan Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of Transient Response Implementation Plan and the Severe Accident Management Plan procedures.

Transient Response Implementation Plan procedures are symptom oriented decision tree flow charts for operator actions based on recognition of critical symptoms and definition of actions to maintain key plant parameters within predetermined ranges. The Transient Response Implementation Plan and the Severe Accident Management Plan procedures have been developed from the BWROG EPG/SAGs.

To ensure feedback, TRIP and SAMP procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures.

Transient Response Implementation Plan and the Severe Accident Management Plan procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.15 Procedure for Preparation of Emergency Plan Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of emergency plan procedures that implement the emergency plan. This procedure shall establish the format and content of the emergency plan procedures.

Emergency plan procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.16 Procedure for Preparation of General Plant Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of general plant procedures that are written to provide integrated instructions for major plant evolutions such as plant startup or shutdown. This procedure shall establish the criteria for general plant procedures, such as:

a. Preparation of startup procedures including reactor startup from cold and hot conditions, generator synchronization, and recovery from reactor trips. These procedures shall implement the authority and responsibilities of reactor operators as defined in other administrative procedures.

b. Preparation of shutdown procedures including controlled shutdown and reactor trips to the establishment and maintenance of hot or cold shutdown conditions.

c. Preparation of procedures covering steady-state and load changing conditions and operations such as use of control rods, coolant flow control, and adjusting operating parameters.

This procedure shall establish the format and content of general plant procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References, including technical specifications, drawings, or procedures as applicable.

d. Prerequisites, including those independent actions or procedures that must be completed and plant conditions that must exist prior to use of the procedure. Prerequisites applicable to only certain sections of the procedure shall be so identified. Startup procedures shall require documentation of completion of prerequisites such as confirmation that necessary instruments are operable and properly set; that necessary valves are properly aligned; that necessary procedures, tests, and calibrations have been completed; and that required approvals have been obtained. Checkoff lists can be used for the purpose of defining and documenting completion of prerequisites.

e. Precautions, where necessary to alert the individual performing the task to those important measures that should be used to protect equipment and personnel, including the public, or to avoid an abnormal or emergency situation.

f. Procedure section. The procedure shall provide the sequence and steps needed to perform the task in the degree of detail necessary to ensure safety and correct

performance without undue reliance on memory or direct supervision. Cautionary notes applicable to specific steps shall be identified and included. System procedures or other detailed instructions not contained in the general plant procedure shall be referenced at the applicable steps. Where appropriate, check off lists shall be included in or appended to the procedure for the purpose of assisting the operator and/or confirming completion of major steps in the proper sequence. Limitations on parameters being controlled and appropriate corrective measures to return the parameter to the proper value shall be specified where appropriate.

To ensure feedback, general plant procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. When determined necessary by the PORC, tests shall be performed to confirm that significant changes to general plant procedures produce the expected results. General plant procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.17 Procedure for Preparation of System Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of system procedures for safety-related systems. The procedure shall require system procedures to address normally expected operations such as energizing, filling, venting, draining, starting up, shutting down, and changing modes of operation as applicable to the system. It is not the intent of these procedures to cover actions, operations, or system conditions that would be unique to a special operation, such as maintenance, and would be covered in a special procedure written at the time the operation is needed.

This procedure shall establish the format and content of system procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References including technical specifications, drawings, procedures, equipment manuals, and vendor documents as applicable.

d. Prerequisites, including those independent actions or procedures that must be completed and plant conditions that must exist prior to use of the procedure. Prerequisites applicable to only certain sections of the procedure shall be so identified.

e. Procedure section. This section shall provide the steps to perform the various operations in the degree of detail necessary to ensure safety and correct performance without undue reliance on memory or direct supervision, and in consideration of the skills possessed by trained operators. Cautionary notes applicable to specific steps shall be identified or included. Limitations on parameters being controlled and appropriate corrective measures to return the parameter to the proper value shall be specified where appropriate. Where appropriate, check off lists shall be included in or appended to the procedure.

To ensure feedback, system procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. When determined necessary by the PORC, tests shall be performed to confirm that significant changes to system procedures produce the expected results. System procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures shall be not used.

13.5.1.18 Procedure for Preparation of Operational Transient Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of operational transient procedures for the restoration of normal operating conditions following a perturbation. This procedure shall establish the format and content of operational transient procedures as follows:

a. Descriptive title and revision number.

b. Entry conditions.

c. Immediate operator actions. This section shall specify immediate actions for operation of controls to restore normal operating conditions.

d. Follow-up actions.

e. Verification of automatic actions. The automatic actions that are expected to occur as a result of the condition shall be identified.

To ensure feedback, operational transient procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. Operational transient procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.19 Procedure for Preparation of Alarm Response Cards

This procedure shall establish the administrative requirements and responsibilities for the preparation of individual alarm response cards. The procedure shall provide for preparation of individual alarm response cards to which operators refer. Alarm response cards shall be maintained in the control room and shall contain the following information:

a. Identification of the alarm

b. Alarm setpoint

c. Identification of the signal source instrument

d. Automatic actions that are expected to occur

e. Operator response (immediate and long-term)

To ensure feedback, safety-related alarm response cards are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of the alarm response card.

Unique numbers have been assigned to each control room alarm based on a sequential number for each annunciator window within a specific panel. Alarm response information is retrieved by identifying the alarm number and referring to the corresponding alarm card or procedure number.

13.5.1.20 Procedure for Preparation of Fuel Handling Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of fuel handling procedures that shall specify actions for core alterations, accountability for fuel, partial or complete refueling operations, receipt and shipment of fuel, and such specific procedures for each refueling outage as necessary to accomplish the required actions in a safe, efficient manner. This procedure shall establish the format and content of fuel handling procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References, including technical specifications, drawings, or procedures as applicable.

d. Prerequisites, including those independent actions or procedures that must be completed and plant conditions that must exist prior to use of the procedure. Prerequisites applicable to only certain sections of the procedure shall be so identified.

e. Precautions, where necessary, to alert the individual(s) performing the task to those important measures that should be used to protect equipment and personnel, including the public, or to avoid an abnormal or emergency situation.

f. Limitations and actions. Limitations on appropriate parameters and corrective action to return the parameter to the proper value or other appropriate action shall be specified.

g. Procedure section. The procedure shall provide the needed steps and requirements to perform the refueling task in the degree of detail necessary to ensure safety and correct performance without undue reliance on memory or direct supervision. Cautionary notes and references applicable to specific steps shall be identified and included. Where appropriate, check off lists shall be included in or appended to the procedure for the purpose of assisting the operator and/or confirming completion of appropriate steps.

This procedure shall require documentation of final fuel and component serial numbers and locations to be developed and maintained.

To ensure feedback, fuel handling procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. Fuel handling procedures shall be distributed to appropriate personnel in

accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.21 Procedure for Preparation of Health Physics Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of health physics procedures that implement the radiation protection program. This procedure shall require preparation of health physics procedures in the following areas:

a. Monitoring external and internal exposures of appropriate employees utilizing accepted techniques.

b. Routine radiation surveys of work areas.

c. Environmental monitoring within the scope of the operating staff responsibility.

d. Radiation monitoring of maintenance and special work activities.

e. Maintenance of records demonstrating the adequacy of measures taken to control radiation exposures of employees and other appropriate personnel.

f. Control, receipt, and shipment of radioactive material.

This procedure shall establish the format and content of health physics procedures as follows:

a. Descriptive title and revision number.

b. Statement of applicability or purpose.

c. References, including technical specifications, drawings, procedures, and operating manuals as applicable.

d. Apparatus, such as instruments or special equipment, as applicable.

e. Precautions, where necessary, to alert the individual performing the task to those important measures that should be used to protect equipment and personnel, including the public, or to avoid an abnormal or emergency situation. Routine precautions that a trained technician is expected to take need not be listed.

f. Procedure section. The procedure shall provide the needed steps to perform the task in the degree of detail necessary to ensure safety and correct performance without undue reliance on memory or direct supervision. Precautions and references important to specific steps in the procedure shall be identified and included at those steps. When appropriate, check off lists shall be included in or appended to health physics procedures.

Health Physics procedures will normally be prepared by members of the LGS Services organization, knowledgeable in Health Physics; however, organizations providing technical support and consultants may assist in procedure development. These procedures will be developed in consultation with the Director of the Radiation Protection Section and his staff.

The Health Physics procedures are primarily administrative and analytic. They represent the most efficient way to administer the Health Physics program. Many are based on either the type of equipment in use in the plant or, in the case of shipping radioactive materials, they are based on regulations. When the regulations change, the Health Physics procedures would be revised if needed. If new equipment for analysis is obtained, new procedures would be written for that new equipment.

To ensure feedback, health physics procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. Health physics procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.22 Procedure for Preparation of Chemistry Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of chemistry procedures that include chemical and radiochemical control activities. This procedure shall establish the format, content, and distribution requirements for chemistry procedures as described for health physics procedures.

13.5.1.23 Procedure for Temporary Changes to Approved Procedures

This procedure shall establish the administrative requirements and responsibilities for making temporary changes to approved procedures. The procedure shall provide that temporary changes, clearly not changing the intent of the approved procedure, shall be documented and approved by two members of the plant staff knowledgeable in the area(s) affected by the procedure. At least one of these individuals shall be a shift manager or a senior licensed operator on the unit affected. Temporary changes shall be incorporated in the next procedure revision if appropriate.

13.5.1.24 Procedure for Preparation of Off-Normal Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of off-normal procedures that are written to specify operator actions following an operator observation of an off-normal (nontransient) condition which requires immediate action to prevent degeneration of the existing condition. This procedure shall establish the format and content of off-normal procedures as follows:

a. Descriptive title and revision number.

b. Symptoms. This section shall include symptoms to aid in identifying or confirming the off-normal condition. Alarm conditions, parameter changes, and other observations shall be considered.

c. Operator actions. This section shall specify actions to be taken to identify, confirm, or correct the cause of the off-normal condition.

To ensure feedback, off-normal procedures are reviewed in accordance with performance enhancement procedures following unusual incidents that reflect adversely on the adequacy of these procedures. Off-normal procedures shall be distributed to appropriate personnel in accordance with current distribution lists to ensure that outdated or inappropriate procedures are not used.

13.5.1.25 Procedure for Preparation of Event Procedures and Special Event Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of event procedures and special event procedures that are written to specify operator actions following an operator observation of an event of an emergency or unusual nature.

13.5.1.25.1 Procedure for Preparation of Event Procedures

This Procedure establishes the format and content of event procedures as follows:

a. Confirming indications.
b. Initial actions.
c. Follow-up actions.

13.5.1.25.2 Procedure for Preparation of Special Event Procedures

This Procedure establishes the format and content of special event procedures as follows:

a. Purpose.
b. Symptoms. Symptoms shall be included to aid in the identification of the plant condition.
c. Immediate operator actions. This section shall specify action to be taken as a result of the identified condition.
d. Follow-up actions.

13.5.1.26 Procedure for Preparation of Radwaste Procedures

This procedure shall establish the administrative requirements and responsibilities for the preparation of radwaste procedures. This procedure shall require administration of the station radwaste program in the following areas:

a. Control handling, packaging, storage, and shipment of radioactive material.

b. Inspection, installation, and use of equipment used to process and package radwaste.

c. Processing and handling of radwaste using vendor equipment.

This procedure shall establish the format, content, and control of radwaste procedures.

13.5.1.27 Procedure for Fire Safe Shutdown Guides

This procedure shall establish the administrative requirements and responsibilities for the preparation of fire safe shutdown procedures that are written to identify available plant instrumentation and equipment which may be relied upon in the event of a fire in a specific fire area. This procedure shall establish the format and content of fire safe shutdown guides as follows:

a. Descriptive title and revision number.

b. Available Equipment. This section shall include a listing of protected equipment which is shown by analysis to be available following an exposure fire in a specific area.

c. Contingency Actions. This section shall specify operator actions to be taken to restore essential equipment and/or system functions which have the potential of being affected by a fire in a specific area.

13.5.2 OPERATING AND MAINTENANCE PROCEDURES

13.5.2.1 Control Room Operating Procedures

Operating procedures which are primarily performed by licensed operators in the control room include general plant procedures, system procedures, operational transient procedures, off-normal procedures, alarm response cards, Transient Response Implementation Plan procedures, event procedures, special event procedures, and fire safe shutdown guides. The format and content of these classes of procedures are described in Section 13.5.1. General plant procedures and system procedures will be developed to cover the activities listed in sections 2 and 4, respectively, of appendix A to Regulatory Guide 1.33 (Rev 2). Examples of the types of activities covered by operating procedures or the anticipated procedure titles are listed below:

General Plant Procedures: Reactor startup from cold conditions; reactor startup from hot conditions; turbine-generator startup; power operation and monitoring; plant shutdown to hot standby; shutdown from hot standby to cold conditions; preparation for refueling operations.

System Procedures: Recirculation system; reactor water cleanup system; residual heat removal system; high pressure coolant injection system; core spray system; reactor core isolation cooling system; standby liquid control system; fuel pool cooling system; containment; control rod drive systems; reactor protection system; main steam system; turbine-generator; condensate and feedwater systems; circulating water system; cooling towers; cooling water systems; main generator; plant electrical systems; dc systems; diesel generators; radwaste systems; solid radwaste processing; standby gas treatment system; heating, ventilation, and air conditioning systems; fire protection systems; nuclear instrumentation.

Operational Transient Procedures: Reactor low level; high drywell pressure; reactor high pressure; positive reactivity insertion; scram discharge volume high level; condenser low vacuum; reactor high level; recirculation pump trip; and inadvertent opening of a relief valve.

Off-Normal Procedures: Failure of a jet pump; loss of isolated phase bus cooling; air ejector discharge high radiation; offgas stack high radiation; control rod uncoupled; stuck control rod; loss of CRD regulating function; low scram air header pressure; total loss of the SRM, IRM, or APRM systems; loss of primary containment; loss of secondary containment; loss of stator cooling; main steam line high radiation; and loss of uninterruptible ac power.

Transient Response Implementation Plan Procedures: Reactor pressure vessel control; primary containment control; secondary containment control; radioactive release control; alternate level pressure control; emergency depressurization; reactor pressure vessel flooding; anticipated transient without scram pressure vessel control; reactor pressure vessel control OPCON 4; containment and radioactivity release control OPCON 4; reactor pressure vessel flooding OPCON 4; decay heat control OPCON 5; and containment and radioactivity release control OPCON 5.

Severe Accident Management Plan Procedures: Reactor pressure vessel control; containment and radioactive release control; reactor pressure vessel control OPCON 5; containment radioactive release control (OPCON 5).

Event procedures and Special Event Procedures: Earthquake; flood; shutdown from outside the control room; control room enclosure toxic gas; oil spills; and fire.

Licensed reactor operators and senior reactor operators are required to know the immediate operator actions in operational transient procedures, event procedures, special event procedures, and the entry condition of Transient Response Implementation Plan procedures. When entry conditions for Transient Response Implementation Plan procedures are met, operator actions are directed by the Transient Response Implementation Plan procedure as a priority over actions described in other procedures.

Fire Safe Shutdown Guides: Contingency steps to operate plant equipment.

13.5.2.2 Control of Unit 2 Construction Activities During Unit 1 Operation

Refer to Section 1.2.5

13.5.2.3 Additional Operating and Maintenance Procedures

In addition to operating procedures related primarily to control room operations, procedures shall be issued to control other plant activities. These procedures shall include emergency plan procedures, fuel handling procedures, chemistry procedures, health physics procedures, maintenance procedures, security procedures, surveillance test procedures, and preventive maintenance procedures. The types of activities covered by these procedures are listed below. The format and content of these procedures are described in Section 13.5.1.

Fuel Handling Procedures: New fuel inspection; irradiated fuel inspection; installation, removal, and transfer of fuel assemblies; installation and removal of control rods; core sipping; installation and removal of source holder; installation and removal of incore detectors.

Health Physics Procedures: Radiation exposure limits; dosimetry requirements; personnel exposure records; radiation work permit; radiation control area classification; radiation/contamination surveys; decontamination; shipment of radioactive material; control and accountability of radioactive material; operation and calibration of radiation monitoring equipment; airborne radioactivity monitoring; various analytical procedures; laboratory calibration procedures.

Security Procedures: Response to industrial security threats; civil disturbance; communications; security force duties and responsibilities; receipt control; key control; guard patrols; personnel identification; access control; vehicle traffic and parking; testing and maintenance of security systems; record keeping; visitor control.

Chemistry Procedures: Sampling reactor water; sampling reactor steam; gaseous samples; sampling condensate storage tank; various analytical procedures; control of radioactive calibration sources; laboratory calibration procedures.

Maintenance Procedures: Reactor recirculation pump seal overhaul; control rod drive repair; hydraulic control unit repair; control rod drive O-ring replacement; removal and replacement of drywell head; removal and replacement of reactor vessel head; removal and replacement of steam dryer; nuclear instrumentation removal and replacement; offgas filter maintenance; motor operator adjustment; standby liquid control explosive valve replacement.

Emergency Plan Procedures: Radiological surveys and monitoring; rescue operations; fire fighting; first aid; decontamination; personnel accountability; communications, repairs and damage control; record keeping; organization, duties.

13.5.3 OPERATIONS TECHNICAL REQUIREMENTS MANUAL (TRM)

The Technical Requirements Manual (TRM) contains the technical requirements and/or supporting information (e.g., tables and component lists) which were once contained in the LGS Technical Specifications (TS) (i.e., Appendix A of the LGS Facility Operating License). Removal of the TS and information was approved by the NRC through individual TS amendments. The TRM is intended to provide operational guidance and requirements for various plant conditions, actions, and testing similar to TS, however, these requirements are in accordance with licensing commitments. Future changes to the relocated requirements and supporting information are processed in accordance with Section 6.0 of the LGS TS, and are subject to a 10CFR50.59 Review.

The TRM is comprised of an index, the individual specification and bases. The manual is intended to provide a single location for the relocated TS items as a convenience for operations and other station personnel. The individual sections of the TRM contain the relocated licensing commitments which are subject to the provisions of 10CFR50.59 as described above.

In accordance with NEI 98-03, Revision 1 (Reference 13.5-1), as endorsed by NRC Regulatory Guide 1.181 (Reference 13.5-2), the TRM is treated in a manner consistent with procedures fully or partially described in the UFSAR, and therefore, is controlled as a procedure in accordance with the applicable established procedure process. For the purposes of 10 CFR 50.59, information presented in the TRM is considered to be information described in the UFSAR, and therefore, is to be treated at the same level as information presented in the UFSAR. (Reference 13.5-3)

13.5.4 SURVEILLANCE FREQUENCY CONTROL PROGRAM (SFCP)

The Surveillance Frequency Control Program (SFCP) was implemented as a result of NRC issuance of Amendment Nos. 186 and 147, dated September 28, 2006, to the Limerick Generating Station (LGS), Unit 1 and Unit 2, Technical Specifications (TS), respectively. Administrative controls for the SFCP were added to the Administrative Controls section of the LGS TS for both units, and are implemented through administrative procedures. The SFCP ensures that surveillance requirements specified in the TS are performed at intervals sufficient to assure the associated TS Limiting Conditions for Operation are met. The SFCP contains a list of frequencies of those surveillance requirements for which the frequency is controlled by the program and changes to the frequencies listed in the SFCP are made in accordance with NEI 04-01, "Risk-Informed Method for Control of Surveillance Frequencies," Revision 0.

13.5.5 RISK INFORMED CATEGORIZATION AND TREATMENT

13.5.5.1 Introduction

Limerick Generating Station has implemented 10 CFR 50.69 using the processes for categorization of Risk-Informed Safety Class (RISC)-1, RISC-2, RISC- 3, and RISC-4 structures, systems, and components (SSCs) using:

- Probabilistic Risk Assessment (PRA) models to evaluate risk associated with internal events, including internal flooding, and internal fire; the shutdown safety assessment process to assess shutdown risk;
- The Arkansas Nuclear One, Unit 2 (ANO-2) passive categorization method to assess passive component risk for Class 2 and Class 3 SSCs and their associated supports;

- The results of non-PRA evaluations that are based on the IPEEE Screening Assessment for External Hazards, i.e., seismic margin analysis (SMA) to evaluate seismic risk, and a screening of other external hazards updated using the external hazard screening significance process identified in ASME/ANS PRA Standard RA-Sa-2009.

13.5.5.2 SSC Categorization

As outlined in the Safety Evaluation Report (SER) for License Amendments 230 and 193 to Renewed Facility Operating License Nos. NPF-39 and NPF-85, respectively (Reference 13.5-4), Limerick will use the methodology described in 13.5.5.1.

10 CFR 50.69(f)(2) requires updating the UFSAR to reflect which systems have been categorized. Table 13.5-1 is revised as part of the periodic UFSAR update to reflect systems that have been categorized. 10 CFR 50.69 system boundaries are defined in the associated System Categorization Document (Reference 13.5-5).

13.5.5.3 SSC Treatment

13.5.5.3.1 Treatment of Component Categories

The programs or processes that implement the special treatment requirements are revised to recognize that the special treatments no longer apply to RISC-3 and RISC-4 SSCs. The programs or processes either allow continued application of the special treatments or acceptable alternative treatments, as applicable, to provide reasonable confidence that these SSCs would perform their safety-related function under design basis conditions.

For those components that are categorized as Low Safety Significant, 10 CFR 50.69(b)(1) allows compliance with alternative requirements in lieu of the following special treatment requirements.

(i) 10 CFR Part 21.

(ii) The portion of 10 CFR 50.46a(b) that imposes requirements to conform to Appendix B to 10 CFR Part 50.

(iii) 10 CFR 50.49.

(iv) 10 CFR 50.55(e).

(v) The in-service testing requirements in 10 CFR 50.55a(f): the in-service inspection and repair, and replacement (with the exception of fracture toughness), requirements for ASME Class 2 and Class 3 SSCs in 10 CFR 50.55a(g); and the electrical component quality and qualification requirements in Section 4.3 and 4.4 of IEEE 279, and Sections 5.3 and 5.4 of IEEE 603-1991, as incorporated by reference in 10 CFR 50.55a(h).

(vi) 10 CFR 50.65, except for paragraph (a)(4).

(vii) 10 CFR 50.72.

(viii) 10 CFR 50.73.

(ix) Appendix B to 10 CFR Part 50.

(x) The Type B and Type C leakage testing requirements in both Options A and B of Appendix J to 10 CFR Part 50, for penetrations and valves meeting the following criteria:

(A) Containment penetrations that are either 1-in. nominal size or less, or continuously pressurized.

(B) Containment isolation valves that meet one or more of the following criteria:

(1) The valve is required to be open under accident conditions to prevent or mitigate core damage events;

(2) The valve is normally closed and in a physically closed, water-filled system;

(3) The valve is in a physically closed system whose piping pressure rating exceeds the containment design pressure rating and is not connected to the reactor coolant pressure boundary; or

(4) The valve is 1-in. nominal size or less.

(xi) Appendix A to Part 100, Sections Vl(a)(1) and Vl(a)(2), to the extent that these regulations require qualification testing and specific engineering methods to demonstrate that SSCs are designed to withstand the Safe Shutdown Earthquake and Operating Basis Earthquake.

Performance monitoring is being performed on all RISC-1, RISC-2, RISC-3, and RISC-4 SSCs and the station adjusts, as necessary, to either the categorization or treatment process so that the categorization process and results are maintained valid.

13.5.5.3.2 Enhanced Treatment of RISC-2 SSCs

The 10 CFR 50.69 procedures and 10 CFR 50.69(d)(1) require that RISC-2 SSCs perform their functions consistent with the categorization process assumptions by evaluating treatment being applied to these SSCs to ensure that it supports the key assumptions in the categorization process that relate to their assumed performance.

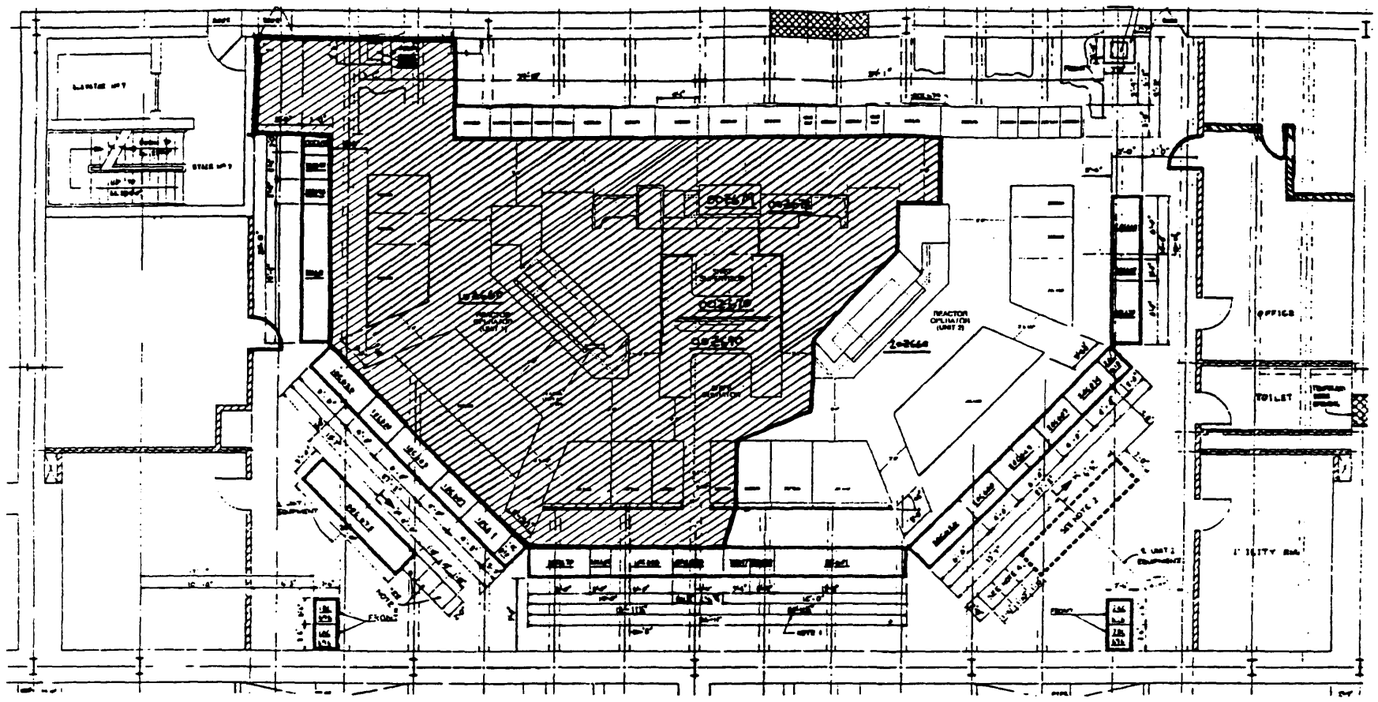
13.6 INDUSTRIAL SECURITY

A physical security plan that describes a comprehensive program of physical protection for the facility has been submitted as a separate part of the license application. The physical security plan is withheld from public disclosure pursuant to 10CFR2.790(d), "Rules of Practice." Implementation of the plan provides protection with high assurance against successful industrial sabotage as described in 10CFR73.55(a) "General Performance Requirements."



The plan addresses the following: physical security organization, physical barriers, access requirements, detection aids, communication requirements, testing and maintenance, and response requirements. Implementation of the plan becomes effective at the time of fuel loading.

CHAPTER 14 - INITIAL TEST PROGRAM

14.1 SPECIFIC INFORMATION INCLUDED IN THE PSAR

This section is not applicable to Chapter 14 of the UFSAR.

14.2 SPECIFIC INFORMATION INCLUDED IN THE FSAR

14.2.1 SUMMARY OF TEST PROGRAM AND OBJECTIVES

As construction of the systems/components is completed, the construction organization relinquishes jurisdictional control of these systems/components through a formal turnover to the licensee. Eventually all plant systems/components are turned over to the licensee.

The initial test program for each unit encompasses the scope of events that commences with system/component turnover and terminates with the completion of power ascension testing. The initial test program is conducted in two separate and sequential subprograms: the preoperational test program and the startup test program. At the conclusion of these subprograms, each unit is ready for normal power operation. Testing during the preoperational and startup test programs is accomplished in four distinct and sequential major phases.

Major Test Phases - Initial Test Program

a. Phase I - Preoperational Testing

b. Phase II - Initial Fuel Loading and Zero Power Testing

c. Phase III - Low Power Testing

d. Phase IV - Power Ascension Testing

Preoperational testing is completed during the preoperational test program. Initial fuel loading and zero power testing, low power testing, and power ascension testing are completed during the startup test program. See Figure 14.2-1 for a pictorial representation of the Unit 1 and Unit 2 initial test programs.

14.2.1.1 Preoperational Test Program

The preoperational test program is defined as that part of the initial test program that commences with system/component turnover, and terminates with the beginning of unit fuel loading. Formal tests, denoted as preoperational tests (Table 14.2-1), are conducted during this program. These tests demonstrate, to the extent practicable, the capability of structures, systems, and components to meet performance requirements, and to satisfy design requirements.

To the extent practicable, the objectives of the preoperational test program are to:

a. Verify the adequacy of plant design.

b. Verify that plant construction is in accordance with design.

c. Demonstrate proper system/component response to postulated accidents and malfunctions.

d. Confirm the adequacy of plant operating and emergency procedures.

e. Familiarize the plant staff operating, technical, and maintenance personnel with the plant operation.

14.2.1.2 Startup Test Program

The startup test program is defined as that part of the initial test program that commences with the start of nuclear fuel loading, and terminates with the completion of power ascension testing. Formal tests, denoted as startup tests (Table 14.2-2), are conducted during this program. Main steam turbine trip test for Unit 2 (ref. Startup test STP-36) at 100% power level will be performed during commercial operation of that unit. These tests confirm the design bases and demonstrate, to the extent practicable, that the plant operates and responds to anticipated transients and to postulated accidents as designed. Startup testing is sequenced to ensure that the safety of the plant is not dependent upon the performance of untested structures, systems, or components.

The objectives of the startup test program are to:

a. Accomplish a controlled, orderly, and safe initial core loading.

b. Accomplish a controlled, orderly, and safe initial criticality.

c. Conduct low power testing sufficient to ensure that design parameters are satisfied, and that safety analysis assumptions are correct or conservative.

d. Perform a controlled, orderly, and safe power ascension with requisite testing, terminating at plant rated conditions.

14.2.2 ORGANIZATION AND STAFFING

The LGS Plant Manager has overall responsibility for the initial test program. Two basic organizational units, the plant staff and the startup group, jointly conduct the different phases of the test program. Test personnel for the preoperational and startup testing will be assigned to the site in a time frame in advance of the need determined by the latest revision of the startup schedule. Sufficient numbers of qualified people will be assigned to support the startup schedule from the licensee, Bechtel Power Corporation, or vendors. In addition to these basic organizational units, the LGS Plant Manager is assisted by two review organizations: the Plant Operations Review Committee, and the Test Review Board. The organization, authority, responsibility, and degree of participation of each of these organizational units during the initial test program are described in the following sections.

14.2.2.1 Plant Staff

The plant staff consists of the permanent onsite licensee personnel responsible for the safe operation and proper maintenance of the plant. Chapter 13 describes the plant staff organization as it exists during the initial test program. Chapter 13 also establishes responsibilities and reporting relationships for principal plant staff supervisory personnel.

The plant staff is utilized, to the fullest extent practicable, during the initial test program. Specific responsibilities of the plant staff during the initial test program include:

a. Performing selected preventive and corrective maintenance.

b. Operating plant equipment.

c. Calibrating instruments, meters, and relays.

d. Performing chemical and radiological inspections and tests.

e. Providing selected required replacement and spare parts.

f. Providing the operator, technician, and appropriate maintenance support to the startup group.

g. Ensuring that vendors, consultants, and other temporary personnel assisting the plant staff, work in accordance with established procedures.

h. Confirming the adequacy of plant operating and emergency procedures.

i. Authorizing and ensuring proper documentation, identification, and restoration of temporary modifications made during the startup test program (for selected systems/components, this function may be assumed by the plant staff during the preoperational test program).

j. Authorizing and monitoring rework, modification, and maintenance during the startup test program (for selected systems/components, this function may be assumed by the plant staff during the preoperational test program).

k. Authorizing and monitoring the performance of testing during the startup test program.

l. Coordinating preparation, review, and approval of startup test procedures.

m. Coordinating performance of startup testing.

n. Coordinating review and approval of startup test results.

o. Planning and scheduling startup test program activities.

14.2.2.2 Startup Group - Organization and Responsibilities

The startup group is a temporary organizational unit established to augment the plant staff during the initial test program; their primary role is during the preoperational test program. The startup group is comprised of individuals from various organizations (Bechtel Startup, GE, the licensee, and others). Figure 14.2-2 shows the organizational structure of the startup group during the preoperational test phase, and the reporting relationships of the major constituents of the startup group. The number and timing of personnel assigned to the startup group are field determined to allow the testing effort of the initial test program to meet projected fuel load and commercial operation dates. The responsibility of principal startup group supervisory personnel, the structure of the basic constituents comprising the group, and the responsibilities delegated to the group are described in the following sections.

14.2.2.2.1 LGS Unit 2 Startup Manager

The LGS Unit 2 Startup Manager has overall responsibility for implementation of the postconstruction electrical and instrument testing, the development and implementation of the

preoperational testing program (Phase I of the initial test program), and the development of the Unit 2 power ascension program (Phases II, III, and IV of the initial testing program). The Startup Manager reports to the Vice President - LGS and coordinates with the LGS Plant Manager to ensure that the safety and reliability of Unit 1 are not compromised by Unit 2 startup activities and that the adequacy and quality of the Unit 2 startup programs prove Unit 2 operability in accordance with design criteria.

The minimum qualifications for the LGS Unit 2 Startup Manager are one of the following:

a. Graduate of a 4 year accredited engineering or science college or university, plus 6 years of experience in design, testing, or operation of power plants, nuclear facilities, or similar industrial installations. At least 3 years of this experience should be associated with nuclear facilities or the individual must have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.

b. High school graduate, plus 15 years of experience in testing or operation (or both) of power plants, nuclear facilities, or similar industrial installations. At least 6 years of this experience should be associated with nuclear facilities or the individual must have training sufficient to acquaint him thoroughly with the safety aspects of nuclear facilities.

14.2.2.2.2 LGS Startup Superintendent - Support

The LGS Startup Superintendent - Support has overall responsibility for supervising the conduct of postconstruction electrical and instrument testing. The LGS Startup Superintendent - Support reports to the LGS Unit 2 Startup Manager on matters pertaining to postconstruction testing. The minimum qualifications for the LGS Unit 2 Startup Superintendent - Support are one of the following:

a. Graduate of a 4 year accredited engineering or science college or university, plus 5 years of experience in design, testing, or operation of power plants, nuclear facilities, or similar industrial installations. At least 2 years of this experience should be associated with nuclear facilities; or the individual must have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.

b. High school graduate, plus 10 years of experience in testing or operation (or both) of power plants, nuclear facilities, or similar industrial installations. At least 2 years of this experience should be associated with nuclear facilities or the individual must have training sufficient to acquaint him thoroughly with the safety aspects of nuclear facilities.

14.2.2.2.3 LGS Startup Superintendent - Operations

The LGS Startup Superintendent - Operations has overall responsibility for supervising the conduct of the startup group. The LGS Startup Superintendent - Operations reports to the LGS Unit 2 Startup Manager on matters pertaining to the initial test program.

The minimum qualifications for the LGS Startup Superintendent - Operations are one of the following:

a. Graduate of a 4 year accredited engineering or science college or university, plus 5 years of experience in design, testing, or operation of power plants, nuclear facilities,

or similar industrial installations. At least 2 years of this experience should be associated with nuclear facilities; or the individual must have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.

b. High school graduate, plus 10 years of experience in testing or operation (or both) of power plants, nuclear facilities, or similar industrial installations. At least 2 years of this experience should be associated with nuclear facilities; or the individual must have training sufficient to acquaint him thoroughly with the safety aspects of nuclear facilities.

14.2.2.2.4 Project Startup Engineer

The Project Startup Engineer performs a line function and reports to the LGS Startup Superintendent - Operations. He assists the LGS Startup Superintendent - Operations in supervising and directing startup personnel during the applicable part of the initial test program. In the absence of the LGS Startup Superintendent - Operations, the Project Startup Engineer assumes the responsibilities of the LGS Startup Superintendent - Operations.

Minimum qualifications for the Project Startup Engineer are the same as those for the LGS Startup Superintendent - Operations.

14.2.2.2.5 Assistant Project Startup Engineer

The Assistant Project Startup Engineer performs a line function, and reports directly to the Project Startup Engineer. The Assistant Project Startup Engineer is specifically responsible for supervision of systems group leaders. Minimum qualifications for the Assistant Project Startup Engineer are one of the following:

a. High school graduate or equivalent, and 4 years of power plant experience.

b. Graduate of 4 year accredited engineering or science college, and 2 years of power plant experience.

14.2.2.2.6 Technical Staff Specialists

Technical Staff Specialists perform a staff function and report to the Project Startup Engineer. Technical Staff Specialists function as advisors to those individuals who have direct system responsibility. Technical Staff Specialists may have a secondary function within the startup group.

Typical Technical Staff Specialists assigned to the startup group might include:

a. Discipline specialists (mechanical, electrical, instrument and control, nuclear, etc.)

b. NSSS specialist

c. Turbine-generator specialist

14.2.2.2.7 Administrative Staff Specialists

Administrative Staff Specialists perform a staff function, and report to the Project Startup Engineer. Administrative Staff Specialists may have a secondary function within the startup group.

Typical Administrative Staff Specialists assigned to the startup group might include:

a. Planning and scheduling specialist

b. Startup quality engineer

c. Startup/operations coordinator

d. Startup/construction coordinator

e. Startup test coordinator

f. Startup administrative (clerical) coordinator

14.2.2.2.8 Systems Group Leaders

Systems group leaders perform a line function, and report to the assistant project startup engineer. Group leaders are assigned a staff of system startup engineers, and leaders have overall responsibility for assigned systems.

Minimum qualifications for a systems group leader are one of the following:

a. Graduate of 4 year accredited engineering or science college, and 2 years of power plant experience.

b. High school graduate or equivalent, and 4 years of power plant experience.

14.2.2.2.9 Startup Responsibilities

Specific responsibilities delegated to the startup group during the initial test program include:

a. Coordinating system/component turnovers.

b. Coordinating initial instrument, relay, and meter calibration.

c. Coordinating initial digital and analog control loop checkout.

d. Coordinating equipment initial operation.

e. Coordinating system cleanliness verification after turnover.

f. Ensuring that assigned vendors and other consultants assisting the startup group work in accordance with approved procedures.

g. Authorizing and ensuring proper identification, documentation, and restoration of temporary modifications made during the preoperational test program (for selected systems/components this responsibility may be assumed by the plant staff prior to the conclusion of the preoperational test program).

h. Documenting and reporting design problems identified during the initial test program, until licensee permanent plant procedures are implemented to perform this function, at which time this becomes a plant staff responsibility.

i. Documenting and reporting construction problems identified during the initial test program, until licensee permanent plant procedures are implemented to perform this function, at which time this becomes a plant staff responsibility.

j. Authorizing and monitoring rework, modification, and maintenance during the preoperational test program (for selected systems/components this responsibility may be assumed by the plant staff prior to conclusion of the preoperational test program).

k. Coordinating preparation, review, and approval of preoperational test procedures.

l. Coordinating performance of preoperational testing.

m. Coordinating review and approval of preoperational test results.

n. Planning and scheduling preoperational test program activities.

14.2.2.3 Plant Operations Review Committee

The PORC consists of the individuals assigned independent review responsibility per the requirements of Chapter 13. The responsibilities and reporting relationships of PORC members are also described in Chapter 13. During the initial test program, additional PORC responsibilities include reviewing startup test procedures prior to testing and reviewing startup test results. Based upon their review findings, PORC recommends to the plant manager whether the procedure and/or procedure results are acceptable or not.

14.2.2.4 Test Review Board

The TRB is a temporary review organization established specifically for the initial test program. TRB members may consist of individuals of various organizations Bechtel Startup, the licensee, PECo, or others. Figure 14.2-3 shows the organization and structure of the TRB. The TRB is responsible for reviewing preoperational test procedures prior to testing, and for reviewing preoperational test results. Based upon its review findings, the TRB recommends to the plant manager whether the procedure and/or procedure results are acceptable or not.

The LGS Plant Manager is responsible for assigning individuals to the TRB. These assignments may be either permanent or temporary. The TRB chairman is responsible for the conduct of the TRB, and reports directly to the LGS Plant Manager.

Minimum qualifications for the TRB chairman are the same as those for the LGS Startup Superintendent, identified in Section 14.2.2.2.3.

Minimum qualifications for TRB members are the same as those for the Assistant Project Startup Engineer, identified in Section 14.2.2.2.5.

14.2.3 TEST PROCEDURES

The initial test program is conducted in accordance with detailed preoperational and startup test procedures. The licensee maintains overall responsibility for test procedure preparation, review, and approval. These activities are completed as described in the following sections.

14.2.3.1 Procedure Preparation

Test procedure drafts are initially prepared by designated organizations (Bechtel Startup, GE, the licensee, or others) in accordance with the standard format of Figure 14.2-4. Specific acceptance criteria are developed using reference material such as plant Technical Specifications, FSAR Chapter 15 accident analyses, other FSAR sections, vendor topical reports, vendor technical documents, Bechtel Power Corporation design diagrams, instrument and equipment indexes, and applicable regulatory guides and codes. These specific criteria are listed in each test procedure, followed by the reference documents from which they were obtained. The completed drafts are then reviewed by cognizant design organization representatives, to ensure that the test procedure objectives and acceptance criteria are consistent with current design document requirements. Review comments are resolved between the writing organization and the cognizant design organization representative. Upon satisfactory resolution of comments, subsequent changes to test procedure objectives or acceptance criteria are based on changes to approved design documents or design organization concurrence.

14.2.3.2 Procedure Review and Approval

Following initial preparation, test procedures are processed through a formal review and approval cycle. The LGS Unit 2 Startup Manager or his designee is responsible for coordinating this process and for resolving review comments.

Preoperational test procedures are reviewed by the TRB, and startup test procedures are reviewed by the PORC. Individuals who are designated review responsibility are responsible for reviewing test procedures for accuracy, technical content, conformance with FSAR requirements, and compatibility with approved design documents. Additional specific review responsibilities include the following:

a. Verifying that procedure references have been updated to latest revisions.

b. Verifying that the procedure has been revised to incorporate design changes.

c. Verifying procedure compatibility with field installation of equipment.

d. Verifying procedure conformance with FSAR amendments, environmental Technical Specifications, and plant operating Technical Specifications.

e. Verifying that procedures reflect reactor operating and testing experiences of similar power plants.

Upon completion of initial reviews and inclusion of required changes, test procedures are submitted to the LGS Plant Manager for final approval.

Test procedure revisions and procedure modifications are processed through the same review and approval cycle.

14.2.4 CONDUCT OF TEST PROGRAM

The administrative controls that govern conduct of the plant staff and of the startup group during the initial test program are specified by administrative procedures. These administrative procedures are licensee controlled and approved documents. Administrative procedures define tasks to be performed, prescribe methods, and assign responsibilities for performing them.

The administrative procedures governing conduct of the startup group are contained in the Startup Administrative Manual. These procedures do not establish the administrative controls of other project groups or organizations, except as they interface with the startup group. Each procedure of the Startup Administrative Manual is approved for use by the appropriate authorities prior to starting the initial test program.

Station administrative procedures govern the conduct of Phases II, III, and IV of the initial test program.

The administrative procedures governing conduct of the plant staff are described in Chapter 13. The preparation, review, and approval of these procedures are also described in Chapter 13. Sufficient time is provided for procedures to be available for use, prior to the time they are required to be implemented.

14.2.4.1 Test Performance

Testing performed during the initial test program is in accordance with approved test procedures. The method for preparing, reviewing, and approving test procedures is detailed in Section 14.2.3. Before testing, a test director is assigned to each procedure. The test director is the individual designated as being responsible for coordinating test performance. Test directors are assigned from the startup group or the vendor-augmented plant staff by the LGS Plant Manager or his designee.

Specific responsibilities of the test director include, but are not limited to:

a. Verifying test prerequisites are complete and properly documented, except as provided by Section 14.2.4.2.

b. Ensuring that required test apparatus and/or equipment is available.

c. Documenting test performance on the official test copy of the procedure.

d. Ensuring that proper precautions are observed during testing.

e. Adhering to the detailed instructions of the approved procedure, except as provided by Section 14.2.4.3.

f. Ensuring that test personnel have been properly briefed.

g. Documenting and reporting test exceptions.

Minimum qualifications for a test director performing preoperational tests are one of the following:

a. High school graduate or equivalent, and 1 year of power plant or industrial experience.

b. Graduate of a 4 year accredited engineering or science college.

Minimum qualifications for a test director performing startup tests are one of the following:

a. High school graduate or equivalent, and 4 years of power plant experience.

b. Graduate of a 4 year accredited engineering or science college, and 1 year of power plant experience.

The plant operating staff is responsible for the safe and proper operation of equipment during testing. Should an unsafe condition arise, the plant operating staff takes whatever action is necessary including, but not limited to, stopping the test in order to restore safe plant conditions. During startup testing, the plant operating staff is specifically responsible for compliance with operating technical specifications, compliance with the provisions of the operating license, and authorization of testing.

14.2.4.2 Test Prerequisites

Specific test prerequisites are identified in each preoperational and startup test procedure. Figure 14.2-8 depicts some of the typical prerequisites that are included in each preoperational test procedure as applicable to the system being tested. The test director verifies that each prerequisite is completed and properly documented prior to sign-off in the official test copy of the procedure. If a prerequisite cannot be satisfied, the test director may waive the prerequisite to expedite testing. Waiving of a prerequisite is permissible only if the prerequisite has a minimal and definable effect on the test.

Waiving of a prerequisite constitutes a procedure modification; the test director is responsible for complying with the requirements of Section 14.2.4.3.

14.2.4.3 Procedure Modifications

Tests are intended to be conducted in accordance with the approved procedure; but, if necessary, a procedure may be modified to complete testing. Such modifications are documented within the text of the procedure and on a special change form for major modifications. The test director marks up the official test copy of the procedure to clearly delineate the required change, and initials and dates the change. For modifications to startup test procedures, the change is also initialed and dated by a licensed senior operator. In addition for major modifications, the test director prepares and processes a change form. The change form becomes an attachment to the official test copy of the procedure. Review and approval requirements for change forms are the same as for the original procedure. Preparation, review, and approval activities are accomplished before or after the performance of associated testing based on one of the following criteria:

a. For minor modifications that obviously preserve the intent of the test, the change is documented within the text of the procedure prior to performance of that part of the test and is reviewed after the performance of associated testing with the test results.

b. For major modifications that alter the intent of the test, the change form is processed before performance of the associated testing.

14.2.4.4 Design Problems

In the process of checkout, preliminary operation, and testing, design problems may be encountered. All such design problems are formally documented and reported to appropriate design organization representatives for resolution. Typical design problems include:

a. Errors or discrepancies in approved project design documents.

b. Items that represent a potential hazard to personnel safety.

c. Proposed facility modifications.

d. Failure of a tested system or component to satisfy design requirements or acceptance criteria.

e. Operating problems where operation is in accordance with approved procedures.

Design response for all such reported items is mandatory. Should the response require a facility modification, the appropriate design documents are revised and issued to the field. Field implementation of the modification is subsequently controlled in accordance with Section 14.2.4.5.

14.2.4.5 Control of Rework, Modifications, and Repairs

A comprehensive listing of outstanding work items is maintained for each system during the initial test program. This listing is maintained to ensure that identified work is performed. Typical listed work items include:

a. Incomplete or incorrect equipment installation

b. Required equipment repairs (corrective maintenance)

c. Approved facility modifications

d. New or additional construction

This work is performed by the construction organization, the plant maintenance staff, or a contract organization in accordance with approved procedures. In any event, in order to maintain the required controls, formal authorization is required to perform the work. This authorization is obtained from the startup group, or from the plant staff through the implementation of appropriate administrative procedures. These administrative procedures, in addition to authorizing performance of the work, specifically identify any retesting required as a result of the work, and document completion of both the work and the retesting. Closure of the associated work list item also requires completion of both the specified work and the specified retesting.

14.2.4.6 Major Test Phase Prerequisites

Completion of each major phase of the initial test program is a prerequisite to starting the succeeding phase. Section 14.2.11 identifies the specific testing scheduled to be conducted during each of the phases. A phase is considered complete only after the results of required testing are evaluated, reviewed, and approved per the requirements of Section 14.2.5.

14.2.5 REVIEW, EVALUATION, AND APPROVAL OF TEST RESULTS

The licensee has overall responsibility for review, evaluation, and approval of test results. The following sections establish the requirements for review, evaluation, and approval of individual test results, major test phase test results, and power ascension test results.

14.2.5.1 Individual Test Results

Upon completion of testing, the test director assembles a test package that includes the official test copy of the procedure and related documentation. Preoperational test packages are submitted to the TRB chairman, who disseminates the information to TRB members responsible for performing an in-depth review and evaluation of test results. Startup test packages are submitted to the PORC chairman, who disseminates the information to PORC members responsible for performing an in-depth review and evaluation of test results.

Test discrepancies, deficiencies, and omissions identified during testing or during review of test results are documented as test exceptions. Test exceptions occurring because of design problems are reported to appropriate design organization representatives for resolution per Section 14.2.4.4. Following review and resolution of review comments, the responsible chairman (TRB or PORC) has three options:

a. Recommend that the entire test be repeated.

b. Recommend that test results are unacceptable until all or part of the outstanding exceptions are resolved.

c. Recommend acceptance of test results with or without exceptions.

Approval of preoperational and startup test results (with or without exceptions) is by the LGS Plant Manager.

14.2.5.2 Test Exceptions

Each exception and its disposition are evaluated and resolved by processing the information through the same review and approval cycle as the original procedure, until such time as the system has been turned over to the plant staff, at which time PORC will perform the review.

14.2.5.3 Major Test Phase - Test Results

Commencement of each major test phase of the startup test program requires that the following test procedure review and approval commitments be satisfied:

a. Commencement of initial fuel loading and zero power testing requires that the results of the preoperational tests of Figure 14.2-6 be reviewed and approved in accordance with Section 14.2.5.1.

b. Commencement of low power testing requires that the results of the initial fuel loading and zero power tests of Figure 14.2-5, be reviewed and approved per the requirements of Section 14.2.5.1.

c. Commencement of power ascension testing requires that the results of the low power tests of Figure 14.2-5 be reviewed and approved per the requirements of Section 14.2.5.1.

14.2.5.4 Power Ascension Testing - Test Results

Figure 14.2-5 prescribes the sequence of testing, during the power ascension testing phase, as a function of reactor power and flow. Commencement of testing specified for each level requires that the test results of the preceding level be reviewed and approved per the requirements of Section 14.2.5.1.

14.2.6 TEST RECORDS

A single copy of each approved procedure, denoted as the official test copy, is used as the official record of the test. The completed official test copy and associated test documents are assembled into a test package at the end of testing. Test packages are retained for the life of the plant, in accordance with licensee procedures for retention of historical records. Each test package contains, either as part of the procedure or as separate documentation, the following information:

a. A description of the test method and objectives

b. A comparison of test data with acceptance criteria

c. Deficiencies relating to design and construction identified during testing

d. Modifications and corrective actions required

e. Justification for acceptance of systems or components not in conformance with design predictions or performance requirements

f. Conclusions regarding system or component adequacy

This test package is intended to serve as the main report for each test because it contains all necessary information concerning the test. Additional individual test reports, summarizing test results, are not contemplated, except as required by plant operation technical specifications.

14.2.7 CONFORMANCE OF TEST PROGRAMS WITH REGULATORY GUIDES

The initial test program to be conducted at LGS is as defined in this chapter. This chapter establishes both the administrative and technical requirements of the test program. Implementation of the initial test program must be in accordance with these requirements.

This program was developed in accordance with the following positions, as related to regulatory guides.

14.2.7.1 General Position - Regulatory Guides

The purpose of the regulatory guides, as related to testing, is to describe the scope and depth (administratively and technically) of an initial test program, acceptable for light-water-cooled nuclear power plants. The basis for the regulatory guides is 10CFR50.34 and 10CFR50, Appendix B. These two items specifically apply to testing structures, systems, and components important to

safety; that is, there must be sufficient testing to provide reasonable assurance that the facility can be operated without undue risk to the health and safety of the public.

Structures, systems, and components important to safety are classified as safety-related and are identified in Section 3.2. The remaining structures, systems, and components are considered nonsafety-related, and the plant design is based upon the concept that failure of a nonsafety-related structure, system, or component cannot jeopardize the health or safety of the public. The regulatory guides, as related to testing, apply administratively and technically only to structures, systems, and components classified as safety-related; however, to comply with the positions in the guides, systems meeting the criteria of Regulatory Guide 1.68, position C.1, will also be tested.

14.2.7.2 Specific Position - Regulatory Guides

In accordance with the general position of Section 14.2.7.1 plant structures, systems, and components classified as safety-related will be tested in accordance with the testing criteria of the following regulatory guides with specific exceptions, if any, noted below.

Only those portions of the regulatory guides that apply to the initial test program are considered. Other portions of the regulatory guides are implemented as applicable in the plant technical specifications. In addition, testing as specified in these guides is in accordance with existing design.

Regulatory Guide 1.20 (Rev 2) - "Comprehensive Vibration Assessment Program for Reactor Internals During Preoperational and Initial Startup Testing" (May 1976).

Regulatory Guide 1.41 - "Preoperational Testing of Redundant Onsite Electric Power Systems to Verify Proper Load Group Assignments" (March 16, 1973).

Regulatory Guide 1.52 (Rev 2) - "Design, Testing, and Maintenance Criteria for Engineered Safety Feature Atmosphere Cleanup System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants" (March 1978).

Regulatory Guide 1.56 (Rev 1) - "Maintenance of Water Purity in Boiling Water Reactors" (July 1978).

Regulatory Guide 1.68 (Rev 2) - "Initial Test Programs for Water-Cooled Reactor Power Plants" (August 1978).

The Unit 2 preoperational test program may use some data and test results from testing conducted outside of and prior to the preoperational test. Where this alternate testing is used to satisfy acceptance criteria of the preoperational test, the associated documentation will be reviewed by Quality Assurance and the TRB during the preoperational test results review cycle.

Additionally, for systems or features provided on both Units 1 and 2 to ensure or support the operation of engineered safety features, an alternative to concurrent testing has been developed. These systems can demonstrate support through flow balancing, or for HVAC systems, as discussed below.

Assurance that the safety-related HVAC systems will maintain the safety-related components within their design temperature range, with the components operating in a manner that produces maximum heat load, is provided by the following:

a. The sizing of the safety-related HVAC equipment was based on the maximum heat loads that would occur for DBA conditions.

b. The safety-related fans were performance tested by the vendor to AMCA Standards.

c. The safety-related cooling coils carry coil ratings as follows:

1. Cooling coils that fall within the parameters of the ARI Certified Rating Program carry an ARI certified performance rating. The ARI ratings are based on qualification test data approved by ARI.

2. Cooling coils with parameters (entering air temperature, etc) that fall outside the ARI Certified Rating Program are performance rated in accordance with the American Air Filter Company Topical Report AAF-TR-7101, "Design and Testing of Fan Cooler-Filter Systems for Nuclear Applications." This topical report presents the interpolation procedure used to extend the ARI rating technique beyond its approved range. The validity of the procedure has been confirmed by performance tests, and it has been approved by ARI and accepted by the NRC.

d. The balancing of the HVAC systems (air and water sides) will be administered by a startup technical procedure. The monitoring of the HVAC balancing will ensure that the design air and water flows are attained.

e. The Control Enclosure Chilled Water Preoperational Test Procedure IP-30.2 will require verification at the 44°F design chilled water temperature is attained.

The combination of equipment selection of maximum DBA heat loads, equipment performance ratings to accepted standards, air and water balancing along with proper chilled water temperature to satisfy coil performance rating parameters, and air balancing to attain design duct air flow rates is verification that the safety-related HVAC systems will function as designed and will maintain design temperatures as required for DBA conditions.

Regulatory Guide 1.68.1 (Rev 1) - "Preoperational and Initial Startup Testing of Feedwater and Condensate Systems for Boiling Water Reactor Power Plants" (January 1977).

The Unit 2 preoperational test program may use some data and test results from testing conducted outside of and prior to the preoperational test. Where this alternate testing is used to satisfy acceptance criteria of the preoperational test, the associated documentation will be reviewed by Quality Assurance and the TRB during the preoperational test results review cycle.

Regulatory Guide 1.68.2 - "Initial Startup Test Program to Demonstrate Remote Shutdown Capability for Water-Cooled Nuclear Power Plants" (January 1977).

Regulatory Guide 1.68.3 - "Preoperational Testing of Instrument and Control Air Systems" (April 1982).

Compliance is demonstrated by preoperational test procedures P-18.1, P-25.1, P-83.1, and P-100.2.

The Unit 2 preoperational test program may use some data and test results from testing conducted outside of and prior to the preoperational test. Where this alternate testing is used to satisfy acceptance criteria of the preoperational test, the associate documentation will be reviewed by Quality Assurance and the TRB during the preoperational test results review cycle.

Regulatory Guide 1.70 (Rev 3) - "Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants" (November 1978).

Regulatory Guide 1.104 - "Overhead Crane Handling Systems for Nuclear Power Plants" (February 1976).

Overhead crane testing exceptions are as outlined in Section 9.1.5.

Regulatory Guide 1.108 (Rev 1) - "Periodic Testing of Diesel Generator Units Used as Onsite Electric Power Systems at Nuclear Power Plants" (August 1977).

Testing of the diesel generators is discussed in Section 8.1.6.1.20.

Regulatory Guide 1.140 (Rev 1) - "Design, Testing, and Maintenance Criteria for Normal Ventilation Exhaust System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants" (October 1979).

14.2.8 UTILIZATION OF REACTOR OPERATING AND TESTING EXPERIENCE IN THE DEVELOPMENT OF THE TEST PROGRAM

The TRB and the PORC are responsible for ensuring that reactor operating and testing experiences of similar power plants are utilized during the initial test program. The primary sources of experience feedback is the Independent Safety Engineering Group and the Operating Experience Assessment Committee who provide relevant information based upon their continuing review of the industry via such sources as INPO Significant Operating Experience

Reports and Significant Event Reports, GE Service Information Letters, and NRC Licensee Event Reports. This review includes at least a two year period prior to the commencement of the initial test program. The TRB chairman and the PORC chairman are each responsible for disseminating this feedback material to individuals who are designated test procedure review responsibility. During their review of assigned test procedures, TRB and PORC members are subsequently responsible for ensuring that pertinent feedback experiences are considered.

14.2.9 TRIAL USE OF PLANT OPERATING AND EMERGENCY PROCEDURES

The preparation, review, and approval of plant operating and emergency procedures are described in Chapter 13. Sufficient time is provided for confirming procedure adequacy by trial use during the initial test program. Those procedures that do not require nuclear fuel are confirmed as adequate during the preoperational test program. Those procedures that require nuclear fuel are confirmed as adequate during the startup test program.

The plant operating staff is responsible for confirming operating and emergency procedures. The LGS Plant Manager is responsible for ensuring that comments and/or changes identified during confirmation are incorporated into finalized procedures.

It is not intended that preoperational and startup test procedures explicitly incorporate or reference plant operating and emergency procedures, although they may do so where appropriate. These tests are intended to stand on their own, since they are not necessarily compatible with configurations and conditions required for confirmation of facility operating and emergency procedures.

14.2.10 INITIAL FUEL LOADING AND INITIAL CRITICALITY

Initial fuel loading is accomplished in accordance with startup test procedure, "Fuel Loading, STP-3." Initial criticality is accomplished in accordance with startup test procedure, "Full Core Shutdown Margin, STP-4." These procedures comply with the general guidelines and regulatory positions contained in Regulatory Guide 1.68 (Rev 2 - August 1978). Test abstracts establishing the objectives, prerequisites, test method, and acceptance criteria for these procedures are presented in Table 14.2-3.

14.2.11 TEST PROGRAM SCHEDULE

The schedule, relative to the initial fuel loading date, for conducting each major test phase of the initial test program is presented in Figure 14.2-1. This figure illustrates that the preoperational test program is scheduled for 15 months duration for Unit 1, 16 months duration for Unit 2, and that the subsequent startup test programs are scheduled at 3 months and 6 months duration for Units 1 and 2, respectively. Approved preoperational test procedures are intended to be available for NRC review at least 60 days prior to scheduled implementation. Copies of approved test procedures for fuel loading, initial startup testing (zero power testing), and supporting activities through Phase II of the initial test program are intended to be available for NRC examination not less than 60 days before the scheduled fuel load date. Copies of test procedures for Phase III (Low Power Testing) and Phase IV (Power Ascension Testing) of the initial test program are intended to be available for NRC examination not less than 60 days prior to the scheduled fuel load date. Every effort will be made to provide approved test procedures for Phases III and IV; however, if such procedures are not available, copies of draft procedures will be provided.

The sequential schedules for conducting individual preoperational tests for each unit are presented in Figures 14.2-6 and Figure 14.2-7. These sequential schedules offer one possible plan for an orderly and efficient progression of testing. While these sequences may be preferred, numerous acceptable alternatives exist because few preoperational tests are dependent on performance of other preoperational tests. The actual test sequences are determined daily at the job-site to reflect construction status, manpower availability, and test prerequisite status.

The sequential schedule for conducting Unit 1 and Unit 2 startup tests is presented in Figure 14.2-5. This schedule establishes the required order of startup testing as a function of test phase and power level. Even though this basic order of testing is required, there is still considerable flexibility in sequencing the startup testing specified to be conducted at each test phase or startup level. Detailed startup testing schedules, commensurate with the requirements of this schedule, are developed at the job-site to schedule startup testing when operationally expedient.

14.2.12 INDIVIDUAL TEST DESCRIPTIONS

Individual abstracts for each preoperational test conducted during the preoperational test program are given in Table 14.2-4. Individual abstracts for each startup test conducted during the subsequent startup test program are given in Table 14.2-3. These abstracts identify each test by title and number, describe the test objectives, identify the test prerequisites, provide a summary

description of the test method, and establish basic test acceptance criteria. Presently known documents that provide sources of acceptance criteria are identified in parentheses in the acceptance criteria section of the individual abstracts. Other documents or FSAR sections referenced within the identified document may also serve as sources of acceptance criteria. The test abstracts are not intended to be ongoing documents that are continuously changed as references are modified. The identification of documents may be modified as specific acceptance criteria are developed and test procedures are written.

Table 14.2-3

STARTUP TEST PROCEDURE ABSTRACTS

(STP-1) Chemical and Radiochemical

Test Objectives - The test objectives are to ensure that the systems provide adequate means to maintain control and knowledge of the quality of the plant systems chemistry and to ensure that the sampling equipment, procedures, and analytic techniques are adequate to supply the data required to demonstrate that the fluids meet quality specifications and process requirements. They must also monitor the integrity of the fuel, the operation of the demineralizers and filters, the condenser tube integrity, the operation of the offgas system, and the tuning of certain process instruments.

Prerequisites - Instrument calibration and preoperational testing of chemical, radiation, and radiochemical monitors are completed, and a set of chemical and radiochemical samples were taken to functionally check sample stations.

Test Method - Prior to fuel loading, a set of chemical and radiochemical samples is taken to determine initial concentrations for selected systems. Subsequent to fuel loading, during reactor heatup, and at each major power level change, samples are taken and measurements are made to determine the chemical and radiochemical quality of reactor water and reactor feedwater, the amount of radiolytic gas in the steam, gaseous activities after the air ejectors, decay times in the offgas lines, and the performance of filters and demineralizers. Monitors in the liquid waste system and liquid process lines are adjusted as required. The chemical and radiochemical monitors and the sample system operation verify that the system is capable of providing true samples at proper flow, temperature, and/or moisture content, as applicable, so that means are available for the reliable analysis of the process by instrumentation or plant personnel.

Acceptance Criteria - Water quality remains within applicable guidelines, and gaseous and liquid effluent activities conform with plant requirements.

(STP-2) Radiation Measurements

Test Objectives - The test objectives are: to determine the background gamma and neutron radiation levels in the plant environs prior to operation in order to provide base data on activity buildup and shielding adequacy; and to monitor radiation at selected power levels to ensure the protection of personnel, and continuous compliance with the guideline standards of 10CFR20 during plant operation.

Prerequisites - A survey of natural background radiation is made at selected locations throughout the plant site.

Test Method - Subsequent to fuel loading, during reactor heatup, and at various selected power levels, gamma radiation level measurements and, where appropriate, neutron dose rate measurements are made at significant locations throughout the plant site. Potentially high radiation areas are surveyed.

Acceptance Criteria - Plant radiation doses and personnel occupancy times are controlled within allowable limits as defined in 10CFR20.

Table 14.2-3 (Cont'd)

(STP-3) Fuel Loading

Test Objective - The test objective is to load fuel safely and efficiently to the full core size.

Prerequisites - The preoperational test program test results have been reviewed and approved, and an NRC license has been issued to PECo. A neutron source is installed near the center of the core. At least three neutron detectors, calibrated and connected in a noncoincident mode to high flux scram trips, are located to produce acceptable signals during loading. Final testing of this reactor protection system and final reactor coolant leak rate testing have been completed.

Test Method - The fuel loading procedure includes the loading sequence, pattern, and records for logging, a running inventory of fuel status, control rod checks, minimum shutdown checks, neutron monitoring, subcritical multiplication behavior, communication requirements, safety requirements, emergency procedures, and additional checks to be performed during fuel loading.

For Unit 1, fuel loading begins at the center of the core and proceeds radially to the fully loaded configuration. During the loading of each cell, two fuel assemblies will be loaded in the location not occupied by the blade guide. The blade guide will be removed, and loading of the cell will be completed. A functional check to verify the operability of the control rod and drive will be performed on each cell after the cell is loaded.

This functional check may also serve as a subcritical check to verify that the next cell may be safely loaded.

For Unit 2, fuel loading will begin off-center so that loading can begin between an SRM and the closest source, and will continue in a spiral pattern to the full loaded configuration. During the loading of each cell, two fuel assemblies will be loaded in the location not occupied by the blade guide. The blade guide will be removed, and loading of the cell will be completed. A functional check to verify the operability of the control rod and drive will be performed on each cell after the cell is loaded. This functional check may also serve as a subcritical check to verify that the next cell may be safely loaded. Subcritical checks are not required for the first 16 fuel bundles loaded since an analysis has been performed which indicates that the first 16 fuel bundles loaded cannot establish a critical geometry.

Acceptance Criteria - The core is fully loaded in accordance with established procedures, and the core is subcritical.

(STP-4) Full Core Shutdown Margin

Test Objective - The test objective is to demonstrate that the reactor is sufficiently subcritical throughout the first fuel cycle, with any single control rod fully withdrawn.

Prerequisites - The core is fully loaded; the subcritical checks are completed; and the SRMs and IRMs are installed in the vessel and connected in a noncoincident mode, to scram at a high neutron level. The rod worth minimizer system is operational.

Table 14.2-3 (Cont'd)

Test Method - The shutdown margin test is performed by fully withdrawing a series of previously selected rods until criticality is reached. The empirical data are analyzed and compared with calculated data to determine the test results.

Acceptance Criteria - The basic criterion for reactivity control is that the core, in its maximum reactivity state at any time in the cycle, be sufficiently subcritical, with the strongest rod withdrawn, and all other rods fully inserted. Satisfactory completion of the shutdown margin test ensures, at the time of fuel loading, that this criterion has been met.

(STP-5) Control Rod Drive System

Test Objectives - The test objectives are to demonstrate that the CRD system operates over the full range of primary coolant temperatures and pressures, from ambient to operating, and to determine the initial operating characteristics of the entire CRD system.

Prerequisites - The process computer, scram time recorder, or equivalent recording equipment is on-line and available to monitor events; the CRD electrical and hydraulic system preoperational testing is completed satisfactorily; and the vessel water level is always above the upper core grid during all CRD movements. The reactor protection system preoperational test is completed, and the scram pilot valves are ready for energization.

Test Method - For Unit 1, during fuel load, a visual check is made of the position indication of each control rod, and the four-rod displays are checked for missing numbers. Insert and withdrawal times are verified during fuel load, and again at rated pressure for selected rods. Scram testing will be performed following fuel loading and at rated pressure. Coupling checks are again verified by the operator. Friction testing is conducted by measuring the pressure differential between the insert and withdrawal lines during the continuous insertion of a control rod.

For Unit 2, during fuel load, a visual check is made of the position indication of each control rod, and the four-rod displays are checked for missing numbers. Insert and withdrawal times are verified during fuel load, and again at rated pressure for selected rods. Scram testing will be performed following fuel loading and at rated pressure. Coupling checks are again verified by the operator. Friction testing is conducted by measuring the pressure differential between the insert and withdrawal lines or between the drive water header pressure downstream of the CRD Friction Testing Station and reactor pressure during the continuous insertion of a control rod.

Acceptance Criteria - Scram times and friction test results fall within acceptance limits. Each CRD has normal insert and withdrawal times within the limits indicated.

(STP-6) SRM Performance and Control Rod Sequence

Test Objective - The test objective is to demonstrate that the sources and SRM system provide sufficient information for knowledgeable and controlled reactor startup at low neutron levels.

Prerequisites - Fuel loading is completed, neutron sources are in place, and the core is clean and cold with all control rods inserted.

Table 14.2-3 (Cont'd)

Test Method - All control rod movement or operation is in compliance with approved owner operating procedures. The SRMs are connected, and subcritical testing verifies SRM response to control rod withdrawal. With the SRMs operational, criticality is approached. Records are maintained of count rate, rod configuration, and times. Criticality is achieved by withdrawing rods in the designated sequence.

Acceptance Criteria - SRMs are operational and read on-scale within the designed range for a cold clean core.

(STP-9) Water Level Reference Leg Temperature

Test Objective - The test objective is to demonstrate the calibration and agreement of the installed reactor vessel water level instrumentation at normal operating pressure and temperature.

Prerequisites - The following are determined and recorded: elevations of instrument taps, condensing chambers, head chambers indicating zero water level, and instrument ranges. The reactor is in a steady-state condition during each stage of testing. Air temperature in the vicinity of the level columns is stabilized.

Test Method - The test will be done at rated temperature and pressure and under steady-state conditions; the reference leg temperature will be measured and compared to the value assumed during initial calibration. If the difference exceeds operating tolerances, the instruments will be recalibrated using the measured value.

Acceptance Criteria - The installed reactor water level indication and controls provide accurate information and sufficient operating tolerances under normal operating conditions.

(STP-10) IRM Performance

Test Objective - The test objective is to demonstrate IRM system response to neutron flux and IRM overlap with the SRM and APRM systems.

Prerequisites - Fuel loading is completed, and the reactor is just critical. IRM gains are set at maximum for conservatism on Unit 1. IRM gains are set conservatively on Unit 2.

Test Method - After criticality and when flux level is sufficient, IRM response to neutron flux and the IRM/SRM overlap is verified. The SRMs and IRMs may then be taken out of noncoincident scram. Following APRM calibration in accordance with another procedure, the IRM gains may be adjusted to optimize the IRM overlap with the SRMs and APRMs.

Acceptance Criteria - Resulting IRM overlap with the SRMs and APRMs is established within acceptable limits.

(STP-11) Local Power Range Monitoring Calibration

Test Objective - The test objective is to calibrate the LPRM system.

Prerequisites - Reactor power and LPRM gains are sufficient to observe chamber response to the adjacent control rod during calibration of any LPRMs. The ability of the APRM system to provide

Table 14.2-3 (Cont'd)

input to the reactor protection system is maintained during this test. The process computer or off-line computer is available.

Test Method - The core is operated in a specified test condition, for a period sufficient to obtain short-term equilibrium conditions. LPRMs are calibrated in accordance with the calibration procedure. The meter reading of each LPRM chamber is proportional to the average heat flux in the four adjacent fuel rods at the height of the chamber.

Acceptance Criteria - LPRM calibration, in accordance with the procedure, is satisfactorily completed.

(STP-12) APRM Calibration

Test Objective - The test objective is to calibrate the APRM system.

Prerequisites - The core is at steady-state condition at the desired power level and core flow rate. Control rod positions and core flow are not changed during the time data are taken for these calibrations.

Test Method - With the core in a steady-state condition, calculations are made of the percent of rated power by heat balance. The APRMs are calibrated to agree with the calculated power value.

Acceptance Criteria - The APRMs are calibrated to read equal to or greater than the calculated core thermal power.

(STP-13) Process Computer Performance Verification (Unit 1)

Test Objective - The test objective is to demonstrate the ability of the process computer to provide accurate information pertaining to plant process variables under operating conditions.

Prerequisites - Fuel loading is completed to the extent necessary to perform this test. Applicable field inputs are terminated, computer room HVAC is operational, and the computer is operational, with plant data available.

Test Method - Following fuel loading, and during plant heatup and ascension to rated power, plant process variables, sensed by the computer as digital or analog signals, are recorded. Performance calculation programs are run, and the results recorded.

Acceptance Criteria - Programs P-1, OD-1, and OD-6 are considered operational when:

a. The MFLCPR, calculated by an independent method, and calculated by process computer, either:

   1. Are in the same fuel assembly and do not differ in value by more than 2%.

   2. When the MFLCPR calculated by the process computer is in a different assembly than that calculated by the independent method, the MFLCPR calculated by the two methods agree within 2%, for each assembly.

Table 14.2-3 (Cont'd)

b. The MFLPD, calculated by the independent method, and by the proces computer, either:

   1. Are in the same fuel assembly and do not differ in value by more than 2%.

   2. When the MFLPD calculated by the process computer is in a different assembly than that calculated by the independent method, the MFLPD calculated by the two methods agree within 2%, for each assembly.

c. The MAPLHGR, calculated by the independent method, and the process computer, either:

   1. Are in the same fuel assembly and do not differ in value more than 2%.

   2. When the MAPLHGR calculated by the process computer is in a different assembly than that calculated by the independent method, the MAPLHGR calculated by the two methods agree within 2%, for each assembly.

d. The LPRM calibration factors calculated by the independent method and the process computer agree to within 2%.

e. The remaining programs are considered operational upon successful completion of the static and dynamic testing.

(STP-13) Plant Monitoring System Performance Verification (Unit 2)

Test Objective - The test objective is to demonstrate the ability the PMS to provide accurate information pertaining to plant process variables under operating conditions.

Prerequisites - Fuel loading is completed to the extent necessary to perform this test. Applicable field inputs are terminated, computer room HVAC is operational, and the computer is operational, with plant data available.

Test Method - Following fuel loading, and during plant heatup and ascension to rated power, plant process variables, sensed by the computer as digital or analog signals, are recorded. Performance calculation programs are run, and the results recorded.

Acceptance Criteria - Programs P-1, OD-1, and OD-6 are considered operational when:

a. The MFLCPR, calculated by an independent method, and calculated by the PMS, either:

   1. Are in the same fuel assembly and do not differ in value by more than 2%.

   2. When the MFLCPR calculated by the PMS is in a different assembly than that calculated by the independent method, the MFLCPR calculated by the two methods agree within 2%, for each assembly.

Table 14.2-3 (Cont'd)

b. The MFLPD, calculated by the independent method, and by the PMS, either:

   1. Are in the same fuel assembly and do not differ in value by more than 2%.

   2. When the MFLPD calculated by the PMS is in a different assembly than that calculated by the independent method, the MFLPD calculated by the two methods agree within 2%, for each assembly.

c. The MAPLHGR, calculated by the independent method, and the PMS, either:

   1. Are in the same fuel assembly and do not differ in value more than 2%.

   2. When the MAPLHGR calculated by the PMS is in a different assembly than that calculated by the independent method, the MAPLHGR calculated by the two methods agree within 2%, for each assembly.

d. The LPRM calibration factors calculated by the independent method and the PMS agree to within 2%.

e. The remaining programs are considered operational upon successful completion of the static and dynamic testing.

(STP-14) Reactor Core Isolation Cooling System Performance Verification

Test Objective - The test objective is to demonstrate operation of the RCIC system over its required operating pressure range.

Prerequisites - The preoperational test of the RCIC system is completed. Fuel loading is completed, and sufficient nuclear steam is available to operate the RCIC pump throughout its operating range.

Test Method - A controlled start of the RCIC system is done at a reactor pressure of nominal 150 psig, and an automatic actuation start is done at rated reactor pressure. Verify the proper operation of the RCIC system and determine the time to reach rated flow. These tests may first be performed with the system in the test mode, so that discharge flow is not routed to the reactor pressure vessel. The final demonstration is made so that discharge flow is routed to the reactor pressure vessel while the reactor is at partial power. A cold quick start is performed with the system on the full flow test loop.

Acceptance Criteria - The RCIC system must have the capability to deliver specified flow, in less than or equal to the rated actuation time, against nominal rated reactor pressure.

Table 14.2-3 (Cont'd)

(STP-14.1) RCIC System Startup After Loss of Ac Power to the System

Test Objective - The test objective is to demonstrate the ability of the system to start without the aid of ac power with the exception of the RCIC dc/ac inverters.

Prerequisites - The preoperational test of the RCIC system is completed. Fuel loading is completed, and sufficient nuclear steam is available to operate the RCIC pump throughout its operating range. Power to RCIC components fed by site ac power is secured, and the station batteries are fully charged.

Test Method - A manual initiation of the RCIC system is accomplished at rated reactor pressure to verify the proper operation of all components to reach rated flow.

Acceptance Criteria - The RCIC system must have the capability to deliver specified flow against nominal rated reactor pressure without the normal ac site power supply.

(STP-14.2) RCIC System Operation with a Sustained Loss of Ac Power to the System

Test Objective - The test objective is to verify the operation of the RCIC beyond its design basis to evaluate the limits of the system operation with extended loss of ac power to the RCIC system and support systems with the exception of the RCIC dc/ac inverters.

Prerequisites - The preoperational test of the RCIC system is completed. Fuel loading is completed, and sufficient nuclear steam is available to operate the RCIC pump throughout its operating range. The RCIC system valves are in a normal standby lineup with suction from the CST. Power to RCIC components fed by site ac power is secured including the RCIC area coolers and battery chargers supplying the station battery from which the RCIC dc loads are powered. The RCIC batteries are fully charged. Instrument air is available for operation and controls of the appropriate valves.

Test Method - Start and operate the RCIC system with return to the CST and run the system for two hours or until any system limiting parameter is approached (e.g.: high RCIC area temperature, low battery voltage or high suppression pool temperature).

Acceptance Criteria - No defined acceptance criteria. The purpose of the test is to verify the operation of RCIC beyond its design basis.

(STP-15) High Pressure Coolant Injection System Performance Verification

Test Objective - The test objective is to demonstrate proper operation of the HPCI system over its required operating pressure range.

Prerequisites - The preoperational test of the HPCI system is completed. Fuel loading is completed, and sufficient nuclear steam is available to operate the HPCI pump throughout its operating range.

Table 14.2-3 (Cont'd)

Test Method - Controlled starts of the HPCI system are done at reactor pressures near 150 and rated during the heatup phase, and an automatic start is initiated. Verify the proper operation of the HPCI System, determine the time to reach rated flow, and adjust the flow controller in the HPCI System for proper flow rate. These tests are performed with the system in the test mode, so that discharge flow is not routed to the reactor pressure vessel. The final demonstration is made so that discharge flow is routed to the reactor pressure vessel, while the reactor is at partial power.

Acceptance Criteria - The HPCI turbine must not trip off during startup. The HPCI system must have the capability to deliver specified flow, in less than or equal to rated actuation time, against nominal rated reactor pressure.

(STP-16) Selected Process Temperatures Verification (Unit 1)

Test Objectives - The test objectives are: to establish the proper setting for the low speed limiter for the recirculation pumps, to keep the bottom head water temperature from being too low; and to demonstrate that the bottom head drain temperature corresponds to bottom head coolant temperature, during normal operation.

Prerequisites - The reactor is in a low power condition.

Test Method - With recirculation pumps at approximately 28% of maximum speed, allow the reactor to attain a steady-state condition. Data are recorded; then the speed of the pumps is slowly lowered until 20% of maximum speed or the minimum stable speed is reached, whichever is greater. Data are again recorded. The empirical data are analyzed to determine the optimum low speed limiter setting.

Acceptance Criteria - The resultant low speed setting maintains upper and lower region coolant temperatures within the specified limits.

(STP-16) Selected Process Temperatures Verification (Unit 2)

Test Objectives - The test objective is: to demonstrate that the bottom head drain temperature corresponds to bottom head coolant temperature, during normal operation.

Prerequisites - The reactor core flow is ≥95% of rated.

Test Method - With core flow at ≥95% of rated compare bottom drain line temperature with recirculation loop coolant temperature.

Acceptance Criteria - The bottom head drain temperature corresponds to the bottom head coolant temperature within specified limits.

(STP-17) System Expansion

Test Objectives - The test objectives are: to demonstrate that major equipment and the piping systems throughout the plant are free and unrestrained, with regard to thermal expansion; and that suspension components are functioning in the specified manner. See Section 3.9.2.1a.2 for nuclear steam supply system (NSSS) piping, and Table 3.9-7 for non-NSSS piping.

Table 14.2-3 (Cont'd)

The test also provides data for calculating stress levels in various critical nozzles and weldments.

Prerequisites - Engineering review of the piping systems is completed. Fuel loading and preservice examination of snubbers is completed and cold plant data are recorded. Preservice examination will include the following (Section 3.9.3.5.2.4):

a. There are no visible signs of damage or impaired operability as a result of storage, handling, or installation.

b. Location, orientation, position setting, and configuration are according to design drawings and specifications.

c. Snubbers are not seized, frozen, or jammed.

d. Adequate swing clearance is provided to allow snubber movement.

e. Structural connections such as pins, fasteners, and other connecting hardware such as lock nuts, tabs, wire, cotter pins are installed correctly.

When the interval between performance of snubber preservice inspection and initial power operation exceeds 6 months, items (a) and (d) above shall be reperformed and documented.

Test Method - During equipment heatup, observations and/or recordings of the horizontal and vertical movements of major equipment and piping in the NSSS and BOP systems are made to ensure that components are free to move as designed. Adjustments are made as necessary for freedom of movement.

Acceptance Criteria - There is no evidence of blocking the displacement of any system component caused by thermal expansion of the system.

Inspected hangers are not bottomed out or fully extended.

The shock suppressor positions allow movement at operating temperature with adequate swing clearance.

All measured displacements of the piping are within the specified acceptable range.

(STP-18) TIP Uncertainty

Test Objectives - The test objectives are: to demonstrate the reproducibility of the TIP system readings.

Prerequisites - The core is at steady-state power level with equilibrium xenon. It remains in this condition with no control rod motion or change in core flow until completion of the TIP traces.

Test Method - The rod pattern and all APRM system and LPRM system readings are recorded. TIP reproducibility is checked with the plant at steady-state condition by producing several TIP traces in the same location, with each TIP machine. The traces are evaluated to determine the extent of deviations between traces from the same TIP machine.

Table 14.2-3 (Cont'd)

Acceptance Criteria - The TIP system error level is within the specified limits.

(STP-19) Core Performance

Test Objective - The test objective is to evaluate the principal thermal and hydraulic parameters associated with core behavior.

Prerequisites - The plant is operating in an essentially steady-state condition.

Test Method - With the core operating in a steady-state condition, the core performance evaluation is used to determine the principal thermal and hydraulic parameters associated with core behavior. These parameters are: core flow rate, core thermal power level, MAPLHGR, MLHGR, core MCPR, and MFLPD.

Acceptance Criteria - The principal thermal and hydraulic parameters associated with core behavior meet appropriately calculated limits (Vendor Test Specifications and plant Technical Specifications).

(STP-20) Steam Production

Test Objective - The objective of this test is to demonstrate that the NSSS is providing steam sufficient to satisfy all appropriate warranties.

Prerequisites - Required preoperational tests have been completed. All required instrumentation is installed and calibrated.

Test method - A NSSS steam output performance test of nominal 100 hours of continuous operation at the warranted steam output will be performed.

Acceptance Criteria - The NSSS shall be capable of supplying steam sufficient to satisfy all appropriate warranties.

(STP-21) DELETED

(STP-22) Pressure Regulator Response

Test Objectives - The test objectives are: to demonstrate the reactor pressure control system responses to pressure regulator setpoint changes, the stability of the reactivity void feedback loop to pressure perturbation, the control characteristics of the bypass and control valves, and the takeover capabilities of the backup pressure regulator; and to optimize the pressure regulator settings to give the best combination of fast response and small overshoot.

Prerequisites - Fuel loading is completed and nuclear steam is available.

Table 14.2-3 (Cont'd)

Test Method - The pressure setpoint is decreased rapidly and then increased rapidly by about 10 psi. The response of the system is measured in each case. The backup regulator is tested by

increasing the operating pressure regulator setpoint rapidly, until the backup regulator takes over control. The load reference setpoint is reduced, and the test is repeated with the bypass valve having control. The response of the system is measured and evaluated, and the regulator settings are optimized.

Acceptance Criteria - The decay ratio is acceptable for each process variable that exhibits oscillatory response to pressure regulator changes.

During the simulated failure of the primary controlling pressure regulator, the backup regulator is expected to control the transient so that the reactor does not scram.

Steady-state hunting or limit cycle characteristics due to control and valve dead band are acceptable at rated steam flow.

(STP-23) Feedwater Control System Demonstration

Test Objectives - The test objectives are: to evaluate and adjust feedwater controls; to demonstrate the capability of the automatic flow runback feature to prevent a low water level scram, following the trip of one feedwater pump; to demonstrate acceptable performance of feedwater pumps and turbine drivers within specifications; to demonstrate adequate response to feedwater heater loss (inlet subcooling change); and to demonstrate acceptable reactor water level control.

Prerequisites - The reactor is operating at a steady-state condition.

Test Method - At power levels of approximately 25%, 50%, 75%, and 100%, the reactor water level setpoint is changed approximately ±6 inches, to evaluate acceptability of the feedwater control systems at all modes of operation.

One of the three operating feedwater pumps is tripped at a power level such that the automatic flow runback circuit acts to drop power to within the capability of the remaining pumps.

The resulting transients from the loss of feedwater heating are evaluated at nominal 90% power.

Feedwater pumps and turbine driver variables are monitored throughout power ascension testing to demonstrate operability within specified limits.

Acceptance Criteria - The decay ratio is acceptable for each process variable that exhibits oscillatory response to feedwater control system setpoint changes, when the plant is operating above the lower limit of the master flow controller. The system has the capacity for automatic flow runback to prevent a low water level scram following the trip of one feedwater pump. The feedwater pumps and turbine drivers perform within specified limits (Vendor Test Specification).

Table 14.2-3 (Cont'd)

(STP-24) Main Turbine Valves Surveillance Test

Test Objective - The test objective is to demonstrate acceptable procedures for routine surveillance testing of the turbine stop, control, and bypass valves at a power level as high as possible, without producing a reactor scram.

Prerequisites - The main turbine is operational, and the power testing program is in progress.

Test Method - The individual turbine valves are closed at several points along the 100% power/flow control line, to establish the maximum possible power level for performance of this test, without producing a reactor scram.

Acceptance Criteria - With the plant at power and testing in progress, peak neutron flux is at a value below the scram setting. Peak reactor pressure is at a value below the high pressure scram setting. Peak steam flow in the main steam lines remains at values below the high flow isolation trip setting.

(STP-25) Main Steam Isolation Valves Performance Verification

Test Objectives - The test objectives are: to functionally check the MSIVs for proper operation at selected power levels; to determine reactor transient behavior during and following simultaneous full closure of all MSIVs, and following closure of one valve; and to determine isolation valve closure time.

Prerequisites - Fuel loading is completed, and nuclear steam is available.

Test Method - Functional checks (at least 10% closure) of each isolation valve are performed at selected reactor power levels. A test of simultaneous full closure of all MSIVs is performed at about 100% of rated thermal power. Operation of the RCIC and SRVs is monitored. Reactor process variables are monitored to determine the transient behavior of the system during and following full isolation. The MSIVs closure times are determined.

Acceptance Criteria - MSIV closure times are within applicable limits. Reactor pressure is maintained below specified values during the transient following full closure of all MSIVs.

(STP-26) Main Steam Relief Valves Performance

Test Objectives - The test objectives are: to demonstrate proper operation of the dual-purpose MSRVs and to demonstrate their leak-tightness following operation.

Prerequisites - Factory calibration data are verified, and setting adjustment mechanism factory seals, if applicable, are intact. The reactor is on pressure control with adequate bypass or main steam flow.

Test Method - The MSRVs are opened manually so that only one is opened at any time. Proper resetting of each MSRV is verified by observing temperatures in the MSRV discharge piping. The capacity of each MSRV is measured by opening the MSRV and observing the corresponding decrease in main steam line flow.

Table 14.2-3 (Cont'd)

Acceptance Criteria - Each MSRV flow compares favorably with the value assumed in the accident analysis at design reactor pressure. The leakage of each MSRV is low enough to allow the temperature measured by the thermocouples, in the discharge side of the valves, to fall within an acceptable margin of the temperature recorded, before the valve was opened.

(STP-27) Turbine Trip and Generator Load Rejection Demonstration

Test Objectives - The test objectives are: to determine the response of the reactor system to a turbine trip or generator load rejection; and to evaluate the response of the bypass, SRV, and the reactor protection systems.

Prerequisites - Logic testing of generator lockouts to produce a direct turbine trip are completed. Fuel loading is completed, and the power testing is completed to the extent necessary for performing this test.

Test Method - Dynamic transients are induced at selected reactor power levels by manual turbine trips. Neutron flux, feedwater flow and temperature, and vessel water level and pressure are monitored. Responses of selected control valves, stop valves, SRVs, and bypass valves are recorded. The peak values and the rate of change of both reactor power and reactor steam dome pressure are recorded. The capacity of the turbine bypass valves is checked.

Acceptance Criteria - The turbine control valves and the stop valves close during the stop valve fast closure test. Feedwater settings prevent flooding of the steam lines following these transients. The measurement of simulated heat flux is not significantly greater than preanalysis. The trip at less than 25% power does not cause a scram. The pressure regulator regains control before a low pressure reactor isolation occurs. Turbine bypass flow capacity compares favorably with the value assumed in the accident analysis (Vendor Test Specification). The flow coast-down characteristics of the recirculation pump are reconfirmed as part of the turbine trip demonstration at near rated power and flow.

(STP-28) Shutdown from Outside the Main Control Room Demonstration

Test Objective - The test objective is to demonstrate that the power plant can be safely shut down from outside the control room, to demonstrate that the power plant can be maintained in a hot standby condition from outside the control room, and to demonstrate that the power plant can be safely cooled from hot standby to cold shutdown conditions from outside the control room.

Prerequisites - Preoperational testing of plant instrumentation, controls, and systems to be used at the remote shutdown station have been completed. Fuel loading is completed, and the power ascension testing program is in progress.

Test Method - Using only the minimum number of personnel in a shift crew required to be onsite at any one time, the reactor is manually scrammed from outside the control room and placed in hot standby condition from the remote shutdown station. The plant is maintained in hot standby condition for at least 30 minutes. Using additional personnel who could be made available prior to the time cooldown would be initiated, initiate a plant cooldown from hot standby conditions from outside the control room. Initiate RHR system operation and demonstrate the ability to achieve cold shutdown conditions from outside the control room.

Table 14.2-3 (Cont'd)

Acceptance Criteria -

a. Shutdown to hot standby can be achieved.

b. Plant can be maintained at stable hot standby. Reactor water level and pressure can be controlled.

c. Reactor coolant temperature and pressure can be lowered sufficiently to place the RHR system in operation.

d. A heat transfer path to the spray pond can be established.

e. Cooldown with the RHR system can be controlled to a rate that would not exceed technical specification limits.

(STP-29) Recirculation Flow Control Demonstration

Test Objective - The test objective is to determine the plant response to a change in recirculation flow, to optimize the setting of the master flow controller, and to demonstrate the plant loading capability in master manual flow control mode.

Prerequisites - The reactor is in a steady-state condition and the feedwater system is operating in three-element control.

Test Method - Data are recorded during the step and ramp changes. The final controller settings for both the master flow controller and the individual loop speed controllers are determined.

Acceptance Criteria - The decay ratio for each process variable that exhibits oscillatory response to flow control changes is acceptable. The plant response to a change in recirculation flow is acceptable. The plant loading capability in the master manual flow control mode is acceptable (Vendor Test Specification).

(STP-30) Recirculation System (Unit 1)

Test Objectives - The test objectives are: to determine transient responses and steady-state conditions following recirculation pump trips at selected power levels; to obtain jet pump performance data; and to demonstrate that no recirculation system cavitation occurs in the operation region of the power/flow map.

Prerequisites - The recirculation system preoperational test is completed; the process computer is available; and power testing is in progress.

Table 14.2-3 (Cont'd)

Test Method - Single-pump and two-pump trips are performed from specified power levels. The single-pump trips are initiated by opening the generator field breaker on the applicable motor generator or by opening the MG set drive motor breaker. The two-pump trip is initiated by tripping the recirculation pump trip breakers. Reactor pressure, reactor level, steam and feedwater flow, and neutron flux are recorded during the transient and steady-state conditions. The data recorded during rated power operation verify the noncavitation performance of the recirculation pumps and the jet pumps.

Acceptance Criteria - All responses to the pump trip test transients are within limits. Pump performance testing under operating conditions verifies the noncavitation within the operating range. Plant stability is within specified limits.

(STP-30) Recirculation System (Unit 2)

Test Objectives - The test objectives are: to determine transient responses and steady-state conditions following recirculation pump trips at selected power levels; and to obtain jet pump performance data.

Prerequisites - The recirculation system preoperational test is completed; the process computer is available, and power testing is in progress.

Test Method - Single-pump and two-pump trips are performed from specified power levels. The single-pump trips are initiated by opening the generator field breaker on the applicable motor generator or by opening the MG set drive motor breaker. The two-pump trip is initiated by tripping the recirculation pump trip breakers. Reactor pressure, reactor level, steam and feedwater flow, and neutron flux are recorded during the transient and steady-state conditions.

Acceptance Criteria - All responses to the pump trip test transients are within limits. Plant stability is within specified limits.

(STP-31) Loss of Turbine-Generator and Offsite Power

Test Objective - The test objective is to demonstrate the performance of the reactor and plant electrical equipment and systems, during the loss of auxiliary power transient.

Prerequisites - The diesel generators are in the automatic start mode, and the plant is operating at power.

Test Method - The loss of auxiliary power test is performed at nominal 25% rated power. The proper response of reactor plant equipment, automatic switching equipment, and the proper sequencing of the diesel generator load are checked. Appropriate reactor parameters are recorded during the resultant transient.

Acceptance Criteria - All safety systems function as required, without manual assistance. Reactor steam dome pressure is maintained below acceptable limits. Normal reactor cooling systems are capable of maintaining adequate suppression pool water temperature, adequate drywell cooling, and of preventing actuation of the ADS.

Table 14.2-3 (Cont'd)

(STP-32) Essential HVAC System Operation and Containment Hot Penetration Temperature Verification

Test Objective - The test objective is to demonstrate, under actual operating conditions, satisfactory performance of the drywell, control enclosure, control room, reactor enclosure, and radwaste enclosure HVAC systems and to verify that concrete temperature surrounding hot penetrations remain within specified limits.

Prerequisites - Air flow balancing, cooling water balancing, and fuel loading are completed; power ascension testing is in progress.

Test Method - Air temperatures are monitored and recorded at nominal 50% and 100% power. Space temperatures are not allowed to exceed predetermined maximum temperatures. Adjustments to air and/or cooling water flows are made, if required, to maintain temperature within specified limits. Concrete temperatures surrounding hot penetrations are monitored and recorded.

Acceptance Criteria - The drywell, control enclosure, control room, reactor enclosure, and radwaste HVAC systems provide adequate cooling, and concrete temperatures surrounding hot penetrations remain within specified limits.

(STP-33) Piping Steady-State Vibration Measurements

Test Objective - The test objective is to obtain vibration measurements on selected safety-related NSSS piping and selected BOP piping (Table 3.9-7), located both inside and outside of the primary containment. The test results are used to demonstrate the mechanical integrity of the selected systems to flow-induced vibration, and to check the validity and accuracy of the analytical models.

Prerequisites - Engineering review of the piping system is complete. The required preoperational test has been completed. Instrumentation has been installed and calibrated.

Test Method - The systems to be tested are operated in their normal modes, and data are collected at specified power levels. The empirical data are analyzed to determine test results.

Acceptance Criteria - Analysis of the empirical data satisfies the requirements of applicable criteria and calculations. The steady-state vibration of the piping system is qualified as acceptable by visual inspection, if the level of vibration is too small to be detected by the naked eye, and, in the analyst's judgement, the possibility of damage is minimal; or the stresses in the piping based on the measured maximum displacement due to steady-state vibration are less than the endurance limit of the material as specified in Section 3.9.2.1b.2.

(STP-34) Offgas System Performance Verification

Test Objective - The test objective is to demonstrate proper operation of the offgas system under its expected operating conditions.

Prerequisites - Fuel loading is completed, and power ascension testing is in progress.

Table 14.2-3 (Cont'd)

Test Method - At startup flow and again at normal flow, the flows, temperatures, and pressures at selected locations are recorded and checked to see if they are within acceptable limits. The hydrogen concentration, drainage of condensate, dilution flow, and charcoal system operability are checked periodically throughout plant startup. The catalytic recombiner is operated, and its operating characteristics are recorded. Grab samples are taken periodically for radionuclide analysis.

Acceptance Criteria - The release of gaseous and airborne radioactive effluents does not exceed the limits specified in the Technical Specifications. The system measured variables are within acceptable limits of design. The catalytic recombiner, carbon beds, and filters perform properly.

(STP-35) Recirculation Flow Calibration

Test Objective - The test objective is to perform a complete calibration of the installed recirculation system flow instrumentation.

Prerequisites - The reactor is operating in a steady-state condition. Flow instrumentation static calibration is completed prior to the first flow calibration. The zero setting on transmitters is checked and adjusted prior to a flow calibration.

Test Method - With the reactor in a steady-state condition, recirculation flow data are recorded. The data are analyzed to determine the required adjustments on APRM and RBM flow units, and the jet pump loop flow proportional amplifiers. The resulting settings are documented on the instrument data sheets, for the owner's records.

Acceptance Criteria - Jet pump flow instruments are adjusted so that the jet pump total flow recorder provides a correct core flow indication at rated conditions. The APRM/RBM flow bias instrumentation is adjusted to function properly at rated conditions.

(STP-36) Piping Dynamic Transient

Test Objectives - The objective of this test is to verify the design adequacy of the piping systems for the transients indicated in Table 3.9-7.

Prerequisites - An engineering review of the piping system after construction is completed. The required preoperational tests have been completed. Instrumentation has been installed and calibrated.

Test Method - Response of the piping system (displacements or restraint loads) is measured during the transient event specified.

Acceptance Criteria - The measured response of the piping system and restraint loads shall be less than the acceptable response determined by analysis as specified in Section 3.9.2.1b.1.

(STP-37) DELETED

(STP-38) DELETED

Table 14.2-3 (Cont'd)

(STP-70) Reactor Water Cleanup System Performance Verification

Test Objective - The test objective is to demonstrate specific aspects of the mechanical operability of the RWCU system.

Prerequisites - The RWCU system preoperational test is completed satisfactorily. The reactor is operated at, or near, rated temperature and pressure, long enough to achieve a steady-state condition.

Test Method - The system is operated in blowdown, hot shutdown, and normal modes to provide data for analysis. The system is allowed to stabilize in each mode prior to recording of data. These data are analyzed to determine the test results.

Acceptance Criteria - The data indicates operation in the listed modes is satisfactory.

(STP-71) Residual Heat Removal System Performance Verification

Test Objectives - The test objectives are to demonstrate the ability of the RHR system to remove residual and decay heat from the nuclear system, so that refueling and nuclear system servicing can be performed.

Prerequisites - The RHR system preoperational test is completed satisfactorily.

Test Method - Two modes are tested to verify system capability under actual operating conditions. The modes to be tested are the shutdown cooling and the suppression pool cooling modes. During the operation, the heat transfer rate is controlled to maintain acceptable reactor pressure vessel RPV cooldown rates. Data are recorded before and during each portion of testing. The empirical data are analyzed to verify the satisfactory operation of the RHR system within the limits of acceptance criteria.

Acceptance Criteria - The RHR system is capable of operating at an acceptable flow rate and heat removal capability.

Table 14.2-4

PREOPERATIONAL TEST PROCEDURE ABSTRACTS

(P-2.1) 125 V (Div III, IV) Dc Safeguard Power System

Unit Scope -

a. 1P-2.1 (Unit 1 and portions of Unit 2 system components)

b. 2P-2.1 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the ability of the 125 V dc safeguard power system to provide an uninterruptible source of power to the 125 V dc distribution panels.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Batteries are filled with electrolyte to normal level, and 440 V ac power is available to provide power to the battery chargers. The load resistor bank is available to support the battery load capacity test. Battery room ventilation and emergency eyewash are available and operational.

Test Method - Battery charger capacity is verified by the application of its full load rating for 8 hours. Battery capacity is verified by the application of a constant test load at the battery manufacturer's 4 hour rate. System response to the design load profile is verified by the application of stepped test currents. Battery system recharge characteristics are determined by integrating amp-hours into the battery following the design load profile discharge test.

Acceptance Criteria -

a. The ac input voltage to the battery chargers is within specified limits. (Vendor Technical Manual)

b. The dc distribution equipment is connected to the proper safety division. (Section 8.3.2.1.1)

c. The battery capacity is equal to or greater than that specified. (Table 8.3-18)

d. The battery capacity is sufficient to supply the specific application requirements with respect to the calculated load discharge profile. (Table 8.3-18)

e. The battery will accept a charge equal to or greater than the number of amp-hours required to restore the energy dissipated during a design load discharge test within 8 hours while the charger maintains normal plant loads. (Section 8.3.2.1.1.3)

f. The battery chargers will supply rated load or greater for 8 hours without degradation. (Section 8.3.2.1.1.3 and Vendor Technical Manual)

g. The battery chargers will supply regulated and conditioned dc within specified limits. (Vendor Technical Manual)

Table 14.2-4 (Cont'd)

h. Battery system off-normal conditions are properly identified and annunciated. (Sections 8.3.2.1.1.2 and 8.3.2.1.1.3)

(P-2.2) 125/250 V (Div I, II) Dc Safeguard Power System

Unit Scope -

a. 1P-2.2 (Unit 1 and portions of Unit 2 system components)

b. 2P-2.2 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the ability of the 125/250 V dc safeguard power system to provide an uninterruptible source of power to the 125/250 V dc motor control centers and to various 125 V dc distribution panels.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Batteries are filled with electrolyte to normal level, and 440 V ac power is available to provide power to the battery chargers. The load resistor bank is available to support the battery load capacity test. Battery room ventilation and emergency eyewash are available and operational.

Test Method - Battery charger capacity is verified by the application of its full load rating for 8 hours. Battery capacity is verified by the application of a constant test load at the battery manufacturer's 4 hour rate. System response to the design load profile is verified by the application of stepped test currents. Battery system recharge characteristics are determined by integrating amp-hours into the battery following the design load profile test.

Acceptance Criteria -

a. The ac input voltage to the battery chargers is within specified limits. (Vendor Technical Manual)

b. The dc distribution equipment is connected to the proper safety division. (Section 8.3.2.1.1)

c. The battery capacity is equal to or greater than that specified. (Table 8.3-18)

d. The battery capacity is sufficient to supply the specific application requirements with respect to the calculated load discharge profile. (Table 8.3-18)

e. The battery will accept a charge equal to or greater than the number of amp-hours required to restore the energy dissipated during a design load discharge test within 8 hours while the charge maintains normal plant loads. (Section 8.3.2.1.1.3)

f. The battery chargers will supply rated load or greater for 8 hours without degradation. (Section 8.3.2.1.1.3 and Vendor Technical Manual)

Table 14.2-4 (Cont'd)

g. The battery chargers will supply regulated and conditioned dc within specified limits. (Vendor Technical Manual)

h. Battery system off-normal conditions are properly identified and annunciated. (Section 8.3.2.1.1.2 and 8.3.2.1.1.3)

(P-3.1) 13.2 kV Unit Auxiliary Power System

Unit Scope -

a. 1P-3.1 (Unit 1, common, and portions of Unit 2 system components)

b. 2P-3.1 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the capability of the 13.2 kV unit auxiliary power system to provide reliable electrical service to the 13.2 kV buses, which include feeder breakers for the 4 kV safeguard power system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Offsite power is available from both the 220 kV and the 500 kV substations. 125 V dc control power is available and operational.

Test Method - The 13.2 kV unit auxiliary buses are energized from both offsite power sources, and alarms and control devices are actuated.

Acceptance Criteria -

a. System breakers operate properly. (Vendor Technical Manual)

b. System automatic transfer circuits operate properly. (Electrical Schematic Diagrams)

c. Feeder breaker interlocks operate properly. (Electrical Schematic Diagrams)

d. System alarms operate properly. (Electrical Schematic Diagrams)

(P-4.1) 4 kV Safeguard Power System

Unit Scope -

a. 1P-4.1 (Unit 1 and common system components)

b. 2P-4.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the 4 kV safeguard power system to provide reliable electrical service to the 4 kV buses.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The 13.2 kV power and 125 V dc control power are available and operational.

Test Method - The 4 kV buses are energized, and system alarms and control devices are actuated.

Acceptance Criteria -

a. System breakers operate properly. (Section 8.3.1.1.2)

b. System automatic transfer circuits operate properly. (Section 8.3.1.1.2)

c. Feeder breaker interlocks operate properly. (Section 8.3.1.1.2)

d. System alarms operate properly. (Section 8.3.1.1.2)

(P-5.1) Safeguard 440 V Load Centers

Unit scope -

a. 1P-5.1 (Unit 1 system components)

b. 2P-5.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the safeguard 440 V load centers to provide reliable power to connected 440 V loads and motor control centers.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The 4 kV buses are available for energization of the 440 V load centers. The 125 V dc control power is available for operation of the 4 kV switchgear breakers.

Test Method - Breakers are operated to energize the 440 V load centers and motor control centers. System alarms and controls, both manual and automatic, are actuated.

Acceptance Criteria -

a. System breakers operate properly. (Section 8.3.1.1.2)

b. System bus voltages meet acceptable voltages. (Section 8.3.1.1.2)

c. System alarms operate properly. (Section 8.3.1.1.2)

(P-6.1) Safeguard 440 V Motor Control Centers

Unit scope -

a. 1P-6.1 (Unit 1 system components)

Table 14.2-4 (Cont'd)

b. 2P-6.1 (Unit 2 system components)

Test Objectives - The test objective is to demonstrate the capability of the safeguard 440 V motor control centers to provide reliable power to the motor control centers panels and loads.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The 440 V Class 1E load centers are available for energization of the 440 V motor control centers. 125 V dc control power is available for operation of the switchgear breakers.

Test Method - Breakers are operated to energize the 440 V motor control centers. System alarms and controls, both manual and automatic, are actuated.

Acceptance Criteria -

a. System breakers operate properly. (Section 8.3.1.1.2)

b. System bus voltages are acceptable. (Section 8.3.1.1.2)

c. System alarms operate properly. (Section 8.3.1.1.2)

(P-7.1) Standby Dc Lighting System

Unit scope -

a. 1P-7.1 (Unit 1 system components)

b. 2P-7.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the standby dc lighting system to provide emergency lighting on loss of normal lighting power.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Offsite ac power and 125 V dc power are available.

Test Method - The standby dc lighting panels are energized from their normal ac supply. The normal power supply is interrupted, and 125 V dc power is verified as an emergency lighting power source. Adequate illumination exists for safe plant operation.

Acceptance Criteria -

a. System breakers operate properly. (Section 9.5.3.2.2)

b. System supply voltages are acceptable. (Section 9.5.3.2.2)

c. System automatic transfer devices operate properly. (Section 9.5.3.2.2)

Table 14.2-4 (Cont'd)

d. Adequate illumination exists for safe plant operation. (Section 9.5.3.2.2)

(P-11.1) Service Water System

Unit Scope -

a. 1P-11.1 (Unit 1, common, and portions of Unit 2 system components)

b. 2P-11.1 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the ability of the service water system to furnish cooling water to the heat exchangers, chillers, coolers, and condensers in the control structure, turbine, reactor, and radwaste buildings; to furnish dilution and injection water to the chlorination and acid systems; and to furnish seal water to miscellaneous components.

Prerequisites - To the extent necessary to perform this test, the construction is completed and instrumentation and controls are operable. The circulating pump structure and cooling tower basin are available and operable to support this test.

Test Method - Operate the service water pumps in single and dual pump modes, and verify adequate flow to the service water components.

Acceptance Criteria -

a. Service water pumps operate properly. (Section 9.2.1)

b. Service water system provides an adequate water supply to system loads in the normal mode of operation. (Section 9.2.1)

c. Service water system provides an adequate water supply to system loads in the winter bypass mode of operation. (Section 9.2.1)

d. System alarms operate properly. (Section 9.2.1)

(P-13.1) Fire Protection Water System

Unit Scope -

a. 1P-13.2 (Unit 1, common, and portions of Unit 2 system components)

b. 2P-13.2 (Unit 2 remaining system components)

Test Objectives - The test objective is to demonstrate that the fire protection water system operates as designed, to supply fire water to required areas.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Sufficient water is available in the cooling tower basin to conduct the test.

Test Method - The fire protection water system is placed in operation, and performance data are obtained for the diesel and electric fire pumps. System controls and alarms are actuated, including auto and manual initiation of system sprinklers. The transformer deluge is activated and the system hose reel and hydrants are operated.

Acceptance Criteria -

a. System pumps meet acceptable head and flow values. (Section 9.5.1)

b. System automatic and manual initiation operate properly. (Section 9.5.1)

c. System sprinklers operate properly. (Section 9.5.1)

d. System hydrants and hose reels operate properly. (Section 9.5.1)

e. System deluge patterns are acceptable. (Section 9.5.1)

(P-13.2) Fire Protection CO_2 System

Unit Scope -

a. 1P-13.2 (Unit 1, common, and portions of Unit 2 system components)

b. 2P-13.2 (Unit 2 remaining system components)

Test Objectives - The test objective is to demonstrate the capability of the fire protection carbon dioxide system to initiate CO_2 release to designated areas, as designed.

Prerequisites - To the extent necessary to perform this test, construction is completed and instrumentation and controls are operable and calibrated. Sufficient CO_2 is available for the required discharge tests.

Test Method - CO_2 discharge is initiated manually. Operation of dampers by CO_2 is verified.

Acceptance Criteria -

a. System manual initiation operates properly. (Section 9.5.1)

b. Damper operation is acceptable. (Section 9.5.1)

c. System alarms operate properly. (Section 9.5.1)

Table 14.2-4 (Cont'd)

(P-13.3) Fire Protection Air Foam System

Unit Scope -

a. 1P-13.3 (Unit 1 and common)

Test Objective - The test objective is to demonstrate that the fire protection air foam system delivers air foam to designated areas.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The fire protection water system is operable and capable of supplying sufficient water to the foam eductor.

Test Method - The air foam system is manually initiated, and foam is produced.

Acceptance Criteria -

a. System manual initiation operates properly. (Section 9.5.1.2.5)

b. System foam production is acceptable. (Section 9.5.1.2.5)

(P-13.4) Smoke Detection System

Unit scope -

a. 1P-13.4 (Unit 1 system components)

b. 2P-13.4 (Unit 2 system components)

Test Objectives - The test objective is to demonstrate the proper operation of the smoke detection system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Smoke, fire, and trouble conditions are simulated, and system local and remote alarms and indication are verified.

Acceptance Criteria -

a. System detectors operate properly. (Section 9.5.1.2.9 and Appendix 9A.2.12)

b. System alarms and indicators operate properly. (Section 9.5.1.2.9 and Appendix 9A.2.12)

Table 14.2-4 (Cont'd)

(P-13.5) Fire Protection Halon System

Unit scope -

a. 1P-13.5 (Unit 1 system components)

b. 2P-13.5 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the fire protection halon to all floor sections, as designed.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Sufficient Halon is available for the required discharge tests.

Test Method - Smoke and heat detectors are activated, and automatic initiation is simulated. System is manually initiated, and proper Halon distribution is verified. Trouble conditions are simulated, and proper alarm annunciation is verified.

Acceptance Criteria -

a. Smoke detectors actuate early warning alarms. (Section 9.5.1.2.7)

b. Heat detectors actuate predischarge alarms followed by automatic discharge after a time-delay. (Section 9.5.1.2.7)

c. System automatic and manual initiation is acceptable. (Section 9.5.1.2.7)

d. Halon distribution to all floor sections is acceptable. (Section 9.5.1.2.7)

e. System alarms operate properly. (Section 9.5.1.2.7)

(P-14.1) Reactor Enclosure Cooling Water System

Unit Scope -

a. 1P-14.1 (Unit 1 system components)

b. 2P-14.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the RECW system to provide sufficient cool water to designated equipment in the reactor enclosure.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The service water system is available to provide cooling water for the system.

Table 14.2-4 (Cont'd)

Test Method - The RECW system is placed in operation, and pump performance data are obtained. System controls and alarms are actuated.

Acceptance Criteria -

a. System pumps meet acceptable head and flow values. (Section 9.2.8.2)

b. System head tank level controls maintain tank level properly. (Section 9.2.8.2)

c. System pump automatic start features operate properly. (Section 9.2.8.2)

d. The reactor recirculation pump seal and motor oil cooler isolation valves and their logic circuits operate properly. (Section 9.2.8.2)

e. Flow is verified to each system component. (Section 9.2.8.2)

f. System alarms operate properly. (Section 9.2.8.5)

(P-15.1) Turbine Enclosure Cooling Water System

Unit Scope -

a. 1P-15.1 (Unit 1 system components)

b. 2P-15.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the TECW system to provide sufficient cooling water to designated equipment in the turbine enclosure.

Prerequisites - To the extent necessary to perform this test, construction is completed and instrumentation and controls are operable and calibrated. The service water system is available to provide cooling water for the system.

Test Method - The TECW system is placed in operation, and pump performance data is obtained. System controls and alarms are actuated.

Acceptance Criteria -

a. System pumps operate properly. (Section 9.2.9)

b. Standby pump automatic starting controls function properly. (Section 9.2.9)

c. System head tank level controls maintain proper tank level. (Section 9.2.9)

d. System provides cooling water to system components. (Section 9.2.9)

e. System alarms operate properly. (Section 9.2.9)

Table 14.2-4 (Cont'd)

(P-16.1) Residual Heat Removal Service Water System

Unit Scope -

a. 1P-16.1 (Unit 1, common, and portions of Unit 2 system components)

b. 2P-16.1 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate that under normal and emergency conditions, the RHRSW system supplies cooling water as designed.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Required portions of the cooling tower are operable, and the spray pond has water to operate the RHRSW pumps. The RHR heat exchangers are installed to provide a flow path for the pumps. The ESW system is available to support the flow verification test, as applicable.

Test Method - The RHRSW pumps and their controls are operated, and flow is measured for normal system operation modes. System automatic valve alignment is initiated for high radiation and ESW pump start. The high radiation pump trip and the manual override operations are conducted. The spray networks are visually inspected for evenly distributed flow. System alarms are also actuated.

Acceptance Criteria -

a. System pumps meet acceptable head and flow values for different system modes of operation. (Section 9.2.3.2)

b. System logic circuits operate properly. (Section 9.2.3.2)

c. System is operable from both the control room and the remote shutdown panel. Remote shutdown panel instrumentation operates properly. (Section 9.2.3.2)

d. RHRSW cross-ties to the cooling towers and to the ESW system pump circuits operate properly. (Section 9.2.3.2)

e. System alarms operate properly. (Section 9.2.3.5)

f. All key-locks and automatic features operate properly. (Section 9.2.3.2)

(P-17.1) Instrumentation Ac Power System

Unit Scope -

a. 1P-17.1 (Unit 1 system components)

b. 2P-17.1 (Unit 2 system components)

Table 14.2-4 (Cont'd)

Test Objectives - The test objective is to demonstrate the capability of the instrumentation ac power system to supply electrical power to the 120 V ac instrument panels.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The 440 V ac power is available for energization of the instrumentation ac panels.

Test Method - Breakers are operated to energize the instrument ac panels, and system alarms and control devices are actuated.

Acceptance Criteria -

a. System 440 V ac breakers operate properly. (Vendor Technical Manual)

b. System bus voltages are acceptable. (Section 8.3.1.1.2)

c. System ac electrical power is available to all system distribution panels and instrument panels. (Electrical Single-Line Diagram)

(P-18.1) Instrument Air System

Unit Scope -

a. 1P-18.1 (Unit 1, common, and portions of Unit 2 system components)

b. 2P-18.1 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the capability of the instrument air system to provide dry compressed air at the rated capacity.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Air dryer chambers are filled with desiccant, and TECW is available.

Test Method - The system is placed in operation both automatically and manually, and performance data are obtained. Proper air distribution is verified. System control devices and alarms are actuated.

Acceptance Criteria -

a. System compressors discharge pressure, temperature, and capacity are within specified limits. (Section 9.3.1.1.2)

b. Compressor trips, interlocks, and automatic start logic operate properly. (Section 9.3.1.1.2)

c. Air dryer cycles are proper, and air moisture content is maintained within specified limits. (Section 9.3.1.1.2)

Table 14.2-4 (Cont'd)

d. System supplies air to each major distribution area. (Section 9.3.1.1.2)

e. System alarms operate properly. (Section 9.3.1.1.5)

(P-23.1) Diesel Generator Fuel Oil System

Unit Scope -

a. 1P-23.1 (Unit 1 and common system components)

b. 2P-23.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the diesel generator fuel oil system is capable of supplying fuel oil to the standby diesel generator day tanks.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are available and operational. Adequate fuel oil is present in the diesel oil storage tanks.

Test Method - The diesel oil transfer pumps are operated, and performance data are measured. System alarms and control devices are also actuated.

Acceptance Criteria -

a. System pumps meet acceptable delivery capability. (Section 9.5.4.2)

b. Automatic operation of the diesel oil transfer pumps is acceptable. (Section 9.5.4.2)

c. Each diesel oil transfer pump is capable of supplying any of the four diesel oil day tanks. (Section 9.5.4.2)

d. System alarms operate properly. (Section 9.5.4.5)

(P-24.1) Standby Diesel Generator System

Unit Scope -

a. 1P-24.1 (Unit 1 system components)

b. 2P-24.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the standby diesel generator system to provide reliable electric power to Class 1E buses.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Temporary cooling water, diesel

generator enclosure HVAC, 125 V dc power, fuel oil, and fire protection are available for diesel generator operation.

Test Method - The diesel generators are started both manually and automatically. Starting times and repetitive starting capability are determined. Diesel generator and auxiliary systems performance is measured and adequate reliability is demonstrated. System protection alarms and controls are also actuated. This test, in conjunction with Tests P-100.1 (Loss of Offsite Power) and P-100.4 (Standby Diesel Generator Loading), constitutes the individual diesel generator preoperational testing program.

Acceptance Criteria -

a. Each diesel generator is automatically started on simulated automatic actuation signals and reaches the required voltage and frequency within an acceptable time. (Section 8.3.1.1.3)

b. Electrical interlocks between the diesel generators and their associated 4 kV buses operate properly. (Section 8.3.1.1.3)

c. Each diesel generator is capable of being stopped and started manually from local and remote locations. (Section 8.3.1.1.3)

d. Each diesel generator air starting system, fuel oil system, oil lubrication system, and its air supply and exhaust systems operate properly. (Sections 9.5.4, 9.5.6, 9.5.7, and 9.5.8)

e. Each system breaker operates properly. (Vendor Technical Manual)

f. System alarms and logics operate properly. (Section 8.3.1.1.3)

g. Each diesel generator operates properly during the transient following a complete loss of load. (Section 8.3.1.1.3)

h. When operating in test (droop) mode parallel to the grid, each diesel generator breaker opens and governor converts to automatic (isochronous) mode upon receipt of a LOCA signal, and continues to operate.

i. Each diesel generator is capable of starting a minimum of 23 consecutive times with no failures.

(P-25.1) Primary Containment Instrument Gas System

Unit Scope -

a. 1P-25.1 (Unit 1 system components)

b. 2P-25.1 (Unit 2 system components)

Test Objective - The test objectives are to demonstrate the capability of the PCIG system to provide compressed gas at proper temperature and moisture content for containment services, and to demonstrate system isolation following a primary containment isolation signal.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The service water system is available to provide the cooling water requirements of the system, as applicable.

Test Method - The system is placed in operation automatically and manually, and performance data are obtained. System controls and alarms are actuated, including operation of the systems containment isolation valves upon a simulated primary containment isolation signal. System valves are realigned to utilize the backup containment instrument gas supply from the plant instrument air system.

Acceptance Criteria -

a. System compressors meet acceptable values of discharge pressure and capacity. (Section 9.3.1.3)

b. Compressor trips, interlocks, and start logic operate properly. (Section 9.3.1.3)

c. System isolation valves operate properly. (Section 6.2.4)

d. System alarms operate properly. (Section 9.3.1.3.5)

e. Gas temperature and moisture content are maintained within specified limits. (Section 9.3.1.3)

f. Both system components fail independently. (Section 9.3.1.3)

(P-28.1) Diesel Generator Enclosure HVAC System

Unit Scope -

a. 1P-28.1 (Unit 1 system components)

b. 2P-28.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the standby diesel generator enclosure HVAC system to provide air flow to respond to simulated room temperature variations.

Prerequisites - To the extent necessary to perform this test, construction is completed and instrumentation and controls are operable and calibrated.

Test Method - The fans are started automatically and manually. System alarms are also actuated.

Acceptance Criteria -

a. Each diesel generator cell's unit heaters operate properly. (Section 9.4.6)

b. Each cell's exhaust fans operate properly. (Section 9.4.6)

c. Enclosure cell exhaust fan and damper operating logic, including automatic start, automatic stop, and standby operation, operates properly. (Section 9.4.6)

d. System alarms operate properly. (Section 9.4.6.5)

(P-28.2) Spray Pond Pumphouse HVAC System

Unit Scope -

a. 1P-28.2 (Common system components)

Test Objective - The test objective is to demonstrate the capability of the spray pond pumphouse HVAC system to provide air flow and temperature control in the pumphouse.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The spray pond pumphouse HVAC system is placed in service. Enclosure temperature variations are simulated and system response verified. System controls, logics, and alarms are actuated. System parameters are monitored and recorded.

Acceptance Criteria -

a. Each system unit heater operates properly. (Section 9.4.7)

b. Each system supply fan operates properly. (Section 9.4.7)

c. Supply fan and damper logic operates properly. (Section 9.4.7.5)

d. System alarms operate properly. (Section 9.4.7.5)

(P-30.1) Control Enclosure HVAC System

Unit Scope -

a. 1P-30.1 (Unit 1, Unit 2 and Common system components)

Test Objective - The test objective is to demonstrate the capability of the control enclosure HVAC system to provide air flow and temperature control in the structure by simulated room temperature variations.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. North vent stack and battery room exhaust fans are available for system operation.

Test Method - Control structure temperature variations are simulated and system response verified. The auxiliary equipment enclosure is purged, and system alarms and control devices are actuated. System parameters are monitored and recorded for systems cooling ESF components.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. System fans operate properly. (Section 9.4.1)

b. System unit heaters operate properly. (Section 9.4.1)

c. System automatic start features and fan interlocks operate properly. (Section 9.4.1)

d. System fan and damper logic operates properly. (Section 9.4.1)

e. System alarms operate properly. (Section 9.4.1.9)

f. Results of in-place filter efficiency testing are acceptable.

(P-30.2) Control Enclosure Chilled Water System

Unit Scope -

a. 1P-30.2 (Common system components)

Test Objective - The test objective is to demonstrate the ability of the CECWS to provide chilled water flow for cooling the air supply to the control room, the auxiliary equipment compartment, the emergency auxiliary switchgear and battery compartments, and the SGTS area.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The demineralized water and ESW systems are available to provide the water requirement of the system.

Test Method - Chiller operation, chilled water circulation pump operation, and system alignment are initiated by automatic start and manual signals. Flow paths are verified. System alarms are also actuated.

Acceptance Criteria -

a. System circulation pumps meet acceptable head and discharge values. (Section 9.2.10.2)

b. System water chillers operate properly. (Section 9.2.10.2)

c. Flow is verified to each system component. (Section 9.2.10.2)

d. System alarms operate properly. (Section 9.2.10.2)

Table 14.2-4 (Cont'd)

(P-32.1) Control Room HVAC System

Unit Scope -

a. 1P-32.1 (Common system components)

Test Objective - The test objective is to demonstrate the capability of the control room HVAC system to provide air flow and temperature control in the control room by simulated room temperature variations.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The fans are placed in operation. Control room temperature variations are simulated and system response is verified. Control devices are actuated to automatically align the system and to maintain positive pressure within the control room. Room air leakage is measured and system alarms are also actuated.

Acceptance Criteria -

a. System fans operate properly. (Sections 9.4.1 and 6.4)

b. System fan automatic start features and interlocks operate properly. (Sections 9.4.1 and 6.4)

c. System fan and damper logic operates properly. (Sections 9.4.1 and 6.4)

d. System alarms operate properly. (Sections 9.4.1 and 6.4)

e. Air leakage from control room does not exceed design. (Sections 9.4.1 and 6.4)

(P-32.2) Control Room Isolation and Purge System

Unit Scope -

a. 1P-32.2 (Common system components)

Test Objective - The test objective is to demonstrate the capability of the control room isolation and purge system to isolate the control room from radiation or chlorine entering through the control room ventilation system and to purge the control room of smoke.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The following systems are available for operation: the control room supply and return air system and the control room emergency fresh air supply system.

Test Method - High radiation and chlorine conditions are simulated to verify the automatic isolation of the control room. The control room purge system is actuated and system response verified. System alarms are actuated.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. The control room is isolated and maintained at a positive pressure during a high radiation condition. (Sections 9.4.1 and 6.4)

b. The control room emergency fresh air supply system automatically starts during a high radiation condition. (Sections 9.4.1 and 6.4)

c. The control room is completely isolated during a high chlorine condition. (Sections 9.4.1 and 6.4)

d. System purge mode operates properly. (Sections 9.4.1 and 6.4)

e. System alarms operate properly. (Sections 9.4.1 and 6.4)

f. Results of in-place filter efficiency testing are acceptable.

(P-33.1) Turbine Enclosure HVAC System

Unit Scope -

a. 1P-33.1 (Unit 1 system components)

b. 2P-33.1 (Unit 2 system components)

Test Objectives - The test objective is to demonstrate the capability of the turbine enclosure HVAC system to provide air flow and temperature control in the structure by simulated room temperature variations.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The turbine enclosure HVAC system is placed in operation. Enclosure temperature variations are simulated, and system response is verified. System controls, logics, and alarms are actuated.

Acceptance Criteria -

a. System fans operate properly. (Section 9.4.4)

b. System fan and damper logic operates properly. (Section 9.4.4)

c. System cooling coils and temperature control valves operate properly. (Section 9.4.4)

d. System heating coils and temperature control valves operate properly. (Section 9.4.4)

e. Results of in-place filter efficiency testing are acceptable.

Table 14.2-4 (Cont'd)

f. System alarms operate properly. (Section 9.4.4.5)

(P-34.1) Reactor Enclosure HVAC System

Unit Scope -

a. 1P-34.1 (Unit 1 system components)

b. 2P-34.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the reactor enclosure HVAC system to provide normal air flow and temperature control in the enclosure.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The turbine enclosure north and south vent stacks are available to support this test.

Test Method - The fans are placed in operation. Control devices are actuated. System alarms are also actuated.

Acceptance Criteria -

a. System fans operate properly. (Section 9.4.2)

b. System fan standby features, interlocks, permissives, and automatic start circuits operate properly. (Section 9.4.2)

c. System alarms operate properly. (Section 9.4.2.2.5)

d. Results of in-place filter efficiency testing are acceptable

(P-34.2) Refueling Area HVAC System

Unit Scope -

a. 1P-34.2 (Unit 1 system components)

b. 2P-34.2 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the refueling area HVAC system to provide normal air flow and fuel handling accident mode air flow and temperature control to the refueling area.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The turbine enclosure north and south vent stacks are available to support this test. The SGTS is operational.

Test Method - The fans are placed in operation. Control devices are actuated to isolate the refueling area, and the system is operated in its fuel handling accident mode. System alarms are also actuated.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. System fans operate properly. (Section 9.4.2)

b. System fan standby features, interlocks, permissives, and automatic start circuits operate properly. (Section 9.4.2)

c. System unit heaters and cooling coil operate properly. (Section 9.4.2)

d. System alarms operate properly. (Section 9.4.2.2.5)

e. Refueling area isolation logic operates properly. (Section 9.4.2)

(P-35.1) Fuel Pool Cooling and Cleanup System

Unit Scope -

a. 1P-35.1 (Unit 1 system components)

b. 2P-35.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the FPCC system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Makeup water from the demineralized water tank is available. The RHR system is capable of supplying water to system diffusers.

Test Method - System pumps are placed in operation and system flow paths are verified. System controls are verified. System filter cycles are verified.

Acceptance Criteria -

a. System pumps meet acceptable head and flow values. (Section 9.1.3)

b. System controls operate properly. (Section 9.1.3)

c. Filter hold, precoat, and backwash controls operate properly, (Section 9.1.3)

d. Siphon breaker holes in the system return lines operate properly. (Section 9.1.3)

e. Fuel transfer canal gates prevent excessive water loss from the spent fuel pool when adjacent cavities are empty. (Section 9.1.3)

f. System alarms operate properly. (Section 9.1.3.5)

Table 14.2-4 (Cont'd)

(P-37.1) Condensate and Refueling Water Transfer System

Unit Scope -

a. 1P-37.1 (Unit 1 and common system components)

b. 2P-37.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the condensate and refueling water transfer system to transfer water from the CSTs and refueling water tanks to various systems.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Demineralized water, plant heating steam, and instrument air systems are operable.

Test Method - System is operated, and power-operated valves are cycled both automatically and manually. Flow is directed through each flow path. Tank levels and temperatures are simulated, and control system operation is verified.

Acceptance Criteria -

a. System pump's head and capacity are within specified limits. (Section 9.2.7)

b. Pump trips and control logic operate properly. (Section 9.2.7)

c. Power-operated valves operate properly. (Section 9.2.7)

d. Condensate and refueling water temperature controls operate properly. (Section 9.2.7)

e. Flow is verified through each major flow path. (Section 9.2.7)

f. System alarms operate properly. (Section 9.2.7.5)

(P-39.1) Condensate Demineralizer System

Unit Scope -

a. 1P-39.1 (Unit 1 system components)

b. 2P-39.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the condensate demineralizer system to maintain condensate feedwater chemistry and the ability of the precoat and backwash systems to operate properly.

Prerequisites - To the extent necessary to support this test, construction is completed, and instrumentation and controls are operable. The condensate system is operable and lined up to recirculate water to the hotwells via the feed pump bypass and startup recirculation lines. The instrument air system and process sampling systems are operational. Refueling water pumps are operational, and sufficient water is available in the refueling water tank to support this test.

Table 14.2-4 (Cont'd)

For Unit 2, the refueling water pumps and refueling water will not be used prior to tie-in to common plant systems. Unit 2 testing will be performed utilizing temporary equipment in order to avoid contamination. Low pressure air blower is operational, and the backwash receiving tank is operational with sufficient volume to support this test.

Test Method - The filter/demineralizer units are placed in operation, and their controls are operated. Effluent water purity is verified. Flow rates, flow controls, and system flow balancing are verified. Automatic precoat cycle operation is verified for each vessel.

Acceptance Criteria -

a. Vessel cleaning and precoat cycles operate properly. (Vendor Technical Manual)

b. Each demineralizer produces effluent water of the proper quality. (Section 10.4.6)

c. The system flow balancing system operates properly. (Section 10.4.6)

d. The cation and anion feeders supply resin to the precoat tank. (Vendor Technical Manual)

e. The precoat pump and the system hold pumps operate properly. (Section 10.4.6)

f. System pneumatic valves operate properly. (Section 10.4.6)

g. System controls, interlocks, and alarms operate properly. (Section 10.4.6)

(P-41.1) Cooling Tower System

Unit Scope -

a. 1P-41.1 (Unit 1 system components)

b. 2P-41.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the cooling tower chlorination system, sulfuric acid injection system, icing control system, and makeup water flow control valves.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The service water system, circulating water system, Schuylkill river makeup water system, instrument air system, circulating water pumphouse domestic water supply, and the circulating water pump structure power roof ventilators are operational as required to support the test.

Test Method - The cooling tower chlorination system, sulfuric acid injection system, icing control system, and makeup water flow control valves are placed in operation. Each system response to simulated cooling tower conditions is verified. System controls logics, and alarms are operated.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. The cooling tower chlorination system operates properly. (Section 10.4.5.1)

b. The cooling tower sulfuric acid injection system operates properly. (Section 10.4.5.1)

c. The cooling tower icing control system operates properly. (Vendor Technical Manual)

d. The cooling tower makeup water flow control valves operate properly. (Section 10.4.5.2)

e. System alarms operate properly. (Section 10.4.5.1.5)

(P-42.1) Circulating Water System

Unit Scope -

a. 1P-42.1 (Unit 1 system components)

b. 2P-42.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the circulating water system delivers cooling water to the main condenser as designed.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The cooling tower is operational, and the circulating water system is filled sufficiently to operate the circulating water pumps. The main condenser is available to receive cooling water.

Test Method - The circulating water pumps and their controls are operated. System flows and flow paths are measured and verified. The water box scavenging pumps and their controls are operated. The main condenser fill and drain system is operated.

Acceptance Criteria -

a. Circulating water pumps head and flow are acceptable. (Section 10.4.5.1)

b. System automatic valves operate properly. (Section 10.4.5.1)

c. System controls, interlocks, and permissives operate properly. (Section 10.4.5.1)

d. Water box scavenging pumps operate properly. (Section 10.4.5.1)

e. Main condenser drain and fill system operates properly. (Section 10.4.5.1)

f. Circulating water winter bypass flow is acceptable. (Section 10.4.5.1)

Table 14.2-4 (Cont'd)

g. System alarms operate properly. (Section 10.4.5.1.5)

(P-43.1) Condenser and Air Removal System

Unit Scope -

a. 1P-43.1 (Unit 1 system components)

b. 2P-43.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the main condenser air removal system to both pull and hold a vacuum in the main condenser.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are calibrated. The main turbine is on the turning gear with steam seals established.

Test Method - With the turbine on turning gear and necessary support systems operating, the mechanical vacuum pumps are operated to initially pull a vacuum on the main condenser. The SJAEs, using auxiliary steam, are then cut in to maintain an acceptable vacuum.

Acceptance Criteria -

a. The mechanical vacuum pump pulls an acceptable vacuum. (Section 10.4.2)

b. The SJAEs maintain an acceptable vacuum. (Section 10.4.2)

c. System logics and alarms operate properly. (Section 10.4.2.5)

d. System offgas isolation operates properly. (Section 10.4.2)

(P-44.1) Condensate System

Unit Scope -

a. 1P-44.1 (Unit 1 system components)

b. 2P-44.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the condensate system to supply water to the feedwater system, and the proper operation of system controls.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

The feedwater system is available to provide a flow path back to the main condenser. The condenser and the condensate storage system have sufficient water to operate the condensate pumps. TECW is available.

Table 14.2-4 (Cont'd)

Test Method - The condensate pumps and their controls are operated. System flows and flow paths are measured and verified. Automatic pump minimum flow control as well as the ability of the makeup and reject system to control hotwell level is demonstrated. Major valves are operated to demonstrate the ability to isolate sections of the system.

Acceptance Criteria -

a. Condensate pump head and flow meet acceptable values. (Section 10.4.7.2.1)

b. Pump controls, interlocks, and permissives operate properly. (Section 10.4.7.2.1)

c. System MOVs operate properly. (Section 10.4.7.2.1)

d. System makeup valves and logics operate properly. (Section 10.4.7.2.1)

e. Condensate pump recirculation flow meets acceptable values. (Section 10.4.7.2.1)

f. System alarms operate properly. (Section 10.4.7.5)

(P-45.1) Feedwater System

Unit Scope -

a. 1P-45.1 (Unit 1 system components)

b. 2P-45.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the reactor feedwater pumps, their turbine drivers, and the feedwater control system, and to verify that the feedwater system functions to the degree that is possible with the limited steam available. For Unit 2 (Test 2P-45.1), an additional objective is to demonstrate the ability of the turbine supervisory system to monitor the operation of the reactor feedwater pump-turbines. For Unit 1 this was tested by Test 1P-93.3.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The condensate system is available for supplying water to the feedwater pumps. The auxiliary steam system is able to supply steam to the feedwater pump-turbine drivers. The main condenser is available to receive the turbine exhaust. The service water system is available to satisfy the system's cooling water requirements.

Test Method - The feedwater pump-turbine drivers are first operated uncoupled from the pumps. After coupling and with the condensate system running, each feedwater pump is operated separately, recirculating water back to the condenser. System controls and alarms are actuated, including operation of the feedwater pump minimum flow valves and the feedwater pump-turbine lube oil system. Feedwater control system inputs are verified. Various inputs are simulated and output response to small and large signal changes is checked.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. The reactor feed pumps and turbines operate properly using the auxiliary steam supply. (Section 10.4.7.2.2)

b. Reactor feed pump recirculation valves operate properly. (Section 10.4.7.2.2)

c. Reactor feed pump turbine lube oil systems operate properly. (Section 10.4.7.2.2)

d. Reactor feed pump seals operate properly. (Section 10.4.7.2.2)

e. Feedwater control system inputs operate properly. (Section 7.7.1.4)

f. Feedwater control system response is proper to simulated small and large signal changes. (Section 7.7.1.4)

g. System MOVs and AOVs operate properly. (Section 10.4.7.2.2)

h. System instruments and alarms operate properly. (Sections 10.4.7.3 and 10.2.5.a and Vendor Technical Manual)

i. Each feed pump and its associated feedwater heater can be isolated for maintenance with pressure in the system. (Section 10.4.7.2.2)

j. Feedwater control system outputs are proper during simulated operation. (Section 7.7.1.4)

(P-46.1) Extraction Steam and Feedwater Heater System

Unit Scope -

a. 1P-46.1 (Unit 1 system components)

b. 2P-46.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate operability of the extraction steam and feedwater heater level control and automatic isolation systems.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Turbine trip and pressure signals are simulated, and automatic isolation valve and bleeder trip check valve operation are verified. Feedwater heater level signals are simulated to verify proper response of drain valves, dump valves, bleeder trip valves, and extraction line drain valves. System alarms are actuated.

Acceptance Criteria -

a. Bleeder trip check valve closing times and extraction steam line drain valve opening times are acceptable. (Section 10.2.2.4)

Table 14.2-4 (Cont'd)

b. Valve interlocks and logic operate properly. (Section 10.2.2.4)

c. System alarms operate properly. (Section 10.2.2.4)

(P-49.1) Residual Heat Removal System

Unit Scope -

a. 1P-49.1 (Unit 1 system components)

b. 2P-49.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the RHR system delivers cooling water for each of the following system modes of operation: shutdown cooling, LPCI, suppression pool cooling, and fuel pool cooling.

Prerequisites - To the extent necessary to perform this test, construction is completed, instrumentation and controls are operable and calibrated, and testing of relief and safety valves is completed. The RPV is available and filled with water above the minimum level required to provide suction to the RHR pumps. The recirculation loops are complete to the extent required for system operation in the shutdown cooling mode. The ESW system is available to provide cooling water to the RHR pumps. The suppression pool is available and filled above the low water level to provide suction to the RHR pumps. The fuel pool and fuel pool skimmer surge tanks are full of water and available for fuel pool cooling mode operation.

Test Method - The operating modes of the RHR system are initiated manually from the control room and remote shutdown panel and, where applicable, automatically. RHR pump performance is determined for each mode. System flow paths are verified. The containment spray flow path is demonstrated by an air flow test that overlaps with the pump water flow path. Adequate NPSH and absence of vortexing is verified by testing the pumps at the lowest suppression pool level allowed by the Technical Specifications (Unit 1), or by testing the pumps at approximately the lowest level that will be reached by the suppression pool during the course of a LOCA while the pumps are operating (Unit 2). System controls and alarms are actuated. Watertight door gaskets and dogs are inspected and operated. Room flood detectors are operated.

Acceptance Criteria -

a. RHR pumps meet acceptable values of head and flow for system operating modes. (Sections 6.3.2.2.4 and 5.4.7)

b. System valves are operable from the control room, and all key-locks operate properly. (Sections 6.3.2.2.4 and 5.4.7)

c. The system operates properly to provide supplemental fuel pool cooling. (Sections 6.3.2.2.4 and 5.4.7)

d. The system operates properly in the shutdown cooling mode. (Sections 6.3.2.2.4 and 5.4.7)

Table 14.2-4 (Cont'd)

e. The system operates properly in the suppression pool cooling mode. (Section 7.2.1.1.5)

f. The system operates properly in the LPCI mode. (Section 7.3.1.1.4)

g. Steam condensing valves and logic operate properly. (Sections 6.3.2.2.4 and 5.4.7)

h. Containment spray valves and logic operate properly. (Section 7.3.1.1.4)

i. The RHR room flood detector operates properly. (Sections 6.3.2.2.4 and 5.4.7)

j. System alarms operate properly. (Sections 6.3.2.2.4 and 5.4.7)

k. The condensate transfer system and the safeguard piping fill pumps are each capable of maintaining full RHR pump discharge lines. (Section 6.3.2.2.6)

l. Remote shutdown panel instrumentation and controls operate properly. (Sections 6.3.2.2.4 and 5.4.7)

m. System overpressure protection interlocks operate properly. (Sections 6.3.2.2.4 and 5.4.7)

n. NPSH is within specified limits, and no vortexing is present. (Section 6.3.2.2.5)

o. Watertight doors exhibit a full seal when dogged down. (Vendor Technical Specification)

(P-50.1) Reactor Core Isolation Cooling System

Unit Scope -

a. 1P-50.1 (Unit 1 system components)

b. 2P-50.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the RCIC system in delivering water to the reactor vessel and to verify proper separation of the RCIC dc components by observing the effect of disconnecting the RCIC dc bus on RCIC operation.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The CST and suppression pool are filled above the low water level to provide suction to the pump, and auxiliary steam is available to supply steam to the RCIC pump-turbine driver.

Test Method - RCIC system operation is initiated from the control room and remote shutdown panel by manual and automatic start signals. Pump and turbine performance is verified. System controls and alarms are actuated. During system testing, the RCIC dc bus will be disconnected to verify inoperability of the RCIC system. Adequate NPSH and absence of vortexing is verified by testing the pumps at the lowest suppression pool level allowed by the Technical Specifications (Unit 1), or

Table 14.2-4 (Cont'd)

by testing the pumps at approximately the lowest level that will be reached by the suppression pool during the course of a LOCA while the pumps are operating (Unit 2).

Watertight door gaskets and dogs are inspected and operated. Room flood detectors are operated.

Acceptance Criteria -

a. The RCIC turbine controls and logic operate properly. (Sections 5.4.6 and 7.4.1.1)

b. The RCIC pump and turbine operate properly using their auxiliary steam supply. (Sections 5.4.6 and 7.4.1.1)

c. System manual and automatic initiation logic operate properly. (Sections 5.4.6 and 7.4.1.1)

d. The RCIC room flood detector operates properly. (Sections 5.4.6 and 7.4.1.1)

e. System alarms operate properly. (Sections 5.4.6 and 7.4.1.1)

f. Securing of the RCIC dc bus results in inoperability of the RCIC system. (Sections 5.4.6 and 7.4.1.1)

g. Remote shutdown panel instrumentation and controls operate properly. (Sections 5.4.6 and 7.4.1.1)

h. NPSH is within specified limits, and no vortexing is present. (Sections 5.4.6 and 7.4.1.1)

i. Watertight doors exhibit a full seal when dogged down. (Vendor Technical Specification)

Full flow and minimum start time criteria are not demonstrated until nuclear steam is available during the power test program.

(P-51.1) Core Spray System

Unit Scope -

a. 1P-51.1 (Unit 1 system components)

b. 2P-51.1 (Unit 2 system components)

Test Objectives - The test objective is to demonstrate the ability of the core spray system to deliver water spray to the reactor core.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The CST and the suppression pool are filled above the low water level. The RPV head is off, and the vessel is available to receive water from the core spray system.

Test Method - Core spray system operation is initiated and pump flow rates are measured in the various design modes of operation. System performance is verified. System controls and alarms are actuated. The safeguard piping fill system is operated and safeguard piping leakage is monitored. Adequate NPSH and absence of vortexing is verified by testing the pumps at the lowest suppression pool level allowed by the Technical Specifications (Unit 1), or by testing the pumps at approximately the lowest level that will be reached by the suppression pool during the course of a LOCA while the pumps are operating (Unit 2).

Acceptance Criteria -

a. The core spray pumps meet acceptable head and flow values. (Sections 6.3.2.2.3 and 7.3.1.1.1)

b. System manual and automatic initiation is acceptable. (Sections 6.3.2.2.3 and 7.3.1.1.1)

c. System MOVs operate properly. (Sections 6.3.2.2.3 and 7.3.1.1.1)

d. The core spray room flood detector operates properly. (Sections 6.3.2.2.3 and 7.3.1.1.1)

e. Systems alarms operate properly. (Sections 6.3.2.2.3 and 7.3.1.1.1)

f. Safeguard piping fill pumps operate properly and keep core spray discharge piping full. (Sections 6.3.2.2.3 and 7.3.1.1.1)

g. The condensate transfer system is capable of maintaining full core spray discharge lines. (Sections 6.3.2.2.3 and 7.3.1.1.1.3)

h. Total leakage from all safeguard piping fed by the safeguard piping fill pumps does not exceed the capability of the fill pumps. (Sections 6.3.2.2.3 and 7.3.1.1.1.3)

i. Core spray flow rates from the suppression pool to the reactor vessel are set to meet acceptance criteria by adjusting the size of the spray line discharge orifice. (Sections 6.3.2.2.3 and 7.3.1.1.1.3)

Table 14.2-4 (Cont'd)

j. System overpressure protection interlocks operate properly. (Sections 6.3.2.2.3 and 7.3.1.1.1.3)

k. NPSH is within specified limits, and no vortexing is present. (Sections 6.3.2.2.3 and 7.3.1.1.1.3)

(P-52.1) High Pressure Coolant Injection System

Unit Scope -

a. 1P-52.1 (Unit 1 system components)

b. 2P-52.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the HPCI system delivers cooling water to the RPV as designed.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The CST and the suppression pool are filled above the low water level to provide suction to the pump. The auxiliary boiler is available to provide steam to the HPCI pump-turbine driver.

Test Method - With the HPCI pumps uncoupled, performance of the turbine driver is measured, including operation of the turbine control and trip system. Limited pump operation (coupled) is conducted for all modes of operation (to the extent possible using auxiliary steam). System performance is determined. System controls and alarms are actuated. Adequate NPSH and absence of vortexing is verified by testing the pumps at the lowest suppression pool level allowed by the Technical Specifications (Unit 1), or by testing the pumps at approximately the lowest level that will be reached by the suppression pool during the course of a LOCA while the pumps are operating (Unit 2). Watertight door gaskets and dogs are inspected and operated. Room flood detectors are operated.

Acceptance Criteria -

a. The HPCI turbine controls and logic operate properly. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

b. The HPCI pump and turbine operate properly using the auxiliary steam supply. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

c. System automatic start, shutdown, and restart occur properly. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

d. Manual operation of system components is acceptable. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

e. Controls affecting the transfer of HPCI pump suction water supplies operate properly. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

Table 14.2-4 (Cont'd)

f. The HPCI room flood detector operates properly. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

g. System alarms operate properly. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

h. The condensate transfer system and a safeguard piping fill pump are each capable of maintaining a full HPCI pump discharge line. (Sections 6.3.1.2.1 and 7.3.1.1.1.1)

i. NPSH is within specified limits, and no vortexing is present. (Sections 6.3.2.2.1.1 and 6.3.2.2.1.2)

j. Watertight doors exhibit a full seal when dogged down. (Vendor Technical Specification)

Full flow and minimum start time criteria are not demonstrated until nuclear steam is available during the startup test program.

(P-53.1) Standby Liquid Control System

Unit Scope -

a. 1P-53.1 (Unit 1 system components)

b. 2P-53.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the proper operation of the SLCS.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The RPV is available for demineralized water injection. The SLCS tank is filled with demineralized water.

Test Method - The SLCS is manually placed in operation to the reactor in conjunction with the test firing of each squib operated valve. System performance is determined, including pump flow rates and tank heater operation. System controls and alarms are actuated.

Acceptance Criteria -

a. The standby liquid pumps meet acceptable values of flow and discharge pressure. (Section 3.9.3.1.12)

b. The standby liquid control tank temperature is controlled properly. (Section 9.3.5)

c. System manual initiation operates properly. (Section 9.3.5)

d. System automatic initiation operates properly. (Sections 7.4.1.2.3.2 and 7.6.1.8.3.4)

e. System alarms operate properly. (Section 9.3.5)

f. For each train, the connected explosive valve opens. (Section 9.3.5)

Table 14.2-4 (Cont'd)

(P-54.1) Emergency Service Water System

Unit Scope -

a. 1P-54.1 (Unit 1 system components)

b. 2P-54.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the ESW system supplies cooling water to safeguard equipment as designed.

Prerequisites - To the extent necessary for performance of this test, construction is completed, and instrumentation and controls are operable and calibrated. The cooling tower basin is operable, and the spray pond is at its normal operating level to provide water for the ESW pumps. The heat exchangers served by this system are available to provide a flow path for the pumps. Applicable portions of the RHRSW system are operable to support the flow verification test.

Test Method - The ESW system pumps are started manually and automatically. System controls in the control room and the remote shutdown station are operated and pump flow rates are measured. System alarms are also actuated.

Acceptance Criteria -

a. System pumps meet acceptable head and flow values for the various design flow paths. (Sections 9.2.2 and 7.3.1.1.11)

b. System pump automatic start features operate properly. (Sections 9.2.2 and 7.3.1.1.11)

c. System valves, controls and instrumentation are operable from both the control room and the remote shutdown panel; all key-locks and valve automatic features operate properly. (Sections 9.2.2 and 7.3.1.1.11)

d. System alarms operate properly. (Sections 9.2.2 and 7.3.1.1.11)

(P-55.1) Control Rod Drive Hydraulic System

Unit Scope -

a. 1P-55.1 (Unit 1 system components)

b. 2P-55.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the proper operation of the CRD hydraulic system, including CRD mechanisms, HCUs, power supply, instrumentation, and controls.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The condensate transfer and storage system, and the RMCS are available and operational to support the system test. The TECW system is available and operational to provide the cooling water requirement of the drive water pumps. The compressed air system is available and operational to provide the instrument air requirements of the system.

Test Method - The CRD hydraulic system is placed in operation utilizing the flow and pressure control stations. Pump controls are operated and flow rates measured. CRDs are exercised to verify latching, position indication, and stroke speeds. Scram times are measured for each control rod.

Acceptance Criteria -

a. The CRD hydraulic supply and discharge sections supply water at acceptable flow and pressure to the HCUs. (Sections 4.6.1 and 4.6.3)

b. Each HCU operates properly to drive its control rod at proper speeds. (Sections 4.6.1 and 4.6.3)

c. Position indication and latching operate properly. (Sections 4.6.1 and 4.6.3)

d. System alarms operate properly. (Sections 4.6.1 and 4.6.3)

(P-56.1) Reactor Manual Control System

Unit Scope -

a. 1P-56.1 (Unit 1 system components)

b. 2P-56.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate proper operation of the RMCS, including relays, control circuitry, switches, rod blocks, indicating lights, and control valves; and proper operation of the RWM system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - System integrated operation is initiated manually. Controls are operated, and simulated signals are applied to verify: rod blocks; alarms and interlocks and control functions of the reactor mode switch; operation of the rod position information system and rod drift alarm circuit; and directional control valve time sequence for insert and withdraw commands. Proper operation of the RWM system is verified.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. The system operates properly during both insert and withdrawal cycles. (Section 7.7.1.2)

b. Rod block functions, interlocks, bypasses, and indications are acceptable. (Section 7.7.1.2)

c. Rod position indication operate properly. (Section 7.7.1.2)

d. System alarms operate properly. (Section 7.7.1.2)

(P-57.1) Uninterruptible Ac Power System

Unit Scope -

a. 1P-57.1 (Unit 1 system components)

b. 2P-57.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the proper operation of the uninterruptible ac power system.

Prerequisites - To the extent necessary to perform this test, construction is completed and instrumentation and controls are operable and calibrated. The 250 V dc and 440 V motor control center buses are available for energization of the 120 V or 120/240 V uninterruptible ac distribution panel.

Test Method - The 120 V or 120/240 V uninterruptible ac distribution panels are energized from the 250 V dc power system and transfer to the 440 V ac power system is initiated. Other system controls and alarms are also actuated.

Acceptance Criteria -

a. System static inverters operate properly while supplying a design value of load. (Vendor Technical Manual)

b. System static inverter transfer time between alternate and preferred sources is acceptable. (Section 7.2.1.1.3)

c. System 440 V ac and 125/250 V dc breakers operate properly. (Vendor Technical Manual)

d. System bus voltages are acceptable. (Vendor Technical Manual)

e. System ac electrical power is available to all system distribution panels. (Electrical Single-Line Diagram)

Table 14.2-4 (Cont'd)

(P-58.1) Reactor Protection System

Unit Scope -

a. 1P-58.1 (Unit 1 system components)

b. 2P-58.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the RPS operates properly during integrated system functions.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The various RPS sensors, sensor relays and devices will be actuated and timed to designated points along the scram chain logic. RPS response measurements will be run twice for each channel. The plant operating technical specification trip setpoints will be demonstrated at least one time by actual application of an input to the sensor/device or stroking an associated valve to actuate position switches as appropriate.

Acceptance Criteria -

a. System input scram function signals cause trips within design values. (Section 7.2)

b. System actuated logics operate properly. (Section 7.2).

c. Scram modes and bypasses operate properly. (Section 7.2)

d. Response time of the scram chain from sensor actuation through initiating logic and 90% rod insertion is within design values. (Section 7.2)

e. System indicators and alarms operate properly. (Section 7.2)

(P-58.2) Redundant Reactivity Control System for ATWS

Unit Scope -

a. 1P-58.2 (Unit 1 system components)

b. 2P-58.2 (Unit 2 system components)

Test Objective - The test objective is to demonstrate proper operation of the RRCS logic and to verify proper response in those systems it affects.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are calibrated and operable. The following systems are available for operation: SLCS, RWCU, CRD, reactor recirculation, APRMs, and feedwater. The reactor vessel, CST, and suppression pool are filled with demineralized water.

Table 14.2-4 (Cont'd)

Test Method - The ATWS logic is operated manually and also automatically by using simulated reactor vessel water level and steam dome pressure signals. APRM power level will also be simulated. Where appropriate, signals from the RPS will be inhibited to allow independent demonstration and redundancy verification of ATWS logic and results. Resultant actions of recirculation pump trip, alternate rod insertion, RWCU isolation and standby liquid control start will be verified. Manual operation or operating limit reset of a system while under the influence of an ATWS logic signal will be demonstrated as appropriate.

Acceptance Criteria -

a. System sensing devices, trip systems, and actuator logics operate and trip within design limits. (Section 7.6.1.8)

b. System alarms and indications operate properly. (Section 7.6.1.8)

c. System logic and its action on other systems is independent and redundant. (Section 7.6.1.8)

(P-59.1) Containment Isolation and Nuclear Steam Supply Shutoff System

Unit Scope -

a. 1P-59.1 (Unit 1 system components)

b. 2P-59.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the primary containment isolation and NSSSS actuates the isolation valves following simulated primary containment isolation signals.

Prerequisites - To the extent necessary to perform this test, construction is completed and instrumentation and controls are operable and calibrated. Isolation valves actuator trip relays are placed in untripped condition. Primary containment isolation valves are operable.

Test Method - The actuator trip relay for each isolation valve is operated using simulated signals as necessary to create a trip condition. The actuator trip relay then operates the corresponding isolation valve. System alarms are also actuated.

Acceptance Criteria -

a. System sensing devices, trip systems, and actuator logics operate and trip within design limits. (Section 7.3.1.1.2)

b. Closing times for valves closed by this system are within acceptable values. (Section 6.2.4)

c. System alarms operate properly.

Table 14.2-4 (Cont'd)

(P-59.2) Primary Containment Integrated Leak Rate Test

Unit Scope -

a. 1P-59.2 (Unit 1 system components)

b. 2P-59.2 (Unit 2 system components)

Test Objective - The test objective is to determine the leakage rate in the primary containment at the peak calculated accident pressure and to determine the bypass leakage from the drywell to the wetwell at the peak drywell to wetwell differential pressure and reduced differential pressure corresponding to approximately the submergence of the vents. In addition, the test will verify the proper connection and tracking of the containment pressure instruments.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The Type B and C testing has been completed in accordance with Chapters 6 and 16. The integrated leakage rate measurement system is calibrated and operational. All containment pressure instruments have been calibrated and are valved into service.

Test Method - The containment is pressurized, and the absolute pressure, dry-bulb temperature, and dew point temperature (water vapor pressure) within the containment and the drywell are recorded to determine the leak rate. The containment is depressurized, the drywell is pressurized to reduced test pressure, and data are taken to determine the drywell bypass leakage rate. As containment pressure is increased during the containment ILRT, proper tracking of all containment pressure instruments is verified.

Acceptance Criteria -

The primary containment and drywell bypass leakage rates are within acceptable limits (Section 6.2.6). All containment instruments track properly, and all affected instrument lines are clear of obstructions.

(P-59.3) Suppression Pool, Pool Cleanup and Vacuum Relief

Unit Scope -

a. 1P-59.3 (Unit 1 system components)

b. 2P-59.3 (Unit 2 system components)

Test Objectives - The test objective is to demonstrate the operability of the suppression pool cleanup and vacuum relief system, the suppression pool level instruments, and system valves.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The suppression pool is sufficiently full of water and the condenser hotwell is available.

Table 14.2-4 (Cont'd)

Test Method - The suppression pool cleanup system is operated, and the pump flow rate measured. The suppression pool level is varied, and the operability of the pool level instruments is verified. Primary containment vacuum relief valves and pressure instruments are also operated.

Acceptance Criteria -

a. The suppression pool cleanup pump meets acceptable head and flow values. (Vendor Technical Specification)

b. Primary containment vacuum relief valves operate properly. (Section 7.3.2.6.1.1)

c. System MOVs operate properly. (Section 6.4.2)

d. Suppression pool level instruments operate properly. (Section 7.5.1.4.2.1)

e. System alarms operate properly. (Section 6.3.2.2.3)

f. Containment pressure indicators used to track accident conditions operate properly. (Section 7.5.1.4.2.1)

(P-60.1) Drywell HVAC System

Unit Scope -

a. 1P-60.1 (Unit 1 system components)

b. 2P-60.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the primary containment ventilation system.

Prerequisites - To the extent necessary to perform this test, construction is completed, instrumentation and controls are operable and calibrated, chilled water flow balancing and drywell air balancing are complete.

Test Method - The ventilation system fans and chillers are operated. Controls and alarms are actuated.

Acceptance Criteria -

a. Drywell unit coolers and fans operate properly. (Section 9.4.5.2)

b. Drywell chilled water circulation pumps operate properly. (Section 9.2.10.1)

c. Drywell water chillers operate properly. (Section 9.2.10.1)

Table 14.2-4 (Cont'd)

d. System isolation and control valves operate properly. (Sections 9.2.10.1 and 9.4.5.2)

e. System alarms operate properly. (Sections 9.2.10.1 and 9.4.5.2)

(P-61.1) Reactor Water Cleanup System

Unit Scope -

a. 1P-61.1 (Unit 1 system components)

b. 2P-61.1 (Unit 2 system components)

Test Objective - The test objectives is to demonstrate the operability of the RWCU system and to verify that the system functions properly.

Prerequisites - To the extent necessary for performance of this test, construction is completed, and instrumentation and controls are operable and calibrated. The demineralizers are precoated, as required, and ready to process system flow. The RECW system is available to satisfy the system's cooling requirements.

Test Method - The recirculation pumps are operated and their performance characteristics are determined. Data are obtained during demineralizer cleanup, backwash, and precoat operations. System controls and alarms are actuated, including operation of the system isolation valves. Simulated signals are used as required.

Acceptance Criteria -

a. System pumps meet acceptable values of head and flow. (Section 5.4.8)

b. Filter precoat and backwash cycles operate properly. (Vendor Technical Manual)

c. System isolation valves operate properly. (Section 5.4.8)

d. System flow circuits operate properly. (Section 5.4.8)

e. System alarms operate properly. (Section 5.4.8)

(P-62.1) Reactor Vessel and Auxiliaries

Unit Scope -

a. 1P-62.1 (Unit 1 system scope)

b. 2P-62.1 (Unit 2 system scope)

Table 14.2-4 (Cont'd)

Test Objective - The test objective is to detect damage, excessive wear, loose parts, or other evidence of unacceptable vibration which could result from assembly errors or undesirable deviations from the previously qualified prototype plant construction.

This test is a quality assurance measure which experimentally confirms the absence of excessive vibration of core support structures, jet pumps, lower plenum components, and other major internal structures. The test is conducted without fuel, and is not intended to be a test of fuel or incore instrument vibration. However, the specified test conditions, without fuel present, provide a level of vibration excitation of major internal structures which is at least as high as that measured in normal power operation.

Prerequisites: To the extent necessary to perform this test, all reactor internals components are installed, except:

a. The core matrix is empty; there are no fuel assemblies, incore instrumentation tubes, or neutron source rods. Control blades are withdrawn or not installed. Fuel support castings are installed.

b. The dryer assembly need not be installed.

c. One of the access hole covers on the shroud support plate must remain unwelded until after the test to provide access for inspection. A temporary closure must be provided.

The reactor vessel is closed, filled, and ready for pressurization. The recirculation pumps are operable. RHR system pumps are operable to provide necessary temperature rise. The CRD system is operable to control reactor vessel pressure. RWCU system heat exchangers are operable for temperature control.

Test Method - A visual inspection is made before and after the required 100% speed pump runs. These flow runs include 35 hours of two-loop operation and 14 hours each for loops A and B. The total run time is 63 hours. These hours may not be sequential, but they must be between the initial and final inspections.

Acceptance Criteria -

Initial and final inspection results are acceptable. (Section 3.9.2.4)

(P-64.1) Reactor Recirculation System

Unit Scope -

a. 1P-64.1 (Unit 1 system components)

b. 2P-64.1 (Unit 2 system components)

Test Objective - The test objectives are to demonstrate that the reactor recirculation system components function properly, and to demonstrate the flow performance of the system to the degree possible prior to fuel loading.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The RPV is available and filled with demineralized water above the minimum level required for reactor recirculation pumps operation. The RECW system and DCWS are available to provide the cooling water requirements of the pumps.

Test Method - The recirculation pumps are operated at various speeds while corresponding pump flow rate and head characteristics are determined. The system is tested by individual and group operation of the pumps, MG sets, valves and controls. System interlocks and alarms are actuated, using simulated signals as required.

Acceptance Criteria -

a. Recirculation pumps meet acceptable values of head and flow for various motor input frequencies. (Sections 5.4 and 7.7.1.3)

b. System flow instrumentation operates properly. (Sections 5.4 and 7.7.1.3)

c. Recirculation pump isolation valves operate properly. (Sections 5.4 and 7.7.1.3)

d. System alarms are operable. (Sections 5.4 and 7.7.1.3)

e. System control logic operates properly. (Sections 5.4 and 7.7.1.3)

f. MG sets operate properly. (Sections 5.4 and 7.7.1.3)

g. MG sets' lube oil system operates properly. (Sections 5.4 and 7.7.1.3)

(P-65.1) Radwaste Enclosure HVAC System

Unit Scope -

a. 1P-65.1 (Common system components)

Test Objective - The test objective is to demonstrate the ability the radwaste enclosure HVAC system to provide air flow and respond to simulated temperature variations in the radwaste enclosure, equipment compartment, service and control, and fume hood areas. Additional objectives are to demonstrate the ability of the charcoal vault cooling system to maintain temperature control in charcoal vaults 1, 2, and 3, and the ability of the radwaste enclosure HVAC system to maintain positive air flow from clean areas to areas of increasing potential contamination.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - System fans and filter units are placed in operation. System controls and interlocks are operated. The charcoal vault cooling system and controls are operated. System temperature control valves response to temperature controls are verified. System alarms are activated.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. System supply and exhaust fans operate properly. (Section 9.4.3)

b. System temperature control valves respond to temperature controls. (Section 9.4.3)

c. Results of in-place filter efficiency testing are acceptable (Table 9.4-18).

d. Supply and exhaust fan controls and interlocks operate properly. (Section 9.4.3)

e. The charcoal vault cooling system operates properly. (Section 9.4.3)

f. Compartment differential pressures are maintained. (Section 9.4.3)

g. System alarms operate properly. (Section 9.4.3.5)

(P-66.1) Reactor Enclosure Unit Cooler System

Unit Scope -

a. 1P-66.1 (Unit 1 system components)

b. 2P-66.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the reactor enclosure unit coolers to provide air flow to the RCIC, core spray, RHR, and HPCI safeguard pump compartments.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The unit coolers are placed in operation. Pump compartment temperature variations are simulated and system response is verified. Unit cooler component interlocks are verified. The ESW system valves are operated throughout the test. System alarms are verified under actual and simulated conditions as practicable. System parameters are monitored and recorded for systems cooling ECCS equipment.

Acceptance Criteria -

a. The unit coolers operate properly. (Section 9.4.2)

b. The unit coolers automatic start features and interlocks operate properly in both the automatic and standby modes. (Section 9.4.2)

c. The unit coolers respond properly to temperature variations within the respective pump compartments. (Section 9.4.2)

d. Cooling water central valves are operated whenever the applicable unit cooler is energized. (Section 9.4.2)

Table 14.2-4 (Cont'd)

e. System alarms operate properly. (Section 9.4.2)

(P-66.2) - Control Enclosure Unit Coolers

Unit Scope -

a. 1P-66.2 (Common system components)

Test Objective - The test objective is to demonstrate the capability of the control enclosure unit coolers to provide cooling air flow to the SGTS room and access.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Applicable portions of the HVAC air balancing test are completed.

Test Method - The unit coolers are placed in operation. SGTS room and access temperature variations are simulated and system response is verified. Unit cooler component interlocks are verified.

Acceptance Criteria -

a. The unit coolers operate properly in the RUN, AUTO, and STBY modes. (Section 9.4.1)

b. Chill water inlet valves open when their associated unit cooler fan starts. (Section 9.4.1)

c. Chill water pumps start whenever one of the unit are operable from both the control room and the remote shutdown panel; coolers they supply starts. (Section 9.4.1)

d. SGTS access dampers open when their associated unit cooler fan starts. (Section 9.4.1)

(P-68.1) Solid Radwaste System

Unit Scope -

a. 1P-68.1 (Common system components)

b. 2P-68.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the solid radwaste system including the radwaste solidification system.

Prerequisite - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Demineralized water is available.

Table 14.2-4 (Cont'd)

Test Method - The solid radwaste system is tested with actual, nonradioactive, representative waste streams, which include backwash resins from RWCU, fuel pool cleanup, and condensate cleanup. The system is tested to ensure that these representative waste streams can be processed from their respective collection tanks through the phase separators, centrifuges and drumming process. Major operations verified in the test include the ability to mix sludge/resins and water in the backwash and sludge tanks to produce transportable mixtures, use of the phase separator tanks to concentrate sludge and resins by the decanting process prior to discharging to the centrifuges and high integrity containers.

Acceptance Criteria -

a. System pumps operate properly and are able to agitate contents of tanks and to transport slurry mixtures. (Section 11.4)

b. System alarms and controls operate properly. (Section 11.4)

c. System components (e.g., centrifuges, tank agitators, transfer carts, radwaste crane, etc.) operate properly. (Section 11.4)

d. System discharge product meets free liquid content limit as identified in Chapter 11.

(P-69.1) Equipment Drain Collection and Storage System

Unit Scope -

a. 1P-69.1 (Unit 1 and common system components)

b. 2P-69.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the equipment drain system to collect, store, and transfer potentially contaminated low conductivity liquid wastes.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - System pumps are operated in both manual and automatic modes. Power-operated valves are cycled in both manual and automatic modes. System alarms are verified by using actual or simulated conditions, as practical. Containment isolation signals are initiated to verify valve interlocks. Sumps fitted with positive exhaust connections are smoke tested.

Acceptance Criteria -

a. System pumps operate satisfactorily. (Sections 9.3.3 and 11.2)

b. System pumps operate in both manual and automatic modes. (Sections 9.3.3 and 11.2)

c. System power-operated valves operate in both manual and automatic modes. (Sections 9.3.3 and 11.2)

Table 14.2-4 (Cont'd)

d. Containment isolation valve interlocks operate. (Sections 9.3.3 and 11.2)

e. Sump exhausts draw room air into sump. (Sections 9.3.3 and 11.2)

f. System alarms operate. (Sections 9.3.3 and 11.2)

(P-69.3) Liquid Radwaste System

Unit Scope -

a. 1P-69.3 (Unit 1 and common system components)

b. 2P-69.3 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the equipment drain subsystem to transfer and process potentially contaminated low conductivity liquid wastes; the flow drain subsystem to collect, transfer, and process potentially contaminated high conductivity liquid wastes; and the fuel pool filter precoat and backwash system to clean and precoat both the equipment drain and floor drain filters. In addition, the ability of the chemical waste subsystem to collect and transfer corrosive liquid wastes; and the laundry drain subsystem to collect, transfer, and process liquid detergent wastes shall be demonstrated.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. System filters have been precoated and system demineralizers have been loaded with resin.

Test Method - The liquid radwaste system is operated with representative nonradioactive waste influent. Equipment and subsystems to be tested include equipment and floor drain processing, chemical waste, and laundry drains. System pumps are operated in both manual and automatic modes. The fuel pool precoat and backwash system is operated to clean and precoat both the equipment drain and the floor drain filters. System alarms are verified by using actual or simulated conditions where practical. The effluent of each filter and demineralizer is sampled to ensure that it is of acceptable quality. Power-operated valves are cycled in both manual and automatic modes.

Acceptance Criteria -

a. System pumps operate properly. (Section 11.2)

b. System pumps operate in both manual and automatic modes. (Section 11.2)

c. Fuel pool filter precoat and backwash system cleans and precoats both the equipment drain and floor drain filters. (Section 11.2)

d. System power-operated valves operate in both manual automatic modes. (Section 11.2)

e. The equipment and floor drain subsystems produce condensate storage quality water. (Section 11.2)

Table 14.2-4 (Cont'd)

f. The laundry drain subsystem produces water of acceptable quality to discharge to the environment. (Section 11.2)

g. Contents of the chemical waste tank can be mixed and neutralized prior to discharge for processing. (Section 11.2)

h. System alarms operate properly. (Section 11.2)

(P-70.1) Standby Gas Treatment System and Reactor Enclosure Air Recirculation, Secondary Containment Isolation

Unit Scope -

a. 1P-70.1 (Unit 1 system components)

b. 2P-70.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the reactor enclosure secondary containment to isolate and of the air recirculation and standby gas treatment systems to function properly.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The reactor enclosure H&V system and the turbine enclosure vent north stack are available and operational to support the system test.

Test Method - The reactor enclosure secondary containment is isolated, the reactor enclosure air recirculation and the standby gas treatment start automatically by a simulated reactor enclosure isolation signal. The SGTS, RERS, and secondary containment isolation performance is determined by measuring secondary containment pressures, system pressures, and fan air flow rates. Systems controls and alarms are actuated.

Acceptance Criteria -

a. System fans, both singularly and in combinations, provide acceptable values of flow through the system filters. (Section 6.5.1)

b. Fan interlocks, automatic start and shutout features, and damper logic operate properly. (Sections 6.5.1, 7.3.1.1.7, and 7.3.1.1.8)

c. Results of in-place filter efficiency testing are acceptable. (Section 6.5.1)

d. System alarms operate properly. (Sections 6.5.1, 7.3.1.1.7, 7.3.1.1.8, and 7.3.1.1.9)

e. Reactor enclosure isolation logic operates properly. (Section 6.2.3)

f. The reactor enclosure ventilation system is shut down and isolated properly. (Section 6.2.3)

Table 14.2-4 (Cont'd)

g. System steam flooding damper operation is proper. (Section 9.4.2.1)

(P-72.1) Gaseous Radwaste Recombiners and Filters

Unit Scope -

a. 1P-72.1 (Unit 1 and common system components)

b. 2P-72.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the gaseous radwaste system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Nitrogen and auxiliary steam are available as required. Service water and RECW are operable, and the turbine enclosure ventilation stack is available for discharges.

Test Method - System recombiner and charcoal treatment trains are operated and their performance is verified.

Acceptance Criteria -

a. System recombiner and charcoal treatment trains operate properly. (Section 11.3)

b. System controls and alarms operate properly. (Section 11.3)

(P-73.1) Containment Atmosphere Control System

Unit Scope -

a. 1P-73.1 (Unit 1 system components)

b. 2P-73.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the CAC system to provide accurate analysis of containment oxygen and hydrogen content and to demonstrate the operability of the hydrogen recombiner packages. The actual hydrogen/oxygen recombination process is not demonstrated at this time.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The combustible gas analyzer packages are operated and system flow rates determined. Gas samples containing known concentrations of oxygen and hydrogen are introduced into the system to verify proper response of the gas concentration indicating and recording equipment. The hydrogen recombiner system is operated, and system flow rates determined. System controls and alarms are actuated.

Table 14.2-4 (Cont'd)

Acceptance Criteria -

a. System atmosphere control isolation valves operate properly. (Section 9.4.5.1)

b. Containment hydrogen recombiners meet acceptable values of flow and temperature. (Section 9.4.5.1)

c. System hydrogen/oxygen analyzers operate properly. (Section 9.4.5.1)

d. System alarms operate properly. (Section 9.4.5.1)

(P-76.1) Process Sampling System

Unit Scope -

a. 1P-76.1 (Unit 1 system components)

b. 2P-76.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the process sampling system to provide various process samples with adequate flow indication to installed analytical monitoring equipment and grab samples stations.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Each sample station is operated and grab samples are drawn as available. Chemical fume hoods and the turbine enclosure sample station drain recovery tank pumps are operated. System alarms are actuated.

Acceptance Criteria -

a. Sample lines are unobstructed. (Section 9.3.2)

b. Grab sample valves operate properly. (Section 9.3.2)

c. The turbine enclosure sample station drain recovery tank pumps operate properly. (Section 9.3.2)

d. The chemical fume hoods operate properly. (Section 9.3.2)

e. System alarms operate properly. (Section 9.3.2)

(P-76.2) Postaccident Sampling System

Unit Scope -

a. 1P-76.2 (Unit 1 system components)

Table 14.2-4 (Cont'd)

b. 2P-76.2 (Unit 2 system components)

Test Objective - The objective is to demonstrate the operability of the postaccident sampling system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The postaccident sampling system and support systems are complete and operational.

Test Method - Component control and status indication will be tested, and base line operating data will be obtained for major components. The system will be operationally checked by taking actual samples.

Acceptance Criteria -

a. System gas pumps, gas breakdown pump, and liquid chiller function properly. (Section 11.5.5)

b. Component control and status indication devices function properly. (Section 11.5.5)

c. The system is capable of obtaining process samples from all design sampling points. (Section 11.5.5)

(P-78.1) Startup Range Detector Drive Control and Neutron Monitoring System

Unit Scope -

a. 1P-78.1 (Unit 1 system components)

b. 2P-78.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the startup range neutron monitoring system which includes both source and intermediate range neutron monitoring equipment.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Each source and intermediate range detector is positioned from its fully inserted position to its fully retracted position to demonstrate the operability of the insert/retract mechanisms. Using simulated input signals, each source and intermediate range detector loop is tested to demonstrate meter indication, trip circuit operation, retract and insert permissives, associated rod block signals, and alarm operation.

Acceptance Criteria -

a. The startup range drive system is capable of positioning each detector through its full length of travel. (Section 7.7.2.6)

Table 14.2-4 (Cont'd)

b. Startup range neutron flux level and rate circuits indicate properly. (Section 7.7.2.6)

c. Startup range trip signals operate properly. (Section 7.7.2.6)

d. Startup range selector switch logic and insert/retract permissives operate properly. (Section 7.7.2.6)

e. Startup range rod block signals are generated per design. (Section 7.7.2.6)

f. System alarms operate properly. (Section 7.7.2.6)

(P-78.2) Power Range Neutron Monitoring System [1]

Unit Scope -

a. 1P-78.2 (Unit 1 system components)

b. 2P-78.2 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of LPRM and APRM systems.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Each LPRM channel is tested using simulated signals to its tripping, alarm, or indicating function. Each APRM channel is tested for its tripping, alarm, or indicating function using simulated signals from the LPRM. Simulated recirculation flow signals are also utilized to provide the bias for varying the rod block and trip setpoints. Simulated signals are used to test the rod block monitor outputs.

[1] This information is for historical reference only.

Acceptance Criteria -

a. The local power range neutron flux circuits operate properly and are capable of providing signals to the APRM system, the RBM system, the process computer, and to LPRM system indicating meters and auxiliary devices. (Section 7.6.1.4)

b. LPRM and APRM system trip signals operate properly. (Section 7.6.1.4)

c. Average power range power level circuits operate properly. (Section 7.6.1.4)

d. System alarms operate properly. (Section 7.6.1.4)

e. Rod block monitor outputs operate. (Section 7.6.1.4)

Table 14.2-4 (Cont'd)

(P-78.3) Traversing Incore Probes Calibration System

Unit Scope -

a. 1P-78.3 (Unit 1 system components)

b. 2P-78.3 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the operability of the TIP calibration system and to verify the system functions properly.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The primary containment instrument gas is available, as required, for purging the system.

Test Method - Verification that the system operates in the manual, automatic, and hand crank modes. Indexer cross-calibration interlock, shear valve control monitor, TIP automatic detector withdrawal, containment secure and squib circuits verification, ball valve control, ball valve open interlock, and purging operations are conducted. System manual and automatic controls and alarms are actuated and the ability to override automatic functions is demonstrated.

Acceptance Criteria -

a. The automatic and manual modes function in the correct designed sequence. (Section 7.7.1.6.3)

b. System drive mechanisms, including position indication, and the drive interlocks and time delays operate properly. (Section 7.7.1.6.3)

c. System signal channels, indicators, recorders, and alarms operate properly. (Section 7.7.1.6.3)

d. The system indexing mechanism and its interlocks operate properly. (Section 7.7.1.6.3)

e. The system automatically withdraws the detectors on a containment isolation signal, after which the containment isolation valves close. (Section 7.7.1.6.3)

(P-79.1) Area Radiation Monitoring System

Unit Scope -

a. 1P-79.1 (Unit 1 system components)

b. 2P-79.1 (Unit 2 system components)

Test Objective - The test objectives are to demonstrate that the area radiation monitoring system is operable and has correct high and low and alarm settings.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Verification of the area radiation monitoring system capability is demonstrated by the integrated operation of the channel trip units, local and remote alarm annunciators, lights, and recorders. The site environs radiation monitoring stations are tested for Unit 1 only, as this equipment is common to both Unit 1 and Unit 2.

Acceptance Criteria -

a. Each area radiation monitoring channel operates properly. (Section 7.7.1.10)

b. Each area radiation monitoring channel high and low trip setpoint is set properly. (Section 7.7.1.10)

c. Each monitor responds properly to its internal check source. (Section 7.7.1.10)

d. The indicator and trip units properly initiate their respective indicators, alarms, and horns. (Section 7.7.1.10)

e. Each trip circuit produces an alarm upon interruption or failure of the ac power supply. (Section 7.7.1.10)

(P-79.2) - Process Radiation Monitoring System

Unit Scope -

a. 1P-79.2 (Unit 1 system components)

b. 2P-79.2 (Unit 2 system components)

Test Objective - The test objectives are to demonstrate that the process radiation monitoring system is operable and has the capability to detect a gross release of fission products from the fuel.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Verification of the process radiation monitoring system's capability is demonstrated by the integrated operation of the channel trip units, alarm annunciators, and lights and recorders. Test signals are fed into the monitors at the control modules.

Acceptance Criteria -

a. Each process radiation monitoring channel operates properly. (Sections 7.7.1.9 and 7.6.1.1)

b. The indicator and trip units properly operate their respective indicators and alarms. (Section 7.7.1.9)

Table 14.2-4 (Cont'd)

c. As applicable, each monitor responds properly to its secondary check source. (Section 7.7.1.9)

d. Provides trip signals to initiate a reactor shutdown and containment isolation on detection of a gross release of fission products from the fuel. (Section 7.7.1.9)

(P-80.1) Reactor Vessel Instrumentation System

Unit Scope -

a. 1P-80.1 (Unit 1 system components)

b. 2P-80.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the reactor non-nuclear instrumentation systems operate properly to provide trip, indication, and alarm information.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Relays that are initiated from the reactor vessel level and pressure sensors are placed in untripped condition.

Test Method - Simulated signals are introduced into the reactor non-nuclear instrument loops and proper trip, alarm, and indication outputs are verified.

Acceptance Criteria -

a. System indications and trips operate properly. (Section 7.7.1.1)

b. System alarms operate properly. (Section 7.7.1.1)

(P-81.1) Fuel Handling System

Unit Scope -

a. 1P-81.1 (Unit 1 system components)

b. 2P-81.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the refueling platform and the various servicing tools can be used for their intended operations.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The RMCS, fuel pool, and the reactor cavity and core structure are available for testing. Dynamic and static load tests of fuel handling equipment are completed.

Table 14.2-4 (Cont'd)

Test Method - The fuel servicing equipment, refueling equipment, and servicing aids are operated. Their associated controls and alarms are actuated.

Acceptance Criteria -

a. The fuel preparation machines operate properly. (Section 9.1.4)

b. The refueling platform operates properly. (Section 9.1.4)

c. Refueling interlocks and logic operate properly. (Section 7.7.1.15)

d. Fuel position indicators operate properly. (Section 9.1.4)

(P-83.1) Main Steam System[1]

Unit Scope -

a. 1P-83.1 (Unit 1 system components)

b. 2P-83.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the proper operation of the main steam system, including the MSIVs, the leakage control system, and the ADS.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Primary containment instrument gas and instrument air are available to operate the main steam line isolation valves and SRVs.

(1) This information is for historical reference only.

Test Method - The MSIV-LCS valves, blowers, heaters, and controls are operated. System logic, valve times, and flows are verified and measured. The MSIVs are stroked and timed in their various modes. The ADS is functionally checked without lifting pressure relief valves. Other main steam system controls and alarms are actuated.

Acceptance Criteria -

a. The MSIVs stroke properly in the manual mode (fast and slow). (Section 5.4.5)

b. The MSIVs automatic closure is within acceptable times. (Section 5.4.5)

c. MSIV control logic, indications, and alarms operate properly. (Section 7.3.1.1.2)

d. The MSIV-LCS operates properly, valve times are as specified and system flows are acceptable. (Sections 6.7 and 7.3.1.1.3)

e. Nuclear system pressure relief valves control circuits operate properly. (Section 5.2.2)

f. The main steam line flow monitors operate properly. (Section 7.3.1.1.2)

Table 14.2-4 (Cont'd)

(P-83.2) Automatic Depressurization System

Unit Scope -

a. 1P-83.2 (Unit 1 system components)

b. 2P-83.2 (Unit 2 system components)

Test Objective - The test objectives are to demonstrate the operability of the ADS and to verify system response to signals from the logic channels.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - High drywell pressure and low reactor water level signals are simulated and system response to the logic channels is verified.

Acceptance Criteria -

a. ADS channel A responds properly to signals from logic channels A and E. (Section 7.3.1.1.1.2)

b. ADS channel C responds properly to signals from logic channels C and G. (Section 7.3.1.1.1.2)

c. The core spray and RHR pump permissive interlocks function properly. (Section 7.3.1.1.1.2)

d. ADS valves operate properly. (Section 5.2.2)

e. System instruments and alarms operate properly. (Section 7.3.1.1.1.2)

(P-83.3) Steam Leak Detection System

Unit Scope -

a. 1P-83.3 (Unit 1 system components)

b. 2P-83.3 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the steam leak detection system is operable and that system instruments have the correct trip and alarm setpoints.

Prerequisites - To the extent necessary to complete this test, construction is completed, and instrumentation and controls are operable and calibrated.

Table 14.2-4 (Cont'd)

Test Method - System temperature changes are simulated at the system control sensors. Capability of system instrumentation to respond to temperature changes and alarm setpoints is verified. The generation of isolation signals to the channel trip units is verified.

Acceptance Criteria -

a. System temperature monitors operate properly. (Sections 5.2.5 and 7.6.1.3)

b. System temperature alarms and temperature indicators operate properly. (Sections 5.2.5 and 7.6.1.3)

c. Steam leak detection temperature isolation signals are generated by the applicable circuitry to the NSSSS, the HPCI system, and the RCIC system. (Sections 5.2.5 and 7.6.1.3)

(P-85.1) Cathodic Protection System

Unit Scope -

a. 1P-85.1 (Unit 1 & 2 and Common system components)

Test Objective - The test objective is to demonstrate the capability of the cathodic protection system to maintain buried steel piping and structures at the design electrical potential.

Prerequisite - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - The cathodic rectifiers are operated and voltage, current, and resistance measurements are made.

Acceptance Criteria -

a. The electrical potential of buried steel piping and structures is maintained within acceptable limits. (Vendor Technical Manual)

b. The cathodic rectifiers operate properly. (Vendor Technical Manual)

(P-85.2) Freeze Protection and Heat Trace Systems

Unit Scope -

a. 1P-85.2 (Unit 1, common, and portions of Unit 2 system components

b. 2P-85.2 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the operability of the freeze protection and heat trace systems.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Each freeze protection and heat trace system is operated. Control setpoints are varied, and system response is verified. System alarms are actuated.

Acceptance Criteria -

a. The freeze protection and heat trace systems energize and de-energize in response to the thermostatic controls. (Electrical Schematic Diagram)

b. System alarms operate properly. (Electrical Schematic Diagram)

(P-91.1) Plant Annunciator Systems

Unit Scope -

a. 1P-91.1 (Unit 1, common, and portions of Unit 2 system components

b. 2P-91.1 (Unit 2 remaining system components)

Test Objective - The test objective is to demonstrate the ability of the plant annunciator systems to provide both audible and visual indications of an alarm condition.

Prerequisites - To the extent necessary to perform this test, construction is completed and plant annunciator panels are operable.

Test Method - Annunciator panel test devices are operated. Alarm contacts are jumpered to demonstrate annunciator operability.

Acceptance Criteria -

a. The main control room annunciators operate properly. (Electrical Schematic Diagram)

b. The radwaste control room annunciators operate properly. (Electrical Schematic Diagram)

(P-93.2) Main Turbine Control System

Unit Scope -

a. 1P-93.2 (Unit 1 system components)

b. 2P-93.2 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the EHC system to operate the turbine-generator.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. The hydraulic fluid reservoir is filled with EHC fluid.

Test Method - The hydraulic system is placed in operation and alarms, trips, and control devices are actuated.

Acceptance Criteria -

a. Hydraulic system pressure meets acceptable values. (Vendor Technical Manual)

b. Turbine stop and bypass valves operate properly. (Vendor Technical Manual)

c. System alarms operate properly. (Sections 7.7.1.5 and 10.2)

d. System trips operate properly. (Sections 7.7.1.5 and 10.2)

(P-93.3) Main Turbine Supervisory System

Unit Scope -

a. 1P-93.3 (Unit 1 system components)

b. 2P-93.3 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the turbine supervisory system to monitor the operation of the main turbine. For Unit 1, this test also demonstrates system ability to monitor operation of the reactor feed pump-turbines. This aspect is accomplished by Test P-45.1 (Feedwater System) for Unit 2.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation is operable and calibrated.

Test Method - Signal inputs are simulated in the turbine supervisory system, and recording equipment and alarms are actuated.

Acceptance Criteria -

a. Instrumentation operates properly. (Vendor Technical Manual)

b. System alarms operate properly. (Section 10.2.5, Items a, b, c, f, h, and p)

(P-99.1) Reactor Enclosure Crane

Unit Scope -

a. 1P-99.1 (Unit 1 and Unit 2 system components)

Test Objective - The test objective is to demonstrate the capability of the reactor enclosure crane to safely move expected loads within the reactor enclosure.

Table 14.2-4 (Cont'd)

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Construction proof testing as identified in Section 9.1.5 has been completed.

Test Method - The crane is used to maintain its nominal rated load in a static position. Test loads are lifted and travel limits, as well as hoist, trolley, and bridge travel speeds, are measured. System controls and alarms are actuated.

Acceptance Criteria -

a. The crane load capacity is acceptable (Section 9.1.5)

b. Crane controls, alarms, interlocks, and limits operate properly. (Section 9.1.5)

c. Crane protective devices and interlocks operate properly. (Section 9.1.5)

d. Equipment safety devices operate properly. (Section 9.1.5)

(P-99.2) Seismographical Monitoring System

Unit Scope -

a. 1P-99.2 (Common system components)

Test Objective - The test objective is to demonstrate the ability of the seismographical monitoring system to measure and record seismic data.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated.

Test Method - Earthquake conditions are simulated by applying a physical force to the seismic sensors. Automatic system operation is verified.

Acceptance Criteria -

a. Peak acceleration recorders operate properly. (Vendor Technical Manual)

b. Strong motion accelerographs operate properly. (Vendor Technical Manual)

c. Seismic triggers operate properly. (Section 3.7.4)

d. Magnetic tape playback system operates properly. (Section 3.7.4)

e. Response spectrum analyzer operates properly. (Section 3.7.4)

f. System alarms operate properly. (Section 3.7.4)

Table 14.2-4 (Cont'd)

(P-99.3) Public Address and Evacuation System

Unit Scope -

a. 1P-99.3 (Unit 1 and Common system components)

b. 2P-99.3 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the ability of the public address system to transmit voice communication and the plant evacuation alarm and river warning systems to broadcast various alarms and prerecorded messages to selected areas.

Prerequisites - To the extent necessary to perform this test, construction is completed, and equipment is operational.

Test Method - Each public address station is operated in both the page and party line modes. Evacuation alarm and river warning signals are simulated, and system operation is verified.

Acceptance Criteria -

a. The public address system is operable from all stations in the page and party line modes. (Section 9.5.2)

b. All public address speakers operate properly. (Section 9.5.2)

c. The evacuation alarm system operates properly. (Section 9.5.2.2.4)

d. The river warning system operates properly. (Section 9.5.2.2.4)

e. The evacuation alarm system automatic transfer power switch operates properly. (Section 9.5.2.2.4)

(P-100.1) Loss of Offsite Power Test

Unit Scope -

a. 1P-100.1 (Unit 1 system components)

b. 2P-100.1 (Unit 2 system components)

Test Objective - The test objective is to demonstrate that the plant emergency systems are capable of operating as expected on an integrated basis in normal and emergency modes, and thus are ready for fuel loading.

Prerequisites - Selected preoperational tests are performed prior to or concurrent with operation of equipment for the cold functional test.

Table 14.2-4 (Cont'd)

Test Method - Plant operating procedures are utilized, to the extent practicable, to place plant emergency systems in service on an integrated basis for normal and emergency modes. The standby diesel generators are operated in all possible combinations, in response to simulated LOOP, and LOCA conditions.

The first of these tests consists of a diesel generator automatic start from standby conditions on receipt of LOCA signal with coincident LOOP. The plant emergency loads are automatically applied, and proper system response to the loading sequence is verified. This test, in conjunction with Tests P-24.1 (Standby Diesel Generator System) and P-100.4 (Standby Diesel Generator Loading), constitute the entire diesel generator preoperational test program.

Equipment parameters are allowed to stabilize for each operational combination, and any abnormal conditions are investigated. Equipment not under test is monitored to verify the absence of voltage.

Testing during the LOOP test or prerequisite tests will be performed using maximum attainable loads (given equipment operating restrictions) during the test. If full accident load conditions are not attained, recorded currents and voltages will be extrapolated and compared with design conditions. Testing during the LOOP test will be conducted using only one source of power to each bus.

Acceptance Criteria -

a. Integrated system performance, to the extent possible during the test, is acceptable. (Vendor test specification)

b. System electrical and mechanical performance is acceptable (Vendor test specification)

c. Each diesel generator operates properly during automatic load shedding and the automatic design accident loading sequence from standby conditions. Voltage and frequency remain within acceptable limits during the transients following each incremental application of load. (Section 8.3.1.1.3)

(P-100.2) Loss of Instrument Air

Unit Scope -

a. 1P-100.2 (Unit 1 and common system components)

b. 2P-100.2 (Unit 2 system components)

Test Objective - The test objective is to demonstrate the design response to a loss of instrument air accident of safety-related components supplied by the system.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. Cooling water is available to meet the requirements of the system. There are no essential plant systems operating that will be affected by performance of this test.

Table 14.2-4 (Cont'd)

Test Method - The system is placed in operation, and components to be tested are placed in their normal operation position in so far as plant conditions allow. Instrument air is shut off in a manner that would simulate an instrument air pipe break. The test is repeated to simulate a loss of instrument air by moisture freezing and plugging the main supply line. Affected components are verified to respond properly.

Acceptance Criteria -

a. Proper movement of affected components is verified. (System P&IDs)

b. Feeders or branches sustain an adequate share of the decaying air supply as required by the operational mode. (System P&IDs)

(P-100.4) Standby Diesel Generator Loading

Unit Scope -

a. 1P-100.4 (Unit 1 system and components)

b. 2P-100.4 (Unit 2 system and components)

Test Objective - The objective of this test is to demonstrate the capability of the standby diesel generators to accept the design accident loading sequence with a coincident LOOP.

Prerequisites - To the extent necessary to perform this test, construction is completed, and instrumentation and controls are operable and calibrated. ESW or temporary cooling water for Unit 2, diesel generator enclosure HVAC, 125 V dc power, fuel oil, and fire protection are available for diesel generator operation. ESF systems are available for operation during accident response testing.

Test Method - Each diesel generator is verified to automatically start and accelerate to rated speed and voltage on receipt of a simulated LOCA signal with coincident LOOP. To the extent that they are available for this test, the plant emergency loads are automatically applied, and proper system response to the loading sequence is verified. The applied loads consist of the major ESF system loads as a minimum, plus as many of the ancillary 440 V loads that are available at the time of the test, and any temporary means so that the actual demand seen by the diesel is simulated as close as practical. This test is conducted on each engine individually, immediately after the engine has been operated at full load temperature conditions for a 24 hour period. In addition, diesel generator synchronization to offsite power and load transfer is verified.

An analogous test will be conducted on each engine from standby conditions as a part of preoperational Test 1P-100.1 (Loss of Offsite Power) except that this test is conducted concurrently on each engine using the actual plant emergency loads. Proper system response to the loading sequence is also verified at this time.

Proper diesel generator and auxiliary system performance is verified during the 24 hour run. From the data taken at this time, the fuel oil storage system, the lube oil system, and the jacket water system are analytically verified to contain enough inventory to sustain each diesel generator for a 7 day period of continuous full load operation.

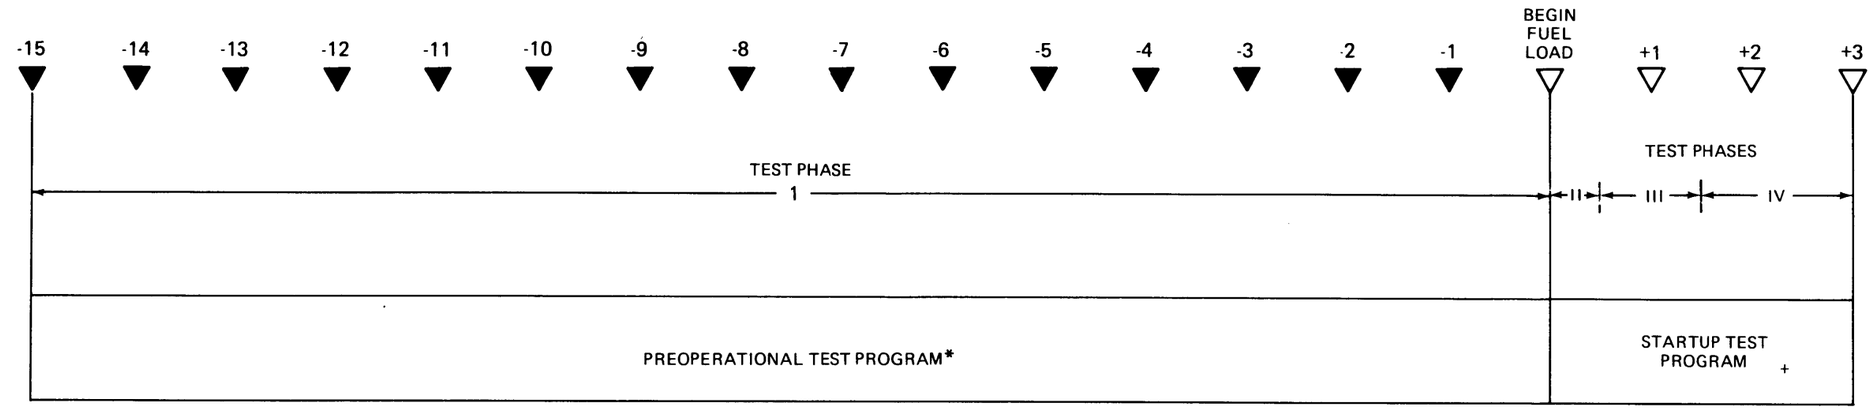
Table 14.2-4 (Cont'd)

This test, in conjunction with Tests P-24.1 (Standby Diesel Generator System) and P100.1 (Loss of Offsite Power) constitutes the entire individual diesel generator preoperational testing program.

Acceptance Criteria -

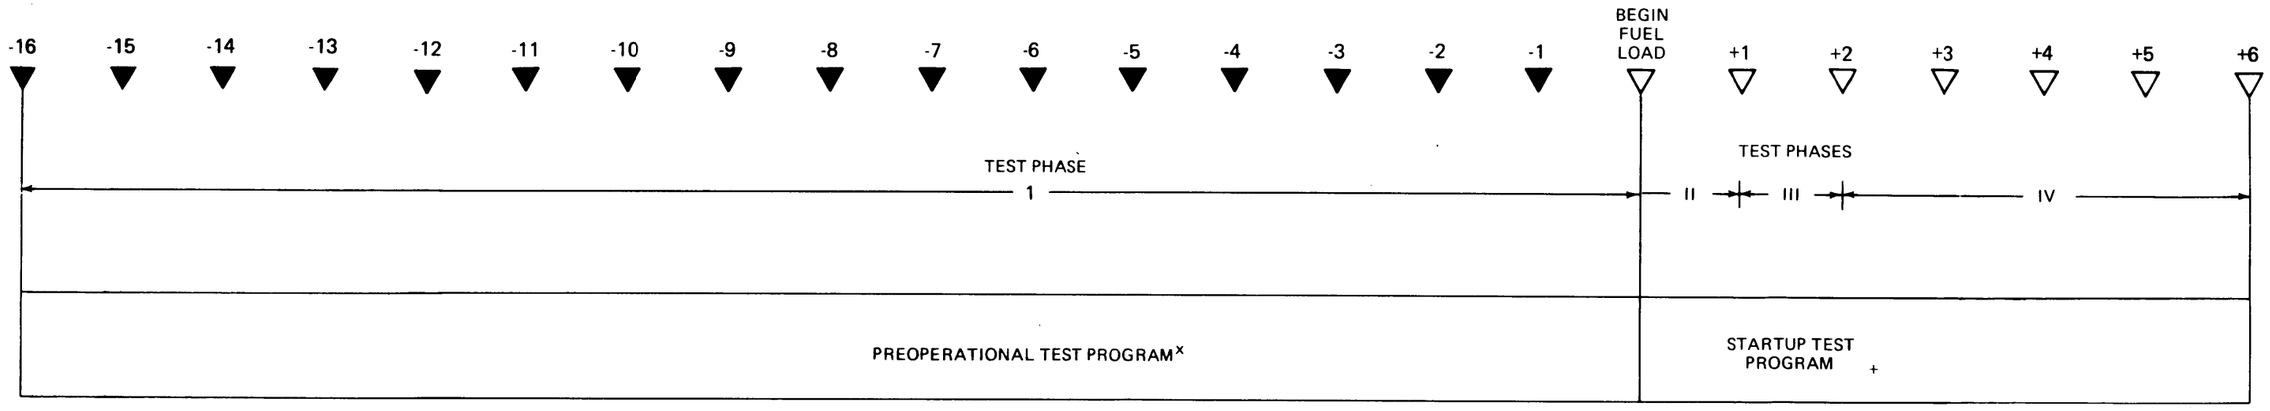
a. Each diesel generator is automatically started on a simulated LOCA with coincident LOOP, and reaches the required voltage and frequency within an acceptable time. (Section 8.3.1.1.3)

b. Each diesel generator is capable of carrying its full load for 24 hour period, the first two hours of which are at a load equivalent to the peak rating of the diesel generator (3135 kW) and the remaining 22 hours are at a load equivalent to the continuous rating of the diesel generator (2850 kW). The engine is permitted to reach temperature equilibrium prior to the application of the peak load. (Section 8.3.1.1.3)



c. Each diesel generator accepts the automatic design accident loading sequence at full load temperature conditions (immediately following the 24 hour test, above), and voltage and frequency are maintained within the required limits. The applied loads consist of the major ESF system loads as a minimum, plus as many of the 440 V auxiliary loads that are available at the time of this test, and any temporary means by which the actual demand seen by the diesel is simulated as close as practical. (Section 8.3.1.1.3)

d. Each diesel generator operates properly during load shedding, including loss of the single largest emergency load (a RHR pump). (Section 8.3.1.1.3)



e. While carrying its emergency loads, each diesel generator is capable of: (1) synchronizing with the offsite power source, (2) transferring its loads to the offsite power source, and (3) returning to standby status. (Section 8.3.1.1.3)

f. Each diesel generator auxiliary system operates properly and the fuel oil, lube oil, and jacket water systems will contain enough inventory to sustain the diesel generator for a 7 day period of continuous full load operation. (Sections 8.3.1.1.3, 9.5.4, 9.5.5, and 9.5.7)

15.9-53 Protection Sequences for Reactor Shutdown Without Control Rods

CHAPTER 15 - ACCIDENT ANALYSIS

15.0 GENERAL

This chapter describes the transient and accident analyses for LGS Units 1 and 2. The original analyses have been updated as part of the Power Rerate Project which increased the licensed rated thermal power to 3458 MWt (Reference 15.0-7). In addition, the original analyses have been supplemented to reflect changes to the licensed reactor operating domain (References 15.0-7, 15.0-10 and 15.0-11). As a result of improvements in plant feedwater flow measurement accuracy, a reduced reactor thermal power uncertainty can be applied. Due to the reduced uncertainty a MUR power uprate has been implemented that increases the licensed rated thermal power to 3515 MWt (1.65%) (See Section 1.1). Transient analyses to support MUR power uprate were performed for the first reload for MUR operation. Results are given in Cycle 14 reload documents. Radiological consequences evaluated for the Power Rerate Project are bounding for MUR because they were performed at a power level of 3527 MWt. The LGS operating domain is described in Appendix 15B. Limerick Units 1 and 2 contain GNF3 fuel only; however, references to GNF2 fuel for some accident analyses, such as CRDA, remain applicable.

The results of the analyses presented in the following sections provide the user with information regarding the general sequence of events, features, system behaviors, and trends and characteristics of each event. The information provided allows for an evaluation of the potential impact of changes to plant systems on the results of a particular analysis. The specific results presented (i.e. peak neutron flux and pressure, ΔCPR, etc.) are explicitly applicable to the LGS Unit 1 Cycle 5 core only, which was the basis of the analyses (unless specified otherwise). The results are, however, representative of the expected plant response for both units.

The limiting transients in each category of event are discussed in detail and have been revised to reflect power rerate conditions. In general, the non-limiting events have not been reanalyzed for power rerate. The results presented in Chapter 15 for the non-limiting events reflect the original plant operating conditions. However, these results continue to provide a reasonable representation of the trends and characteristics of the event.

For each core reload, a cycle specific safety analysis is performed utilizing the methods described in References 15.0-2 to 15.0-5, 15.0-13, 15.0-15, and 15.0-16. The limiting transient events are re-evaluated for each reload. The results of these analyses are documented in the cycle specific Supplemental Reload Licensing Report (SRLR). Information from the SRLR is used in the development of the cycle specific Core Operating Limit Report (COLR).

The scope of the situations analyzed includes anticipated (expected) operational occurrences (e.g., loss of electrical load); off design, abnormal (unexpected) transients that induce system operation disturbances; postulated accidents of low probability (e.g., the sudden loss of integrity of a major component); and hypothetical events of extremely low probability (e.g., an ATWS).

15.0.1 ANALYTICAL OBJECTIVE

The spectrum of postulated initiating events is divided into categories based upon the type of disturbance and the expected frequency of the initiating occurrence; the limiting events in each combination of category and frequency are quantitatively analyzed. The plant safety analysis evaluates the ability of the plant to operate within regulatory guidelines, without undue risk to the public health and safety.

15.0.2 ANALYTICAL CATEGORIES

Transient and accident events contained in this report are discussed in individual categories as required by Reference 15.0-1. The results of the events are summarized in Table 15.0-1, for the initial core, and in Table 15.0-1A for rerated conditions. Each event evaluated is assigned to one of the following applicable categories:

a. Decrease in Core Coolant Temperature - Reactor vessel water (moderator) temperature reduction results in an increase incore reactivity. This could lead to fuel cladding damage.

b. Increase in Reactor Pressure - Nuclear system pressure increases threaten to rupture the RCPB. Increasing pressure also collapses the voids in the core moderator, thereby increasing core reactivity and power level which threaten fuel cladding due to overheating.

c. Decrease in Reactor Core Coolant Flow Rate - A reduction in the core coolant flow rate threatens to overheat the cladding as the coolant becomes unable to adequately remove the heat generated by the fuel.

d. Reactivity and Power Distribution Anomalies - Transient events included in this category are those that cause rapid increases in power and are due to increased core flow disturbance events. Increased core flow reduces the void content of the moderator, increasing core reactivity and power level.

e. Increase in Reactor Coolant Inventory - Increasing coolant inventory could result in excessive moisture carryover to the main turbine, feedwater turbines, etc.

f. Decrease in Reactor Coolant Inventory - Reductions in coolant inventory could threaten the fuel as the coolant becomes less able to remove the heat generated in the core.

g. Radioactive Release from Subsystems and Components - Loss of integrity of a radioactive containment component is postulated.

h. Anticipated Transients Without Scram - In order to determine the capability of plant design to accommodate an extremely low probability event, a multisystem maloperation situation is postulated.

15.0.3 TRANSIENT OR ACCIDENT EVALUATION

15.0.3.1 Identification of Causes and Frequency Classification

Situations and causes that lead to the initiating event analyzed are described within the categories designated above. The frequency of occurrence of each transient or accident is summarized based upon currently available operating plant history for the transient, or accident. Transients, or accidents, for which inconclusive data exist are discussed separately within each section.

Each initiating event within the major groups is assigned to one of the following frequency groups:

a. Incidents of moderate frequency - These are accidents that may occur from once during a calendar year to once per 20 years for a particular plant. These events are referred to as "anticipated (expected) operational transients."

b. Infrequent incidents - These are accidents that may occur occasionally during the life of a particular plant, ranging in time from once in 20 years to once in 100 years. These events are referred to as "abnormal (unexpected) operational transients."

c. Limiting faults - These are accidents that are not expected to happen, but are postulated because they may result in the release of significant amounts of radioactive material. These events are referred to as "design basis (postulated) accidents."

d. Normal operation - Operations of high frequency are not discussed here, but are examined, along with (a), (b), and (c), in the nuclear systems operational analyses in Section 15.9.

15.0.3.1.1 Unacceptable Results for Incidents of Moderate Frequency - Anticipated (Expected) Operational Transients

The following are considered to be unacceptable safety results for incidents of moderate frequency (anticipated operational transients):

a. A release of radioactive material to the environs that exceeds the limits of 10CFR20.

b. Reactor operation induced fuel cladding failure.

c. Nuclear system stresses in excess of those allowed for the transient classification by applicable industry codes.

d. Containment stresses in excess of those allowed for the transient classification by applicable industry codes.

15.0.3.1.2 Unacceptable Results for Infrequent Incidents - Abnormal (Unexpected) Operational Transients

The following are considered to be unacceptable safety results for infrequent incidents (abnormal operational transients):

a. Release of radioactivity that results in dose consequences that exceed a small fraction of 10CFR50.67.

b. Failure of fuel cladding which could cause changes in core geometry such that core cooling would be inhibited.

c. Generation of a condition that results in consequential loss of function of the reactor coolant system.

d. Generation of a condition that results in a consequential loss of function of a necessary containment barrier.

e. Nuclear system stresses in excess of those allowed for the accident classification by applicable industry codes.

15.0.3.1.3 Unacceptable Results for Limiting Faults - Design Basis (Postulated) Accidents

The following are considered to be unacceptable safety results for limiting faults (DBAs):

a. Radioactive material release that results in dose consequences that exceed the guideline values of 10CFR50.67.

b. Failure of fuel cladding which could cause sufficient changes in core geometry such that core cooling would be inhibited.

c. Nuclear system stresses in excess of those allowed for the accident classification by applicable industry codes.

d. Containment stresses in excess of those allowed for the accident classification by applicable industry codes when containment is required.

e. Radiation exposure to plant operations personnel in the main control room in excess of 5 rem TEDE (total effective dose equivalent).

15.0.3.2 Sequence of Events and System Operation

Each transient, or accident, is discussed and evaluated in terms of the following:

a. A step-by-step sequence of events, from initiation to final stabilized condition.

b. The extent to which normally operating plant instrumentation and controls are assumed to function.

c. The extent to which plant and reactor protection systems are required to function.

d. The credit taken for the functioning of normally operating plant systems.

e. The operation of engineered safety systems that is required.

f. The effect of a single active failure, or of a single operator error.

g. The effects of plant equipment out-of-service.

15.0.3.2.1 Single Active Failures or Single Operator Errors

15.0.3.2.1.1 General

This paragraph discusses a very important concept pertaining to the application of single active failures and single operator errors in analyses of the postulated events. Single active failure criteria have been required, and successfully applied, in past NRC-approved docket applications to DBA categories only. Reference 15.0-1 infers that "single active failures and single operator errors" requirements should be applied to transient events (including high, moderate, and low probability occurrences) as well as to accident (very low probability) situations.

Transient evaluations have been judged against a criterion of one single active failure, or one single operator error, as the initiating event, with no additional single failure assumptions to the protective sequences, although a great majority of these protective sequences are utilized in safety systems that can accommodate single active failures aspects. Even under these postulated transients, or

accidents, the plant damage allowances, or limits, were very much the same as those for normal operation.

Reference 15.0-1 suggests that the transient and accident scenarios should now include multifailure event sequences. The format requested follows:

a.	For initiating occurrence	1 -	An equipment failure or an operator error, and
b.	For single active failure or operator error analysis	2 -	Another equipment failure or failures and/or another operator error or errors.

Most transients, or accidents, postulated for consideration are the result of a single active failure or a single operator error that have been postulated during any normal or planned mode of plant operations. The types of operational single active failures and single operator errors considered as initiating events, and subsequent protective sequence challenges, are identified in the paragraphs below.

15.0.3.2.1.2 Initiating Event Analysis

a. The undesired opening or closing of any single valve (a check valve is not assumed to close against normal flow), or

b. The undesired starting or stopping of any single component, or

c. The malfunction or maloperation of any single control device, or

d. Any single electrical component failure, or

e. Any single operator error.

Operator error is defined as "an active deviation from written operating procedures or nuclear plant standard operating practices." The result of a single operator error is the set of actions that follows a single erroneous decision. The set of actions is limited as follows:

a. Those actions that could be performed by one person.

b. Those actions that would have constituted a correct procedure had the initial decision been correct.

c. Those actions that are subsequent to the initial operator error and have an effect on the designed operation of the plant, but are not necessarily directly related to the operator error.

Examples of single operator errors are as follows:

a. An increase in power above the established flow control power limits from control rod withdrawal in the specified sequences.

b. The selection and complete withdrawal of a single control rod out-of-sequence.

c. The incorrect calibration of an APRM.

d. Manual isolation of the main steam lines as a result of operator misinterpretation of an alarm or indicator.

15.0.3.2.1.3 Single Active Failure or Single Operator Error Analysis

a. The undesired action or maloperation of a single active component, or

b. Any single operator error as defined in Section 15.0.3.2.1.2.

15.0.3.2.2 Analyzed Transients and Nonsafety-Grade Systems or Components

The thermal and pressure safety limits are not compromised by inclusion of the simulated response of nonsafety-grade systems when analyzing transients.

Referring to Table 15.0-6, the analysis for each of the transients is based on the single failure criterion associated with abnormal transients (i.e., abnormal transients are defined as events that occur as a result of equipment malfunctions as a result of a single active component failure or operator error). Following this single failure, the resulting transient is simulated in a conservative fashion to show the response of primary system variables and how the various plant systems would interact and function. In the transients, the consideration of any additional failures is not considered appropriate within the realm of the abnormal transient definition, but shifts them to infrequent events (infrequent events being those not expected in the 40 year plant lifetime).

Although certain transient events assume the operation of specific nonsafety-grade equipment to provide a realistic transient signature, failures of such equipment would not make these events more thermal or pressure limiting than the limiting accidents already addressed in Chapters 5 and 15. In fact, many of the events that have a Level 8 turbine trip (nonsafety-grade trip) would be less severe if the Level 8 trip was assumed not to function.

For example, failure of the Level 8 turbine trip or failure of the bypass to open when the Level 8 trip does occur was studied for a BWR similar to the LGS design. The increase in ΔCPR was about 0.02 for a delay in the turbine trip and 0.08 for failure of bypass. Although thermal margins are reduced, no significant (if any) fuel damage is expected. The offsite doses (if any) would be negligible and therefore would have no impact from a health and safety viewpoint. The loss of feedwater event is analytically about the same with or without the recirculation runback ahead of the Level 2 trip.

15.0.3.3 Core and System Performance

15.0.3.3.1 Introduction

Reactor core and system performance analysis must demonstrate that:

1. The margin of safety for Anticipated Operational Occurrences (AOOs) remain within all applicable criteria.

2. All fuel and thermal mechanical transient overpowers are within the applicable design bases.

3. The maximum reactor vessel pressure does not exceed the ASME code allowable peak pressure of 1375 psig.

4. Primary containment integrity is not comprised.

Section 4.4 describes the various fuel failure mechanisms. Avoidance of mechanisms (a) and (b) for incidents of moderate frequency is verified statistically with consideration given to data, calculating, manufacturing, and operating uncertainties. An acceptable criterion was determined to be that 99.9% of the fuel rods in the core would not be expected to experience boiling transition (References 15.0-2, 15.0-15, and 15.0-16). Limerick has adopted TSTF-564, which established a revised safety limit basis. The revised basis will ensure that there is a 95% probability at a 95% confidence level that no fuel rods will be susceptible to boiling transition using a safety limit based on the critical power ratio statistics. For TRACG applications, an operating limit MCPR (OLMCPR) is calculated for the transient initial condition that will result in no more than 0.1% of the fuel rods susceptible to boiling transition. For non-TRACG AOO analyses, this criterion is met by demonstrating that incidents of moderate frequency do not result in a MCPR less than the established Safety Limit $MCPR_{99.9\%}$. The reactor steady-state CPR operating limit is derived by determining the decrease in MCPR for the most limiting transient, or accident. All other transients, or accidents, result in smaller MCPR decreases and are not reviewed in depth in this chapter. The MCPR during significant abnormal transient, or accident, is calculated using a transient core heat transfer analysis computer program. The computer program for historical non-TRACG AOO analysis is based upon a multinode, single channel thermal-hydraulic model that requires simultaneous solution of the partial differential equations for the conservation of mass, energy, and momentum in the bundle, and that accounts for axial variation in power generation. The primary inputs to the model include a physical description of the bundle, channel inlet flow and enthalpy, and pressure and power generation as functions of time.

A detailed description of the analytical model may be found in Reference 15.0-2 or Reference 15.0-13 for TRACG reload AOO methodology. The initial condition assumed for all full power transient MCPR calculations is that the bundle is operating at or above the applicable Safety Limit $MCPR_{99.9\%}$ documented in the cycle-specific Core Operating Limits Report (COLR). Maintaining MCPR greater than the cycle-specific Safety Limit $MCPR_{99.9\%}$ is a sufficient, but not necessary, condition to assure that no fuel damage occurs.

For situations in which fuel damage is sustained, the extent of damage is determined by correlating fuel energy content, cladding temperature, fuel rod internal pressure, and cladding mechanical characteristics.

These correlations are substantiated by fuel rod failure tests, and are discussed in Section 4.4 and Section 6.3.

The closure of all MSIVs causes an abrupt pressure increase in the reactor vessel. System pressure increase is mitigated by the actuation of the SRVs within their design and operating limits. Operating limits are placed on all RCPB component to ensure compliance to ASME overpressure protection criteria. Limits are also placed on reactor dome operating pressure and on SRVs out-of-service. These limits assure that the ASME code allowable value for peak vessel pressure is not exceeded and RCPB integrity is maintained.

The Mark II primary containment is designed to accommodate pressures, temperatures, and dynamic loads resulting from pipe breaks within the drywell or reactor blowdown through the SRV discharge and thereby limit the release of radioactive material to the plant and its environs. Core and containment cooling systems assure a coolable fuel geometry and control drywell and wetwell pressure and temperature conditions within primary containment design limits. Limits placed on reactor and core operating conditions assure that containment integrity is maintained.

15.0.3.3.2 Input Parameters and Initial Conditions for Analyzed Events

In general, the transients, or accidents, analyzed within this section have values for input parameters and initial conditions as specified in Table 15.0-2, for the initial core, and in Table 15.0.2A for power rerate. Analyses that assume data inputs different from these values are designated accordingly in the appropriate event discussion.

The transient analyses herein includes an RPT actuated by either fast closure of the turbine control valves or closure of the turbine stop valve.

For the original Cycle 1 transient event evaluations, low water level MSIV closure was simulated at Level 2. Subsequent design modifications have lowered the closure setpoint to Level 1. However, HPCI and RCIC initiation at Level 2 will prevent the water level from dropping to Level 1, and no MSIV closure will occur. Because no safety limits are approached during events for which the level is predicted to reach Level 2, reanalysis for the setpoint change is not required for the Cycle 1 analyses. The power rerate analysis utilized the Level 1 MSIV closure setpoint.

The UFSAR evaluates a wide range of process disturbances and component failures of varying severity to demonstrate conformance to plant safety and licensing criteria (Reference 15.0-1).

Generic guidelines for uprating BWRs (Reference 15.0-8) and established LGS reload licensing practice identify transient and accident events that are limiting to BWRs or are otherwise sufficient to demonstrate that all NRC protection criteria are met for LGS power rerate operation. The evaluations, where appropriate, are based on the characteristics of the LGS Unit 1 Cycle 5 core configuration. Comparisons of the results of the baseline evaluations for power rerate conditions and originally licensed operating conditions using improved models and methods are provided.

Input parameters consist of heat balance information, core characteristics, and reactor protection specifications. The inputs include the initial power and flow conditions, core pressure drop, nuclear dynamic parameters (scram times, void fraction, Doppler coefficient) and system set points (SRVs,reactor scram, recirculation and feedwater pump trips, etc.). The analyses cover the full spectrum of core conditions from the beginning to the end of the fuel cycle, whichever is more limiting for the event in consideration.

The analyses are based on the core loading characteristic of LGS Unit 1 Cycle 5. The GEMINI methodology is applied as recommended in the generic power uprate guidelines (Reference 15.0-8), which is consistent with the LGS reload licensing practice.

The key system input parameters used in the power rerate transient analysis are shown in Table 15.0-2A; corresponding evaluation results are summarized in Table 15.0-1A.

15.0.3.3.3 Initial Power/Flow Operating Constraints

The analysis basis for most of the transient and accident analyses is the most limiting point on the power/flow operating map. Typically, this is at the maximum licensed core thermal power. Depending on the event being analyzed, the core thermal power is adjusted, either directly or indirectly, to account for the required licensing power uncertainty as described in GESTAR II (Reference 4.1-1) (See Section 15.0.4, Regulatory Guide 1.49). The limiting core flow rate is also dependent on the event being analyzed.

The operating power/flow map shown in Figure 15.0-1 includes the Maximum Extended Load Line Limit (MELLL) and Increased Core Flow (ICF) to 110% core flow operating domain.

The following performance improvement features are also included in the transient analyses: the FFWTR option used in conjunction with ICF at the end of the cycle, TBSOOS (formally documented as 'TBVOOS', which is now separate; see Sections 15B.4.1 and 15B.4.6), EOC-RPTOOS, TCVOOS and/or TSVOOS, PLUOOS, 1 MSIVOOS, 2 SRVOOS, 1 TBVOOS, FWHOOS, and PROOS. Additional details related to the combination of equipment OOS options with ARTS, MELLL, and ICF operation can be found in References 15.0-10 and 15.0-11.

The operating and performance improvement features described above are part of the LGS licensed operating domain. A detailed discussion of the LGS licensed operating domain is found in Appendix 15B.

Certain localized events are evaluated at other than the above mentioned conditions. These other conditions are discussed with the appropriate transient, or accident.

15.0.3.3.4 Results

The results of analytical evaluations are provided for each transient, or accident. In addition, critical parameters are shown in Table 15.0-1 for Cycle 1 conditions and in Table 15.0-1A for power rerate conditions. From the data in Table 15.0-1, an evaluation of the limiting event for that particular category and parameter can be made. In Table 15.0-3, a summary of applicable accidents is provided. This table compares the GE calculated amount of failed fuel to that used in worst case radiological calculations.

The results of each transient or accident for subsequent cycles can be found in the Supplemental Reload Licensing Report.

15.0.3.4 Barrier Performance

This section primarily evaluates the performance of both the RCPB and the containment system during transients and accidents.

During transients that occur with no release of coolant to the containment, only RCPB performance is considered. If release to the containment occurs, as in the case of limiting faults, then challenges to the containment are evaluated as well.

Containment integrity is maintained as long as internal pressures remain below the maximum allowable values. The design internal pressures are as follows:

Drywell (primary containment)	55 psig
Suppression Chamber (Primary Containment)	55 psig
Secondary Containment	7 in H2O

The LOCA radiological analyses account for the radiation released from the secondary containment during the time that the pressure exceeds minus 0.25 inch wg.

Damage to any of the radioactive material barriers as a result of accident-initiated fluid impingement, and jet forces, is considered in the other portions of the UFSAR where mechanical design features

of the systems and components are described. Design basis accidents are used in determining the size and strength requirements of the essential nuclear system components. A comparison of the accidents considered in this section with those used in the mechanical design of equipment reveals that either the applicable accidents are the same, or that the accident in this section results in less severe stresses than those assumed for mechanical design.

15.0.3.5 Radiological Consequences

In this chapter, the consequences of radioactivity release during the three types of events are considered:

a. Incidents of moderate frequency (anticipated operational transients)

b. Infrequent incidents (abnormal operational transients)

c. Limiting faults (DBA).

For all transients, or accidents, whose consequences are limiting, a detailed quantitative evaluation is presented. For nonlimiting transients, or accidents, a qualitative evaluation is presented, or results are referenced from a more limiting or enveloping case.

The original plant design basis included the analyses of radiological consequences based on the source terms of TID-14844 and Regulatory Guides 1.3, 1.5 and 1.25.

Regulation 10CFR50.67, "Accident Source Term," provides a mechanism to replace the traditional TID-14844 accident source term with an "Alternative Source Term" (AST). The methodology of approach to this replacement is provided in Regulatory Guide 1.183 and its associated Standard Review Plan 15.0.1.

In support of a full scope implementation of AST in accordance with Regulatory Guide 1.183, AST radiological consequence analyses were performed for the four Design Basis Accidents that result in offsite exposures. These include the Loss of Coolant Accident (LOCA), Main Steam Line Break (MSLB). Fuel Handling Accident (FHA) and Control Rod Drop Accident (CRDA). The dose consequences for these accidents are discussed elsewhere in Chapter 15 and result in doses that are within the guidelines of 10CFR50.67.

Although only the four major accidents have been evaluated using the AST methodology, the AST analytical methods described in Regulatory Guide 1.183 and dose limits defined in 10CFR50.67 comprise the design basis for Limerick for all design basis accidents.

Short-term, site specific X/Qs were calculated as described in Section 2.3 and are shown in Table 15.0-4.

15.0.4 REGULATORY GUIDE CONFORMANCE

The regulatory guides pertinent to accident analyses, and LGS conformance, are as follows:

Regulatory Guide 1.3 (Radiological Consequences of a LOCA)

The Limerick original LOCA dose consequences were determined in accordance with Regulatory Guide 1.3. With the implementation of Alternative Source Term in accordance with 10CFR50.67, the dose consequence analytical methodology of Regulatory Guide 1.183 applies

and supersedes the methodology of Regulatory Guide 1.3. LGS is in conformance with Regulatory Guide 1.183 requirements.

Regulatory Guide 1.5 (Radiological Consequences of a Steam Line Break)

The Limerick original main steam line break dose consequences were determined in accordance with Regulatory Guide 1.5. With the implementation of Alternative Source Term in accordance with 10CFR50.67, the dose consequence analytical methodology of Regulatory Guide 1.183 applies and supersedes the methodology of Regulatory Guide 1.5. LGS is in conformance with Regulatory Guide 1.183 requirements.

Regulatory Guide 1.25 (Radiological Consequences of a Fuel Handling Accident)

The Limerick original fuel handling accident dose consequences were determined in accordance with Regulatory Guide 1.25. With the implementation of Alternative Source Term in accordance with 10CFR50.67, the dose analytical methodology of Regulatory Guide 1.183 applies and supersedes the methodology of Regulatory Guide 1.25. LGS is in conformance with Regulatory Guide 1.183 requirements as noted in NRC Safety Evaluation Reports dated September 8, 2006, and March 15, 2017.

Regulatory Guide 1.49 (Power Levels of Nuclear Power Plants).

The power levels assumed in the analyses are in accordance with this guide.

NOTE: Transient analyses were performed at the licensed rated thermal power of 3515 MWt for the first reload for MUR operation. Radiological consequences evaluated for the Power Rerate Project are bounding because they were performed at a power level of 3527 MWt (102% of the Power Rerate Project thermal power of 3458 MWt).

Regulatory Guide 1.98 (radiological consequences of an offgas system failure).

LGS is in conformance with this guide, with the following clarifications:

a. In reference to Paragraph c.4.a of the guide, the LGS total whole body dose is calculated based upon the radiation at a depth of 5 cm, the average depth of the blood-forming organs. This is standard practice and is endorsed for use in Appendix E, Paragraph 3, of Regulatory Guide 1.109 (doses for routine releases).

b. Dose conversion factors are taken from the most recent data available, rather than the reference given in Paragraph c.4.b of the guide.

Regulatory Guide 1.183 (Alternative Source Terms for Evaluating Design Basis Accidents)

Regulation 10CFR50.67, "Accident Source Term, "provides a mechanism to replace the traditional TID-14844 accident source term with an "Alternative Source Term" (AST). The methodology of approach to this replacement is provided in Regulatory Guide 1.183 and its associated Standard Review Plan 15.0.1.

In support of a full scope implementation of AST in accordance with Regulatory Guide 1.183, AST radiological consequence analyses were performed for the four Design Basis Accidents that result in offsite exposures. These include the Loss of Coolant Accident (LOCA), Main Steam Line Break (MSLB), Fuel Handling Accident (FHA) and Control Rod Drop Accident

(CRDA). The dose consequences for these accidents are discussed elsewhere in Chapter 15 and result in doses that are within the guidelines of 10CFR50.67.

Although only the four major accidents have been evaluated using the AST methodology, the AST analytical methods described in Regulatory Guide 1.183 and dose limits defined in 10CFR50.67 comprise the design basis for Limerick for all design basis accidents.

LGS is in conformance with the requirements of Regulatory Guide 1.183 as noted in NRC Safety Evaluation Reports dated September 8, 2006, and March 15, 2017.

15.0.5 NUCLEAR SAFETY OPERATIONAL ANALYSIS RELATIONSHIP

Section 15.9 is a comprehensive, total plant, system level, qualitative FMEA, relative to all the Chapter 15 events considered, the protective sequences utilized to accommodate the transients, or accidents, and their effects, and the systems involved in the protective actions.

Interdependency of analysis, and cross-referral of protective actions, are an integral part of this chapter and the section.

A summary table that classifies events by frequency only (i.e., not just within a given category such as decrease in core coolant temperature) is in Section 15.9.

15.0.6 LICENSING BASIS VS. EMERGENCY PROCEDURE GUIDELINES

The NRC Staff review of the BWR Owners' Group Emergency Procedure Guidelines (EPGs), Revision 4 (NEDO-31331, March 1987) is documented in an NRC Safety Evaluation Report (SER) dated September 12, 1988. In this SER, the NRC Staff concluded that the guidelines are acceptable for implementation; however, the NRC stated that each BWR Licensee who wishes to incorporate Revision 4 of the EPGs should assure that the EPGs will not impact its licensing bases.

To ensure that implementation of EPGs, Rev. 4 did not conflict with the LGS licensing based analyses, a review of the Cycle 1 analyzed transients was conducted. This review (documented in reference 15.0-6) identified the Pressure Regulator Failure-Open Direction event as the only analyzed transient in which operator action, as instructed by the Transient Response Implementation Plan (TRIP) Procedures, could interfere with the analyzed transient response as discussed in Section 15. For the Pressure Regulator Failure-Open Direction transient, it was concluded that procedural actions are sufficient to make the end result for the transient the same as that analyzed in Section 15.

This review was performed based on the following position regarding Licensing Basis vs. EPGs:

> Implementation of the TRIP procedures for events within the design basis does not conflict with the licensing basis as long as the successful implementation of operator actions makes the end result for the transient response the same as or more conservative than that analyzed in the UFSAR.

The Revision 4 BWROG EPGs already included, to a considerable degree, operator actions required to prevent or mitigate what are termed severe accidents (considered to begin with the onset of core damage). Subsequent to the issue of the Revision 4 EPGs, the preparation of Individual Plant Examinations (IPE) for nuclear plants, in conjunction with industry research, have provided additional severe accident mitigation information that was not available during the development of the

Revision4 EPGs. To ensure that the EPG strategies reflect the most current severe accident mitigation information available, a review of the EPG strategies, to the additional available severe accident mitigation information, was conducted. As a result of this review, the BWROG developed the Emergency Procedure and Severe Accident Guidelines (EPG/SAG). The SAG, together with the modified EPGs, form an integrated set of symptomatic instructions that attempt to cover all possible mechanistic accident sequences. The EPGs contain strategies applicable prior to the transition to a severe accident, and the SAG contain strategies applicable after the transition. EPG/SAG has superseded EPG, Revision 4 as the basis for the Emergency Operating Procedures (EOPs) at LGS.

To ensure that the implementation of EPG/SAG did not conflict with the LGS licensing-based analysis, a review of the SAR analyzed accidents, transients, and special events was conducted. The conclusions of this review are contained in the 10CFR50.59 Reviews prepared for the Plant Specific Technical Guidelines (PSTGs) and Plant Specific Severe Accident Management Guidelines (PSSAMGs) which support the transition from EPG, Revision 4 to EPG/SAG. Plant-unique variations from the EPG/SAG guidance have been evaluated in the 10CFR50.59 Reviews, the Plant Specific Technical Guidelines (PSTGs), and the Plant Specific Severe Accident Management Guidelines (PSSAMGs).

Table 15.0-1A (Cont'd)

TRANSIENT ANALYSIS RESULTS FOR POWER RERATE
(UNIT 1 CYCLE 5 CHARACTERISTICS)

Footnote

(a) TTNBP = turbine trip with no bypass
LRNBP = load rejection with no bypass
FWCF = feedwater controller failure to maximum demand
MSIVF = main steam isolation valve closure, flux scram
HPCI = inadvertent actuation of high pressure coolant injection system
LFWH = loss of 100F° feedwater heating
RWE = rod withdrawal error
BOC, MOC, EOC = beginning-of-cycle 5, mid-of-cycle 5, end-of-cycle 5
RPSE = recirculation pump seizure

(b) 100RP = rerate power of 3458 MWt
100F = rated core flow of 100.0 Mlb/hr

110F = ICF flow point (110M lb/hr) at rerate power

81F = MELLL flow point (81M lb/hr) at rerate power

(c) ΔCPR based on initial CPR which yields MCPR = 1.07, uncorrected for ODYN options A and B for TTNBP, LRNBP and FWCF events. GE8x8NB refers to the most limiting of all the 8x8 array fuel types in LGS Units 1 Cycle 5 core.

(d) EOC-RPT out-of-service (EOC-RPTOOS)

(e) Reduced feedwater temperature 320°F (105°F reduction at rerate conditions).

(f) Turbine bypass valves out-of service (TBVOOS)

(g) Three SRVs out-of-services (3SRVOOS)

(h) Unit 1, Cycle 8, TCV modified for full arc admission, GE 13 fuel.

(i) Representative for the Inadvertent HPCI with scram on Level 8 GNF3 design conditions.

15.2.7	Loss of Feedwater Flow	Recirculation Runback(2)
15.3.1	Recirculation Pump Trip - Two Pumps	Level 8 Turbine Trip, Turbine Bypass
15.3.2	Recirculation Flow Control Failure - Decreasing Flow	Level 8 Turbine Trip, Turbine Bypass
15.4.1	Rod Withdrawal Error - Low Power	Rod Worth Minimizer System
15.4.2	Rod Withdrawal Error - At Power	Rod Block Monitor

(1) Level 8 (high water level) trip potentially activated following the initial part of these events, but it is not a significant factor in fuel or vessel protection evaluation.

(2) Neglected in the analysis.

15.1 DECREASE IN REACTOR COOLANT TEMPERATURE

15.1.1 LOSS OF FEEDWATER HEATING

15.1.1.1 Identification of Causes and Frequency Classification

15.1.1.1.1 Identification of Causes

Feedwater heating can be lost in at least two ways:

a. Steam extraction line valves to one heater string are closed.

b. Feedwater train is isolated automatically by high water level in either the first or second heaters.

The first case produces a gradual cooling of the feedwater. The second case produces a slight cooling of the feedwater. In both cases the reactor vessel receives cooler feedwater. The maximum number of feedwater heaters that can be isolated by a single event represents the most severe transient for analysis considerations. This transient has been conservatively estimated to incur a loss of up to 100°F of the feedwater heating capability of the plant and causes an increase in core inlet subcooling. This increases core power due to the negative void reactivity coefficient.

The design specification of the feedwater heater system requires that the maximum temperature decrease caused by a single failure should be less than or equal to 100°F. In the unlikely event that a drop in feedwater temperature in excess of 100°F occurs, and assuming no operator action, the decrease in the MCPR and increase in reactor power would still be bounded by the limiting event (i.e. generator load rejection trip with failure of bypass).

15.1.1.1.2 Frequency Classification

The feedwater heating system is designed to provide and maintain adequate heating such that under any single failure condition, the loss of feedwater heating is limited to less than 100°F. The loss of feedwater heating event is categorized as an incident of moderate frequency in the General Electric Standard Application for Reactor Fuel (Supplement for United States) (GESTAR II). This event is considered to be one of the limiting Anticipated Operational Occurrences (AOOs) events. Therefore, this transient is analyzed as an incident of moderate frequency; a 100°F drop of feedwater temperature at full power is postulated.

15.1.1.2 Sequence of Events and System Operation

15.1.1.2.1 Sequence of Events

Table 15.1-2 lists the sequence of events for this transient. An APRM Simulated Thermal Power Upscale alarm alerts the operator to insert control rods or to reduce recirculation flow. The operator should determine from existing tables the maximum allowable turbine-generator output with feedwater heaters out of service. If reactor scram occurs, the operator should monitor the reactor water level, pressure controls, and turbine-generator auxiliaries during coast-down.

15.1.1.2.2 System Operation

In establishing the expected sequence of events and simulating plant performance, it is assumed that normal functioning occurs in the plant instrumentation and controls, plant protection, and reactor protection systems.

Required operation of ESF is not expected in either case for this transient. The APRM Simulated Thermal Power - Upscale scram is the primary protection system trip in mitigating the consequences of this event.

15.1.1.2.3 The Effect of Single Failures and Operator Errors

This transient generally leads to an increase in reactor power level. Single failures are not expected to result in a more severe transient than analyzed. See Section 15.9 for a detailed discussion of this subject.

15.1.1.3 Core and System Performance

15.1.1.3.1 Mathematical Model

Due to its slow progression, this event is treated as a quasi-steady-state transient and is analyzed with a steady-state, three dimensional BWR core simulator. The core simulator is used to evaluate the differences, including thermal margins, between the initial conditions of the event and the final equilibrium state point after the loss of feedwater heating.

15.1.1.3.2 Input Parameters and Initial Conditions

These analyses have been performed, unless otherwise noted, with plant conditions as tabulated in Table 15.0-2A. The events are analyzed for full cycle exposures at the BOC, MOC, and EOC conditions in order to bound the LGS operating domain described in Appendix 15B.

In addition to the inadvertent loss of feedwater heating event, consideration has also been given to planned operation with partial feedwater heating as follows.

There are two distinct periods of concern when operating with reduced feedwater temperature:

a. Before EOC - Reducing the feedwater temperature before EOC may occur during routine maintenance. The peak pressure will be lower because of the reduced steam production. The basis for the plant safety analysis covers this operating condition, and a cycle specific analysis is performed to confirm the plant safety.

b. After EOC - Operating with reduced feedwater temperature may occur as a result of an extended fuel cycle. The basis for the plant safety analysis covers this operating condition, and a cycle specific analysis is performed to confirm the plant safety.

The safety analyses for operation with reduced feedwater temperature evaluates: anticipated operational transients, including the LFWH event; Design Basis Accidents, including LOCA containment response; thermal-hydraulic instability; and reactor vessel internals, including feedwater nozzle and sparger fatigue. (Refer to Sections 15B.1.2 and 15B1.3 for more information.)

15.1.1.3.3 Results

The LFWH event is initiated from a closure of a steam extraction line to a feedwater heater or when feedwater is bypassed around one or more feedwater heaters. In either case, the feedwater temperature is reduced and core inlet subcooling is gradually increased. As a result, core power increases due to the negative void reactivity coefficient.

Vessel steam flow increases and the system pressure increase is slight so the RCPB is not threatened. The increased core inlet subcooling aids core thermal margins and the minimum MCPR is maintained above the Safety Limit $MCPR_{99.9\%}$. The ΔCPR for this event is 0.09 which is significantly less than the ΔCPR for the limiting event (generator load rejection with bypass failure). Therefore, the safety limit is satisfied.

Sensitivity studies have shown that the effect of initial power level on core thermal margin is negligible, with the event occurring at high power slightly more severe.

The results at the low core flow condition (MELLL case) are actually slightly more severe than for the high core flow condition (ICF case) because of increased inlet subcooling into the reactor core.

15.1.1.3.4 Considerations of Uncertainties

Important factors (such as reactivity coefficient, scram characteristics, magnitude of the feedwater temperature change) are assumed to be at the worst configuration so that any deviations seen in the actual plant operation reduce the severity of the transient.

15.1.1.4 Barrier Performance

As noted above consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.1.1.5 Radiological Consequences

Since this transient does not result in any additional fuel failures or any release of primary coolant to either the secondary containment or the environment, there are no radiological consequences associated with this transient.

15.1.2 FEEDWATER CONTROLLER FAILURE - MAXIMUM DEMAND

15.1.2.1 Identification of Causes and Frequency Classification

15.1.2.1.1 Identification of Causes

This transient is postulated on the basis of a single failure of a control device, specifically one which can directly cause an increase in coolant inventory by increasing the feedwater flow. The most severe applicable transient is a feedwater controller failure during maximum flow demand. The feedwater controller is forced to its upper limit at the beginning of the transient.

15.1.2.1.2 Frequency Classification

This transient is considered to be an incident of moderate frequency.

15.1.2.2 Sequence of Events and System Operation

15.1.2.2.1 Sequence of Events

With excess feedwater flow the water level rises to the high level reference point at which time the feedwater pumps and the main turbine are tripped and a scram is initiated. Table 15.1-3 lists the sequence of events for Figure 15.1-3. The figure shows the changes in important variables during this transient.

The operator should:

a. Observe that high feedwater pump trip has terminated the failure event.

b. Switch the feedwater controller from automatic to manual control in order to try to regain a correct output signal.

c. Identify causes of the failure and report all key plant parameters during the transient.

15.1.2.2.2 System Operation

To properly simulate the expected sequence of events, the analysis of this transient assumes normal functioning of plant instrumentation and controls, plant protection, and reactor protection systems. Important system operational actions for this transient are high level tripping of the main turbine, turbine stop valve scram trip initiation, RPT, and low water level initiation of the RCIC system and the HPCI system to maintain long-term water level control following tripping of feedwater pumps.

15.1.2.2.3 The Effect of Single Failures and Operator Errors

In Table 15.1-3 the first sensed event to initiate corrective action to the transient is the vessel high water level (Level 8) trip. Multiple level sensors are used to sense and detect when the water level reaches the Level 8 setpoint. At this point in the logic, a single failure will not initiate or prevent a turbine trip signal. Turbine trip signal transmission, however, is not built to single failure criterion. The result of a failure at this point would have the effect of delaying the pressurization "signature." High levels in the turbine's moisture separators will result in a trip of the unit before high moisture levels enter the low pressure turbine.

Scram trip signals from the turbine are designed such that a single failure neither initiates nor impedes a reactor scram trip initiation. See Section 15.9 for a discussion of this subject.

15.1.2.3 Core and System Performance

15.1.2.3.1 Mathematical Model

The predicted dynamic behavior has been determined using a computer simulated, analytical models of a generic direct-cycle BWR. The models are described in detail in Reference 15.0-4 (ODYN) and Reference 15.0-13 (TRACG). These computer models have been improved and verified through extensive comparison of their predicted results with BWR test data.

The nonlinear computer simulated analytical model is designed to predict associated transient behavior of this reactor. Some of the significant features of the ODYN model are:

a. An integrated one-dimensional core model is assumed which includes a detailed description of hydraulic feedback effects, axial power shape changes, and reactivity feedbacks.

b. The fuel is represented by an average cylindrical fuel and cladding node for each axial location in the core.

c. The steam lines are modeled by eight pressure nodes incorporating mass and momentum balances which will predict any wave phenomena present in the steam line during pressurization transient.

d. The core average axial water density and pressure distribution is calculated using a single channel to represent the heated active flow and a single channel to represent the bypass flow. A model, representing liquid and vapor mass and energy conservation, and mixture momentum conservation, is used to describe the thermal-hydraulic behavior. Changes in the flow split between the bypass and active channel flow are accounted for during transient events.

e. Principal controller functions such as feedwater flow, recirculation flow, reactor water level, and pressure and load demand, are represented together with their dominant nonlinear characteristics.

f. The ability to simulate necessary reactor protection system functions is provided.

g. The control systems and reactor protection system models are, for the most part, identical to those employed in the point reactor model, which is described in detail in Reference 15.0.4-2 and used in analysis for other transients.

The TRACG model has similar features except it is a three-dimensional model.

15.1.2.3.2 Input Parameters and Initial Conditions

These analyses have been performed, unless otherwise noted, with the plant conditions as tabulated in Table 15.0-2A.

This event is typically analyzed at the limiting EOC (all-rods-out) statepoint, and at the limiting conditions (i.e. core flow, feedwater temperature, etc.), which bound the allowable LGS operating domain (see Appendix 15B). The cycle-specific maximum feedwater system runout capability is specified, with 5% additional feedwater runout capability applied for conservatism. The results

presented (LGS Unit 1, Cycle 5) are based on a 149% runout capability (144% + 5%) (where 100% feedwater flow is defined as 15.0×10^6lb/hr).

15.1.2.3.3 Results

The simulated feedwater controller transient is shown in Figure 15.1-3. The high water level turbine trip and feedwater pump trip are initiated at approximately 8.6 seconds. Scram occurs simultaneously from stop valve closure and limits the neutron flux peak and fuel thermal transient so that no fuel damage occurs. MCPR remains considerably above the safety limit. The turbine bypass system opens to limit peak pressure at the bottom of the vessel to about 1218 psig.

Consequently, the nuclear system process barrier pressure limit is not endangered.

The bypass valves subsequently close to re-establish pressure control in the vessel during shutdown. The level would gradually drop to the low level isolation reference point, activating the RCIC/HPCI systems for long-term level control.

15.1.2.3.4 Consideration of Uncertainties

All systems utilized for protection in this transient were assumed to have the most conservative allowable response (e.g., relief setpoints, scram stroke time, and reactivity characteristics). Expected plant behavior is, therefore, expected to lead to a less severe transient.

15.1.2.4 Barrier Performance

As noted above, the consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed; therefore, these barriers maintain their integrity and function as designed.

15.1.2.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established technical specifications and, at the worst, would only result in a small increase in yearly integrated exposure level.

15.1.2.6 Additional Transients Evaluated

Additional transients have been considered for LGS. Table 15.0-1A shows the peak transient responses for the various cases analyzed. For the ICF and the MELLL conditions, the FWCF event becomes more limiting due to the TBSOOS and the EOC-RPTOOS analysis assumptions. The fuel thermal margin results are within the acceptable limits for the fuel types analyzed. The sequence of events with an inoperative bypass system is shown on Table 15.1-3 and the transient parameters are on Figure 15.1-1. The MCPR values for these transients are also shown in Table 15.0-1A.

15.1.3 PRESSURE REGULATOR FAILURE - OPEN

15.1.3.1 Identification of Causes and Frequency Classification

15.1.3.1.1 Identification of Causes

The total steam flow rate to the main turbine resulting from a pressure regulator malfunction is limited by a maximum flow limiter imposed at the turbine controls. This limiter is set to limit maximum steam flow to approximately 115% NBR.

If the controlling regulator fails, the backup controller will take over control with a bumpless switchover. If both controllers fail to the open position, the turbine control valves can be fully opened and the turbine bypass valves can be partially or fully opened until the maximum steam flow is established.

15.1.3.1.2 Frequency Classification

This transient is categorized as an incident of moderate frequency.

15.1.3.2 Sequence of Events and System Operation

15.1.3.2.1 Sequence of Events

This is a non-limiting event that has not been reanalyzed for power rerate. The sequence of events presented in Table 15.1-4 are based on Cycle 1 conditions. An analysis of this event for rerate conditions is not expected to result in a change in the general trends and characteristics as shown.

Table 15.1-4 lists the sequence of events for Figure 15.1-4.

When a fault is detected with the controlling pressure regulator and preceded by spurious or erratic behavior of the controlling device, an automatic "bumpless" failover will occur to the back-up redundant pressure regulator controller. The operator does not have the ability to select the primary or backup controller. If both controllers fail to the open position, and if the reactor scrams as a result of the isolation caused by the low pressure at the turbine inlet in the run mode, the following is the sequence of operator actions expected during the course of the Once isolation occurs the pressure will increase to a point where the relief valves open. Operator actions for the case where high level (Level 8) trip occurs before the isolation are essentially identical. The operator should:

a. Monitor that all rods are in.

b. Monitor reactor water level and pressure.

c. Observe turbine coast-down and break vacuum before the loss of steam seals. Check turbine auxiliaries.

d. Observe that the reactor pressure relief valves open at their setpoint.

e. Observe that RCIC and HPCI initiate on low water level.

f. Secure both HPCI and RCIC when reactor pressure and level are under control.

g. Monitor reactor water level and continue cooldown per the normal procedure.

h. Complete the scram report and initiate a maintenance survey of pressure regulator before reactor restart.

15.1.3.2.2 System Operation

To simulate the expected sequence of events properly, the analysis of this transient assumes normal functioning of plant instrumentation and controls, plant protection, and reactor protection systems except as otherwise noted.

Initiation of HPCI and RCIC system functions will occur when the vessel water level reaches the Level 2 setpoint. Normal startup and actuation can take up to 30 seconds before full flow is realized. The 30 seconds is based on the cycle 1 conditions. This event was not reanalyzed for power rerate. If these events occur, they will follow sometime after the primary concerns of fuel thermal margin and overpressure effects have occurred, and are expected to be less severe than those already experienced by the system.

15.1.3.2.3 The Effect of Single Failures and Operator Errors

This transient leads to a loss of pressure control such that the increased steam flow demand causes a depressurization. Instrumentation for pressure sensing of the turbine inlet pressure is designed to be single failure proof for initiation of MSIV closure.

Reactor scram sensing, originating from limit switches on the turbine stop valves, is designed to be single failure proof. It is therefore concluded that the basic phenomenon of pressure decay is adequately terminated. See Section 15.9 for a detailed discussion of this subject.

15.1.3.3 Core and System Performance

15.1.3.3.1 Mathematical Model

The nonlinear dynamic model described in Reference 15.0-3 is used to simulate this transient.

15.1.3.3.2 Input Parameters and Initial Conditions

This transient is simulated by assuming both the primary and backup regulator outputs to a high value, which causes the turbine admission valves and the turbine bypass valves to open fully. Regulator failure with 135% steam flow was simulated as a worst case since 115% is the normal maximum flow limit.

A 5 second isolation valve closure instead of a 3 second closure is assumed when the turbine pressure decreases below the turbine inlet low pressure setpoint for main steam line isolation initiation. This is within the specification limits of the valve and represents a conservative assumption.

This analysis has been performed, unless otherwise noted, using Cycle 1 plant conditions as listed in Table 15.0-2.

15.1.3.3.3 Results

The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

A Pressure Regulator Failure-Open (PRFO), is non-limiting for fuel cladding integrity because the Critical Power Ratio (CPR) increases during the event, and they are not typically included in the scope of reload evaluations including uprate conditions and or raising the MSIV low pressure isolation setpoint. The following evaluation predicts that reactor vessel water level would swell during a PRFO transient; the depressurization would be terminated by a high level turbine trip.

Reactor vessel water level swell is difficult to predict and the reactor vessel water level swell portion of transient models have larger uncertainties than other portions of the transient models. Recent evaluations by GE with improved transient models have determined that the reactor vessel water level swell may not be sufficient to reach the high level trip, in which case the depressurization could be terminated by MSIV closure at the LPIS. The analysis of this scenario is provided In References 15.1-2, 15.1-3 and 15.1-4.

Figure 15.1-4 shows the response of important nuclear system variables for this transient. The water level rises to the high level trip setpoint and initiates trip of the main turbine and feedwater turbines. Closure of the turbine stop valves initiates scram and RPT. After the pressurization resulting from the turbine stop valve closure, pressure again drops and continues to drop until the turbine inlet pressure is below the low turbine pressure isolation setpoint when the main steam line isolation finally terminates the depressurization.

Reactor high level trip limits the duration and severity of the depressurization so that no significant thermal-stresses are imposed on the nuclear system process barrier. After the rapid portion of the transient is complete, the MSRVs operate intermittently to relieve the pressure rise that results from decay heat generation. No significant reductions in fuel thermal margins occur. Because the rapid portion of the transient results in only momentary depressurization of the nuclear system, the MSRVs need operate only to relieve the pressure increase caused by decay heat, the nuclear system process barrier is not threatened by high internal pressure for this pressure regulator malfunction.

15.1.3.3.4 Consideration of Uncertainties

If the maximum flow limiter were set higher or lower than normal, there would result a faster or slower loss in nuclear steam pressure. The rate of depressurization may be limited by the bypass capacity. For example, the turbine valves will open to the wide open state admitting slightly more than the rated steam flow, and with the limiter in this analysis set to fail at 135%, no more than 25% is expected to be bypassed. This is therefore not a limiting factor on this plant. If the rate of depressurization does change it will be terminated by the low turbine inlet pressure trip setpoint.

The depressurization rate has a proportional effect upon the voiding action of the core. If it is not large enough, the sensed vessel water level trip setpoint (Level 8) may not be reached and a turbine and feedwater pump trip will not occur in the transient. In this case, the turbine inlet pressure will drop below the low pressure isolation setpoint and the expected transient signature will conclude with an isolation of the main steam lines. The reactor will be shut down by the scram initiated from MSIV closure.

15.1.3.4 Barrier Performance

This is a non-limiting event that has not been reanalyzed for power rerate or for raising the MSIV low pressure isolation setpoint. The results presented are based on Cycle 1 conditions. An analysis of this event for rerate conditions is not expected to result in a change in the general trends and

characteristics as shown. Raising the MSIV low pressure isolation setpoint would terminate the event sooner and be less limiting.

Barrier performance analyses are not required since the consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which fuel, pressure vessel, or containment are designed. Peak pressure in the bottom of the vessel reaches 1165 psig which is below the ASME code limit of vessel dome pressure, 1375 psig for the RCPB. Vessel dome pressure reaches 1149 psig, just slightly below the setpoint of the second pressure relief group.

15.1.3.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established technical specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.1.4 INADVERTENT MAIN STEAM RELIEF VALVE OPENING

15.1.4.1 Identification of Causes and Frequency Classification

15.1.4.1.1 Identification of Causes

Cause of inadvertent MSRV opening is attributed to malfunction of the valve or an operator initiated opening. Opening and closing circuitry at the individual valve level (as opposed to groups of valves) is subject to a single failure event. It is therefore simply postulated that a failure occurs and the transient is analyzed accordingly. Detailed discussion of the valve design is provided in Chapter 5.

15.1.4.1.2 Frequency Classification

This transient is categorized as an infrequent incident. However, it is analyzed as an incident of moderate frequency.

15.1.4.2 Sequence of Events and System Operation

15.1.4.2.1 Sequence of Events

This is a non-limiting event that has not been reanalyzed for the power rerate. The sequence of events is based on Cycle 1 conditions. An analysis of this event for rerate conditions is not expected to result in a change in the general trends and characteristics as shown.

Table 15.1-5 lists the sequence of events for this transient.

The plant operator must "reclose" the valve as soon as possible and check that reactor and turbine-generator output return-to-normal. If the valve cannot be closed, plant shutdown should be initiated.

The operator will have the time period between the valve first sticking full open and the bulk pool temperature reaching 110°F before he must scram the reactor to be in compliance with the Technical Specifications.

If it is assumed that the suppression pool is at its maximum operating temperature (95°F) and minimum operating volume with no pool cooling systems in operation when the valve first opens, the operator will have more than 6 minutes before the pool scram temperature of 110°F is reached. If the above worst case assumptions were relaxed, the time for operator action would increase.

Delaying the reactor scram to 10 minutes after the valve sticks full open would have no adverse effect on plant safety. Even though the suppression pool temperature would approach 120°F at the time of scram, the maximum allowable suppression pool temperature limits would not be exceeded.

15.1.4.2.2 System Operation

This transient assumes normal functioning of normal plant instrumentation and controls, specifically the operation of the pressure regulator and levels control systems.

15.1.4.2.3 The Effect of Single Failures and Operator Errors

Failure of additional components (e.g., pressure regulator, feedwater flow controller) is discussed elsewhere in this chapter.

15.1.4.3 Core and System Performance

15.1.4.3.1 Mathematical Model

The computer model used to simulate this transient is discussed in detail in Reference 15.1-1. It has been determined that this transient is not limiting from a core performance standpoint. Therefore, a qualitative presentation of results is described below.

15.1.4.3.2 Input Parameters and Initial Conditions

This event is based on Cycle 1 conditions (see Table 15.0-2).

For this event it is assumed that the reactor is operating at an initial power level of 3458 MWt when an MSRV is inadvertently opened. Flow through the valve at normal plant operating conditions stated above is approximately 7% of original rated steam flow.

15.1.4.3.3 Results

This is a non-limiting event that has not been reanalyzed for power rerate. The results presented are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

The opening of an MSRV allows steam to be discharged into the suppression pool. The sudden increase in the rate of steam flow leaving the reactor vessel causes a mild depressurization transient.

The pressure regulator senses the nuclear system pressure decrease and within a few seconds closes the turbine control valve far enough to stabilize reactor vessel pressure at a slightly lower value, and reactor power settles at nearly the initial power level. Thermal margins decrease only slightly through the transient, and no fuel damage results from the transient. MCPR is essentially unchanged and therefore the safety limit margin is unaffected.

15.1.4.4 Barrier Performance

As discussed above, the transient resulting from an inadvertent MSRV opening is a mild depressurization which is within the range of normal load-following and therefore has no significant effect on RCPB and containment design pressure limits.

15.1.4.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with the established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.1.5 SPECTRUM OF STEAM SYSTEM PIPING FAILURES INSIDE AND OUTSIDE OF CONTAINMENT IN A PWR

This event is not applicable to BWR plants.

15.1.6 INADVERTENT RHR SHUTDOWN COOLING OPERATION

15.1.6.1 Identification of Causes and Frequency Classification

15.1.6.1.1 Identification of Causes

At design power conditions no conceivable malfunction in the shutdown cooling system could cause temperature reduction.

If the reactor were critical or near critical in a startup or cooldown condition, a very slow increase in reactor power could result. A shutdown cooling malfunction leading to a moderator temperature decrease could result from misoperation of the cooling water controls for the RHR heat exchangers. The resulting temperature decrease would cause a slow insertion of positive reactivity into the core. If the operator did not act to control the power level, a high neutron flux reactor scram would terminate the transient without violating fuel thermal limits and without any measurable increase in nuclear system pressure.

15.1.6.1.2 Frequency Classification

Although no single failure could cause this transient, it is conservatively categorized as a transient of moderate frequency.

15.1.6.2 Sequence of Events and System Operation

15.1.6.2.1 Sequence of Events

A shutdown cooling malfunction leading to a moderator temperature decrease could result from misoperation of the cooling water controls for RHR heat exchangers. The resulting temperature decrease causes a slow insertion of positive reactivity into the core. Scram will occur before any thermal limits are reached if the operator does not take action. The sequence of events for this transient is shown in Table 15.1-1.

15.1.6.2.2 System Operation

A shutdown cooling malfunction causing a moderator temperature decrease must be considered in all operating states. However, this transient is not considered while at power operation since the nuclear system pressure is too high to permit operation of the RHR shutdown cooling mode.

No unique safety actions are required to avoid unacceptable safety results for transients as a result of a reactor coolant temperature decrease induced by misoperation of the shutdown cooling heat exchangers. In startup or cooldown operation, where the reactor is or nearly is critical, the slow power increase resulting from the cooler moderator temperature would be controlled by the operator in the same manner normally used to control power in the source or intermediate power ranges.

15.1.6.2.3 The Effect of Single Failures and Operator Errors

No single failures can cause this transient to be more severe. If the operator takes action, the slow power rise will be controlled in the normal manner. If no operator action is taken, scram will terminate the power increase before thermal limits are reached (Section 15.9).

15.1.6.3 Core and System Performance

The increased subcooling caused by misoperation of the RHR shutdown cooling mode could result in a slow power increase due to the reactivity insertion. This power rise would be terminated by a flux scram before fuel thermal limits are approached. Therefore, only a qualitative description is provided here.

15.1.6.4 Barrier Performance

As noted above, the consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed, therefore, these barriers maintain their integrity and function as designed.

15.1.6.5 Radiological Consequences

Since this transient does not result in any fuel failures, no analysis of radiological consequences is required for this transient.

Table 15.1-4

SEQUENCE OF EVENTS FOR PRESSURE REGULATOR FAILURE[1]

TIME (sec)	EVENT
0	Simulate maximum limit flow to main turbine.
0.4	Main turbine bypass opens.
0.7(est)	Turbine control valves open wide.
4.7	Vessel water level (Level 8) trip initiates main turbine and feedwater turbine trips.
4.7	Main turbine stop valve position initiates reactor scram and RPT.
4.8	Turbine stop valves closed.
4.9	Recirculation pump motor circuit breakers open causing decrease in core flow to natural circulation.
46.8	Main steam line isolation on low turbine inlet pressure.
51.8	MSIVs closed. Bypass valves remain open, exhausting steam in steam lines downstream of isolation valves.
52.0	RCIC AND HPCI systems initiation on low level (Level 2).
>100.0	Group 1 MSRVs actuate and cycle.

(1) See Figure 15.1-4.

NOTE: This is a non-limiting event that has not been re-analyzed for power rerate or for raising the MSIV low pressure isolation setpoint. The results of this event are based on Cycle 1 conditions. An analysis of this event for the rerate conditions is not expected to result in a change in the general trends and characteristics as shown. Raising the MSIV low pressure isolation setpoint would terminate the event sooner and be less limiting.

Table 15.1-5

SEQUENCE OF EVENTS FOR INADVERTENT MAIN STEAM RELIEF VALVE OPENING

TIME (sec)	EVENT
0	Initiate opening of one MSRV.
0.5(est)	MSRV flow reaches full flow.
15.0(est)	System establishes new steady-state operation.

NOTE: This is a non-limiting event that has not been re-analyzed for power rerate. The results of this event are based on Cycle 1 conditions. An analysis of this event for the rerate conditions is not expected to result in a change in the general trends and characteristics as shown.

15.2 INCREASE IN REACTOR PRESSURE

15.2.1 PRESSURE REGULATOR FAILURE - CLOSED

15.2.1.1 Identification of Causes and Frequency Classification

15.2.1.1.1 Identification of Causes

The Digital Electro-Hydraulic Control (DEHC) pressure regulator control function is performed via application software running on redundant controllers. The main steam pressure indications and pressure setpoint adjustments and indications are located on the HMI workstation of the turbine control panel. Each functional controller in the redundant pair executes the same application program, although only one controller at a time accesses the I/O and runs in the control mode. The partner processor runs in the backup mode. The transfer between the primary and the backup regulator controllers is automatic. The operator does not have the ability to select the primary or backup regulator controller. It is assumed, for the purposes of this transient analysis that a single failure occurs, erroneously causes the controlling regulator processor to close the main turbine control valves. Failure of the primary controlling regulator processor results in the automatic bumpless transfer between the primary and the backup regulator controllers, thereby preventing an increase in reactor pressure.

15.2.1.1.2 Frequency Classification

This transient is treated as a moderate frequency event.

15.2.1.2 Sequence of Events and System Operation

15.2.1.2.1 Sequence of Events

When a fault is detected with the controlling pressure regulator processor, as discussed in Section 15.2.1.1.1, an automatic "bumpless" failover will occur to the back-up redundant regulator controller. The pressure increase will be small, if any. Both regulators receive the same setpoint value from the operator input via the HMI, thus, pressure will be controlled at approximately the same value prior to the assumed failure.

15.2.1.2.2 Systems Operation

Normal plant instrumentation and control is assumed to function. This transient requires no protection system, or safeguard systems, operation.

15.2.1.2.3 The Effect of Single Failures and Operator Errors

The nature of the first assumed failure produces a slight pressure increase in the reactor until the backup processor gains control. The control system is designed to provide a bumpless transfer between control modes and various control functions throughout the reactor power range (0-100%), such as primary to backup pressure regulator controller, valve tests, and automatic cool down. Also, upon detection of a primary controller fault, the control of the I/O interface is automatically transferred to the backup controller. To minimize the effects from transferring control from the primary to backup regulator control processor (bumpless transfer), the algorithms track the output values, pass the information upstream, and apply the data during the first pass of execution. Each processor has its own network connection that is integrated

into the process module and provides complete redundancy. To ensure redundant communications, each processor in the redundant pair is attached to a different switch. This ensures that there is no single point of failure. The term "bumpless" is defined as not exceeding 2 psi as set forth for pressure control. This means that mode changes and switching of functions will not cause a step change in throttle pressure greater than 2 psi operating throttle pressure variations.

15.2.1.3 Core and System Performance

The disturbance is mild, similar to a pressure setpoint change, and no significant reductions in fuel thermal margins occur. This transient is much less severe than the generator and turbine trip transients described in Sections 15.2.2 and 15.2.3.

15.2.1.3.1 Mathematical Model

Qualitative evaluation provided only.

15.2.1.3.2 Input Parameters and Initial Conditions

Qualitative evaluation provided only.

15.2.1.3.3 Results

Response of the reactor during this primary pressure regulator control processor failure is such that the pressure change at the turbine inlet is small, and no pressure disturbance in the vessel. Thus, neutron flux and pressure trip margins will be maintained.

15.2.1.3.4 Consideration of Uncertainties

All systems utilized for protection in this transient were assumed to have the most conservative allowable response (e.g., relief setpoints, scram stroke time, and worth characteristics). Normal plant behavior is, therefore, expected to reduce the actual severity of the transient.

15.2.1.4 Barrier Performance

The consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel or containment are designed. Therefore, these barriers maintain their integrity and function as designed.

15.2.1.5 Radiological Consequences

Because this transient does not result in any fuel failures, or any release of primary coolant to either the secondary containment or to the environment, there are no radiological consequences associated with this transient.

15.2.2 GENERATOR LOAD REJECTION

15.2.2.1 Identification of Causes and Frequency Classification

15.2.2.1.1 Identification of Causes

Fast closure of the turbine control valves is initiated whenever electrical grid disturbances occur that result in significant loss of electrical load on the generator. The turbine control valves are required to close as rapidly as possible to prevent excessive overspeed of the turbine-generator. Closure of the main turbine control valves will cause a sudden reduction in steam flow that results in an increase in system pressure and a reactor shutdown.

15.2.2.1.2 Frequency Classification

15.2.2.1.2.1 Generator Load Rejection

This transient is categorized as an incident of moderate frequency.

15.2.2.1.2.2 Generator Load Rejection with Bypass Failure

Frequency Basis: Thorough searches of domestic plant operating records have revealed three instances of bypass failure during 628 bypass system operations. This gives a probability of bypass failure of 0.0048. Combining the actual frequency of a generator load rejection with the failure rate of the bypass yields an event frequency of a generator load rejection with bypass failure of 0.0036/plant year.

15.2.2.2 Sequence of Events and System Operation

15.2.2.2.1 Sequence of Events

15.2.2.2.1.1 Generator Load Rejection - Turbine Control Valve Fast Closure

A loss of generator electrical load from high power conditions produces the sequence of events listed in Table 15.2-1.

15.2.2.2.1.2 Generator Load Rejection with Failure of Bypass

A loss of generator electrical load at high power with bypass failure produces the sequence of events listed in Table 15.2-2.

15.2.2.2.1.3 Identification of Operator Actions

The operator should:

a. Verify proper bypass valve operation.

b. Observe that the feedwater/level controls have maintained the reactor water level at a satisfactory value.

c. Observe that the pressure regulator is controlling reactor pressure at the desired value.

d. Record peak power and pressure.

e. Verify relief valve operation.

15.2.2.2.2 System Operation

15.2.2.2.2.1 Generator Load Rejection with Bypass

This is a non-limiting event that has not been reanalyzed for power rerate.

In order to properly simulate the expected sequence of events, the analysis of this transient assumes normal functioning of plant instrumentation and controls, plant protection, and reactor protection systems, unless stated otherwise.

Turbine control valve fast closure initiates a trip signal for power levels greater than 30% NBR. In addition, RPT is initiated. Both of these trip signals satisfy single failure criteria, and credit is taken for these protective features.

The nuclear pressure relief system, which operates the MSRVs independently when system pressure exceeds relief valve instrumentation setpoints, is assumed to function normally during the time period analyzed.

15.2.2.2.2.2 Generator Load Rejection with Failure of Bypass

This is the same as Section 15.2.2.2.2.1, except that failure of the main turbine bypass valves is assumed for the entire transient.

15.2.2.2.3 The Effect of Single Failures and Operator Errors

Mitigation of pressure increase, the basic nature of this transient, is accomplished by the RPS functions. Turbine control valves trip and RPT are designed to satisfy single failure criteria. An evaluation of the most limiting single failure (i.e., failure of the bypass system) was considered in this transient. Single failure analysis can be found in Section 15.9.

15.2.2.3 Core and System Performance

15.2.2.3.1 Mathematical Model

The computer models described in Section 15.1.2.3.1 are used to simulate this transient.

15.2.2.3.2 Input Parameters and Initial Conditions

These analyses have been performed, unless otherwise noted, with the plant conditions tabulated in Table 15.0-2A for rerate conditions.

The turbine EHC system detects load rejection before a measurable speed change takes place.

The closure characteristics of the turbine control valves are assumed to have a full stroke closure time, from fully open to fully closed, of 0.15 seconds.

Auxiliary power would normally be independent of any turbine- generator overspeed effects, and be continuously supplied at rated frequency as automatic fast transfer to auxiliary power supplies occurs. For the purposes of worse case analysis, the recirculation pumps are assumed to remain tied to the main generator, and thus increase in speed with the turbine-generator overspeed until tripped by the RPT system.

The reactor is operating in the manual flow control mode when load rejection occurs.

The bypass valve opening characteristics are simulated, using the specified delay together with the specified opening characteristic required for bypass system operation.

Actual closure of MSIVs as caused by low water level trip (Level 1), and actual flow from initiation of RCIC and HPCI core cooling system functions do not occur during the duration of the simulation. If these events occur, they will follow sometime after the primary concerns of fuel margin and overpressure effects have passed and are expected to result in effects less severe than those already experienced by the reactor system.

15.2.2.3.3 Results

15.2.2.3.3.1 Generator Load Rejection with Bypass

The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Figure 15.2-1 shows the results of the generator trip from 104.3% rated power. Peak neutron flux rises to 178.5% of NBR conditions.

The average surface heat flux peaks at 101.2% of its initial value. The change in CPR for this event is only 0.03, and CPR does not significantly decrease below its initial value.

15.2.2.3.3.2 Generator Load Rejection with Failure of Bypass

Beginning with Cycle 8 of Unit 1, the turbine control valves (TCV) have been modified to operate in full arc admission. In this configuration the TCVs close sooner than the turbine stop valves to shut off steam flow. As a result, the Generator Load Rejection with Failure of Bypass event (LRNBP) is more limiting than the turbine trip with failure of bypass (TTNBP). Table 15.0-1A provides the results of the LRNBP analyses for several different conditions, including one for the TCVs in full arc admission configuration. Figure 15.2-2 depicts the transient response of various plant parameters following a LRNBP event. The LRNBP is also analyzed assuming the EOC-RPT function is inoperable to provide a basis for this possible mode of operation. A similar analysis has been performed to address power load unbalance (PLU) function failure. For cycle specific reload licensing analysis the LRNBP event is evaluated at the limiting operating domain condition (see Appendix 15B).

Additionally, an analysis of Generator Load Rejection and Turbine Trip events with simultaneous Failure of Bypass and End of Cycle Recirculation Pump Trip (EOC-RPT) was performed using the ODYN code. The Generator Load Rejection event bounds the turbine trip. Table 15.2-14 presents a summary of the initial conditions and significant results for the Generator Load Rejection with no bypass and no EOC-RPT event, while Figure 15.2-14 shows its time history.

15.2.2.3.4 Consideration of Uncertainties

The full stroke closure time of the turbine control valves of 0.15 seconds is conservative. Typically, actual closure time is more like 0.2 seconds. Thus, the shorter time chosen for closure results in a more severe pressurization effect.

All systems utilized for protection in this transient were assumed to have the poorest allowable response (e.g., relief setpoints, scram stroke time, and work characteristics). Anticipated plant behavior is, therefore, expected to reduce the actual severity of the transient.

15.2.2.4 Barrier Performance

15.2.2.4.1 Generator Load Rejection

Peak pressure remains within normal operating range and no threat to the barrier exists.

15.2.2.4.2 Generator Load Rejection with Failure of Bypass

As shown in Table 15.0-1A the peak nuclear system pressure at the bottom of the vessel remains well below the nuclear barrier transient pressure limit of 1375 psig.

15.2.2.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is restricted to the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.2.3 TURBINE TRIP

15.2.3.1 Identification of Causes and Frequency Classification

15.2.3.1.1 Identification of Causes

A variety of turbine or nuclear system malfunctions will initiate a turbine trip. Some examples are: moisture separator and heater drain tank high levels, operational lockout, loss of control fluid pressure, low condenser vacuum, and reactor high water level.

15.2.3.1.2 Frequency Classification

15.2.3.1.2.1 Turbine Trip with Bypass

This transient is categorized as an incident of moderate frequency. In defining the frequency of this transient, turbine trips that occur as a by-product of other transients, such as loss of condenser vacuum or reactor high level trip events, are not included. However, spurious low vacuum or high level trip signals, which cause an unnecessary turbine trip, are included in defining the frequency. In order to get an accurate event-by-event frequency breakdown, this division of initiating causes is required.

15.2.3.1.2.2 Turbine Trip with Failure of the Bypass

Frequency Basis: As discussed in Section 15.2.2.1.2.2, the failure rate of the bypass is 0.0048. Combining this with the turbine trip frequency of 1.33 events/plant year yields the frequency of 0.0064/plant year.

15.2.3.2 Sequence of Events and System Operation

15.2.3.2.1 Sequence of Events

15.2.3.2.1.1 Turbine Trip with Bypass

This event is non-limiting and was not reanalyzed at power rerate conditions. A turbine trip at high power with bypass produces the sequence of events listed in Table 15.2-3 for Cycle 1 conditions.

15.2.3.2.1.2 Turbine Trip with Failure of the Bypass

A turbine trip at high power with bypass failure produces the sequence of events listed in Table 15.2-4.

15.2.3.2.1.3 Identification of Operator Actions

The operator should:

a. Verify automatic transfer of buses supplied by generator to incoming power. If automatic transfer does not occur, manual transfer must be made.

b. Monitor and maintain reactor water level at required level.

c. Check turbine for proper operation of all auxiliaries during coast-down.

d. Depending upon conditions, initiate normal operating procedures for cooldown, or maintain pressure for restart purposes.

e. Put the mode switch in the shutdown position and verify all control rods are inserted.

f. Secure the RCIC operation if automatic initiation occurred due to low water level.

g. Monitor CRD positions and insert both the IRMs and SRMs.

h. Cool down the reactor per standard procedure if a restart is not intended.

15.2.3.2.2 System Operation

15.2.3.2.2.1 Turbine Trip with Bypass

All plant control systems maintain normal operation unless otherwise noted.

Turbine stop valve closure initiates a reactor trip via position signals to the protection system. Credit is taken for successful operation of the RPS.

Turbine stop valve closure initiates RPT, thereby terminating the jet pump drive flow.

The nuclear pressure relief system, which consists of the MSRVs that operate independently when system pressure exceeds relief valve setpoints, is assumed to function normally during the time period analyzed.

15.2.3.2.2.2 Turbine Trip with Failure of the Bypass

Same as Section 15.2.3.2.2.1 except that failure of the main turbine bypass system is assumed for the entire transient time period analyzed.

15.2.3.2.2.3 Turbine Trip at Low Power with Failure of the Bypass

Same as Section 15.2.3.2.2.1 except that failure of the main turbine bypass system is assumed.

It should be noted that, below 30% NBR power level a main stop valve trip inhibit signal is actuated by the first-stage pressure of the turbine. This is done to eliminate the stop valve trip signal from scramming the reactor, provided the bypass system functions properly. In other words, the bypass would be sufficient at this low power to accommodate a turbine trip without the necessity of shutting down the reactor. All other protection system functions remain operative as before, and credit is taken for those protection system trips.

15.2.3.2.3 The Effect of Single Failures and Operator Errors

15.2.3.2.3.1 Turbine Trips at Power Levels Greater Than 30% NBR

Mitigation of pressure increase, the basic nature of this transient, is accomplished by RPS functions. The main stop valve closure trip is designed to satisfy the single failure criterion.

15.2.3.2.3.2 Turbine Trips at Power Levels Less Than 30% NBR

This is the same as in Section 15.2.3.2.3.1, except RPT and stop valve closure trip is normally inoperative. Since protection is still provided by high flux, high pressure, etc., these factors will scram the reactor should a single failure occur.

15.2.3.3 Core and System Performance

15.2.3.3.1 Mathematical Model

The computer model described in Section 15.1.1.3.1 was used to simulate these transients with normal bypass operation. The infrequent event of turbine trip with bypass failure is simulated with the computer models in Section 15.1.2.3.1.

15.2.3.3.2 Input Parameters and Initial Conditions

These analyses have been performed, unless otherwise noted, with plant conditions as tabulated in Table 15.0-2 for Cycle 1 and in Table 15.02A for rerate.

Turbine stop valves full stroke closure time is 0.1 second.

A reactor scram is initiated by position switches on the stop valves when the valves are not fully open. This stop valve trip signal is automatically bypassed when the reactor is below 30% NBR power level.

Reduction in core recirculation flow is initiated by position switches on the main stop valves that trip the recirculation pumps.

15.2.3.3.3 Results

15.2.3.3.3.1 Turbine Trip with Bypass

The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

A turbine trip with the bypass system operating normally is simulated at 104.3% NBR steam flow conditions in Figure 15.2-3.

Neutron flux increases rapidly because of the void reduction caused by the pressure increase. However, the flux increase is limited to 163.3% of rated value by the stop valve scram and the RPT system. Peak fuel surface heat flux does not exceed 102% of its initial value. The ΔCPR is less than that for turbine trip with assumed bypass failure (Section 15.2.3.3.3.2) and the MCPR remains well above the safety limit.

15.2.3.3.3.2 Turbine Trip with Failure of Bypass

The TTNBP event is caused by the rapid closure of the turbine stop valves. A reactor scram signal is immediately initiated from the position switches on the TSVs. The turbine bypass system is conservatively assumed to be inoperable.

With the TCVs configured for full arc admission, the TTNBP is bounded by the LRNBP event. The TTNBP event is also analyzed assuming the EOC-RPT function is inoperable to provide a basis for this possible mode of operation. The TTNBP transient results are summarized in Table 15.0-1A. The system response curves are shown in Figure 15.2-4. The fuel transient thermal and mechanical overpower results are below the design criteria.

15.2.3.3.3.3 Turbine Trip with Bypass Valve Failure, Low Power

This transient is less severe than a similar one at high power. Below 30% of rated power, the turbine stop valve and turbine control valve closure scrams are automatically bypassed. At these lower power levels, the turbine first-stage pressure is used to initiate the scram logic bypass. The scram which terminates the transient is initiated by high neutron flux or high vessel pressure. The bypass valves are assumed to fail; therefore, system pressure will increase until the pressure relief setpoints are reached. At this time, because of the relatively low power of this transient event, relatively few MSRVs will open to limit reactor pressure. Peak pressures are not expected to greatly exceed the MSRV setpoints, and will be significantly below the RCPB transient limit of 1375 psig. Peak surface heat flux and peak fuel center temperature remain at relatively low values, and MCPR remains well above the GETAB safety limit.

15.2.3.3.4 Consideration of Uncertainties

Uncertainties in these analyses involve protection system settings, system capacities, and system response characteristics. The most conservative values are used in all the analyses. For example:

a. Control rod scram speed based on conservative statistical aproach consistent with GEMINI methodology option A/B.

b. Scram worth shape for all rod-out conditions is assumed.

c. Minimum specified MSRV capacities are utilized for overpressure protection.

d. Setpoints of the MSRVs include errors (high) for all valves.

15.2.3.4 Barrier Performance

15.2.3.4.1 Turbine Trip with Bypass

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Peak pressure in the bottom of the vessel reaches 1196 psig, which is below the ASME code limit of 1375 psig for the RCPB. Vessel dome pressure does not exceed 1174 psig. The severity of turbine trips from low initial power levels decreases to the point where a scram can be avoided if auxiliary power is available and the power level is within bypass capability.

15.2.3.4.2 Turbine Trip with Failure of the Bypass

The MSRVs open and close sequentially as the stored energy is dissipated and the pressure falls below the setpoints of the valves. As shown in Table 15.0-1A, the peak nuclear system pressure at the vessel bottom remains below the RCPB transient pressure limit of 1375 psig.

15.2.3.4.2.1 Turbine Trip with Failure of Bypass at Low Power

Qualitative discussion is provided in Section 15.2.3.3.3.3.

15.2.3.5 Radiological Consequences

Although the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.2.4 MSIV CLOSURES

15.2.4.1 Identification of Causes and Frequency Classification

15.2.4.1.1 Identification of Causes

Various steam line and nuclear system malfunctions, or operator actions, can initiate MSIV closure. Examples are: low steam line pressure, high steam line flow, low water level, or manual action.

15.2.4.1.2 Frequency Classification

15.2.4.1.2.1 Closure of All Main Steam Isolation Valves

This transient is categorized as an incident of moderate frequency. To define the frequency of this transient, as an initiating transient and not the byproduct of another transient, only the following contribute to the frequency: manual action (purposely or inadvertent), spurious signals such as low pressure, low reactor water level, low condenser vacuum, etc.; and, finally, equipment malfunctions such as faulty valves or operating mechanisms. A closure of one MSIV may cause an immediate closure of all the other MSIVs, depending upon reactor conditions. If this occurs, it is also included in this category. During the MSIV closure, position switches on the valves provide a reactor scram if the valves in three or more main steam lines are not fully open, except for interlocks which permit proper plant startup. Protection system logic, however, permits the test closure of one valve without initiating scram from the position switches.

15.2.4.1.2.2 Closure of One Main Steam Isolation Valve

This transient is categorized as an incident of moderate frequency. RPS logic allows for one MSIV at a time to be closed without generating a half scram signal. Operator error or equipment malfunction may cause a single MSIV to be closed inadvertently. If reactor power is greater than approximately 90% when this occurs, a high flux scram or high steam line flow scram may result. If all MSIVs close as a result of the single closure, the transient is considered as a closure of all MSIVs.

15.2.4.2 Sequence of Events and System Operation

15.2.4.2.1 Sequence of Events

This is a non-limiting event that has not been reanalyzed for power rerate. The sequence of events is Table 15.2-5 is based on Cycle 1 conditions. The general trend and characteristics shown here are not expected to change for current conditions.

Table 15.2-5 lists the sequence of events for Figure 15.2-5.

The following is the sequence of operator actions expected during the course of the transient, assuming no restart of the reactor. The operator should:

a. Observe that all rods have been inserted.

b. Observe that the relief valves have opened for reactor pressure control.

c. Check that RCIC/HPCI automatically starts on the impending low reactor water level condition.

d. Switch the feed pump controllers to the manual position.

e. When the reactor vessel level has recovered to a satisfactory level, secure RCIC/HPCI.

f. When the reactor pressure has decayed sufficiently, initiate shutdown cooling.

g. Before resetting the MSIV isolation, determine the cause of valve closure.

h. Observe turbine coast-down and break vacuum before the loss of sealing steam. Check turbine-generator auxiliaries for proper operation.

j. Reset and open MSIVs if conditions warrant and assure that the pressure regulator setpoint is above vessel pressure.

15.2.4.2.2 System Operation

15.2.4.2.2.1 Closure of All Main Steam Isolation Valves

MSIV closures initiate a reactor scram trip through position signals to the protection system. Credit is taken for successful operation of the protection system.

The nuclear pressure relief system, which opens the MSRVs when system pressure exceeds relief valve setpoints, is assumed to function normally during the time period analyzed.

All plant control systems maintain normal operation unless otherwise noted.

15.2.4.2.2.2 Closure of One Main Steam Isolation Valve

The closure of a single MSIV at any given time will not initiate a reactor scram. This is because the valve position scram trip logic is designed to accommodate single valve operation and testability during normal reactor operation at limited power levels. Credit is taken for the operation of the pressure and flux signals to initiate a reactor scram.

All plant control systems maintain normal operation unless otherwise noted.

15.2.4.2.3 The Effect of Single Failures and Operator Errors

Mitigation of pressure increase is accomplished by initiation of the reactor scram via MSIV position switches and the protection system. MSRVs also operate to limit system pressure. All of these functions are designed to single failure criteria, and additional single failures would not alter the results of this analysis.

Failure of a single MSRV to open is not expected to have any significant effect. Such a failure is expected to result in less than a 20 psi increase in the maximum vessel pressure rise. The peak pressure will still remain considerably below 1375 psig. The design basis and performance of the pressure relief system is discussed in Section 5.2.

15.2.4.3 Core and System Performance

15.2.4.3.1 Mathematical Model

The computer model described in Section 15.1.1.3.1 was used to simulate these transient events.

15.2.4.3.2 Input Parameters and Initial Conditions

These analyses have been performed, unless otherwise noted, with plant conditions tabulated in Table 15.0-2.

The MSIV closing time is adjustable between 3 and 10 seconds. The worst case, the 3 second closure time, is assumed in this analysis.

Position switches on the valves initiate a reactor scram when the valves are not fully open. Closure of these valves inhibits steam flow to the feedwater turbines, terminating feedwater flow.

Because of the loss of feedwater flow, water level within the vessel decreases sufficiently to initiate the HPCI and RCIC systems.

15.2.4.3.3 Results

15.2.4.3.3.1 Closure of All Main Steam Isolation Valves

This is a non-limiting event that has not been reanalyzed for power rerate. The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Figure 15.2-5 shows the changes in important nuclear system variables for the simultaneous isolation of all main steam lines while the reactor is operating at 104.3% of NBR steam flow. Peak neutron flux reaches 190.9% of rated value in the first few seconds of the event. At the time of peak neutron flux, the nonlinear valve closure becomes a strong effect, and the conservative scram characteristic assumption has not yet allowed credit for the full shutdown of the reactor. As pressure increases, recirculation pumps trip on the high vessel pressure.

Water level decreases cause initiation of the HPCI and RCIC systems. Although there is a delay of up to 30 seconds before the water supply enters the vessel, there is no change in the thermal margins. The 30 seconds is based on cycle 1 conditions. This event was not reanalyzed for power rerate.

15.2.4.3.3.2 Closure of One Main Steam Isolation Valve

This is a non-limiting event that has not been reanalyzed for power rerate. The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

RPS logic is such that only one isolation valve at a time can be closed without generating a half scram signal. With a 3 second closure of one MSIV with reactor power greater than approximately 90%, the steam flow disturbance may raise vessel pressure and reactor power enough to initiate a high neutron flux scram. This transient is considerably milder than the closure of all MSIVs at power.

No quantitative analysis is furnished for this transient. However, no significant change in thermal margins is experienced, and no fuel damage occurs. Peak pressure remains below MSRV setpoints.

For testing purposes, one MSIV at a time is partially slow closed using a test push button to verify the RPS logic.

Inadvertent closure of one or all of the isolation valves while the reactor is shut down (such as operating state C, as defined in Section 15.9) will produce no significant transient. Closures during plant heatup (operating state D) will be less severe than the maximum power cases (maximum stored and decay heat) discussed in Section 15.2.4.3.3.1.

15.2.4.3.4 Consideration of Uncertainties

Uncertainties in these analyses involve protection system settings, system capacities, and system response characteristics. In all cases, the most conservative values are used in the analyses. For example:

a. Slowest allowable control rod scram motion is assumed.

b. Scram worth shape for all rod-out conditions is assumed.

c. Minimum specified MSRV capacities are utilized for overpressure protection.

d. MSRV setpoints are assumed to be 3% higher than the valves' nominal setpoints. Additionally, Unit 2, cycle 4 parameters were used for the performance of the 3% analysis (Reference 5.3-10).

15.2.4.4 Barrier Performance

15.2.4.4.1 Closure of All Main Steam Isolation Valves

The MSRVs begin to open within the first few seconds after the start of isolation. The valves close sequentially as the stored heat is dissipated, but continue to discharge the decay heat intermittently. Peak pressure at the vessel bottom reaches 1220 psig, clearly below the pressure limits of the RCPB. Peak pressure in the main steam line is 1185 psig.

15.2.4.4.2 Closure of One Main Steam Isolation Valve

No significant effect is imposed on the RCPB, since if closure of the valve occurs at an unacceptably high operating power level, a flux or pressure scram will result. The main turbine bypass system will continue to regulate system pressure through the other three "live" steam lines.

15.2.4.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with

established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.2.5 LOSS OF CONDENSER VACUUM

15.2.5.1 Identification of Causes and Frequency Classification

15.2.5.1.1 Identification of Causes

Various system malfunctions that can cause a loss of condenser vacuum are designated in Table 15.2-6.

15.2.5.1.2 Frequency Classification

This transient is categorized as an incident of moderate frequency.

15.2.5.2 Sequence of Events and System Operation

15.2.5.2.1 Sequence of Events

This event was not reanalyzed for power rerate. The sequence of events in Table 15.2-7 is based on Cycle 1 conditions.

Table 15.2-7 lists the sequence of events for Figure 15.2-6.

The operator should:

a. Verify automatic transfer of buses supplied by generator to incoming power. If automatic transfer has not occurred, manual transfer must be made.

b. Monitor and maintain reactor water level at required level.

c. Check turbine for proper operation of all auxiliaries during coast-down.

d. Depending upon conditions, initiate normal operating procedures for cooldown, or maintain pressure for restart purposes.

e. Put the mode switch in the STARTUP position before the reactor pressure decays to the turbine inlet low pressure setpoint.

f. Secure RCIC operation if automatic initiation occurred due to low water level.

g. Monitor CRD positions and insert both the IRMs and SRMs.

h. Cool down the reactor following standard procedures if a restart is not intended.

15.2.5.2.2 System Operation

In establishing the expected sequence of events and simulating the plant performance, it was assumed that normal functioning occurred in the plant instrumentation and controls, and plant protection and reactor protection systems.

Tripping functions associated with a loss of main turbine condenser vacuum are listed in Table 15.2-8.

15.2.5.2.3 The Effect of Single Failures and Operator Errors

This transient does not lead to a general increase in reactor power level due to the protection system initiating a scram.

Failure of the integrity of the offgas treatment system is considered to be an accident situation and is described in Section 15.7.1.

Single failures will not affect the vacuum monitoring and turbine trip devices which are redundant. The protective sequences of the anticipated operational transient are shown to be single failure proof (Section 15.9).

15.2.5.3 Core and System Performance

15.2.5.3.1 Mathematical Model

The computer model described in Section 15.1.1.3.1 was used to simulate this transient event.

15.2.5.3.2 Input Parameters and Initial Conditions

This analysis was performed with plant conditions tabulated in Table 15.0-2 unless otherwise noted.

Turbine stop valves full stroke closure time is 0.1 second.

A reactor scram is initiated by position switches on the stop valves when the valves are not fully open. This stop valve closure trip signal is automatically bypassed when the reactor is below 30% NBR power level.

The analysis presented here is a hypothetical case with a conservative 2 in. Hg/sec vacuum decay rate. The bypass system was assumed to be available for several seconds by simulating bypass valve closure at a vacuum level of 10 inches Hg less than the stop valve closure vacuum level.

15.2.5.3.3 Results

This is a non-limiting event that has not been reanalyzed for power rerate. The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Under this hypothetical 2 in. Hg/sec vacuum decay condition, the turbine bypass valve and MSIV closure would follow main turbine and feedwater turbine trips about 5 seconds after being initiated by the transient. This transient, therefore, is similar to a normal turbine trip with bypass. The effect of MSIV closure tends to be minimal, since the closure of main turbine stop valves, and subsequently the bypass valves, has already shut off the main steam line flow. Figure 15.2-6 shows the transient expected for this event. It is assumed that the plant is initially operating at 105% NBR steam flow conditions. Peak neutron flux reaches 160.9% of NBR power, while average fuel surface heat flux reaches 101.9% of rated value. MSRVs open to limit the pressure rise, then sequentially reclose as the stored energy is dissipated.

15.2.5.3.4 Consideration of Uncertainties

The reduction, or loss, of vacuum in the main condenser sequentially trip the main and feedwater turbines, and close the MSIVs and bypass valves. While these are the major events occurring, other resultant actions will include scram (from stop valve closure) and bypass opening with the main turbine trip. Because the protective actions are actuated at various levels of condenser vacuum, the severity of the resulting transient is directly dependent upon the rate at which the vacuum is lost. Normal loss of vacuum, due to loss of cooling water pumps or steam jet air ejector problems, produces a very slow rate of loss that is timed in minutes, not seconds (Table 15.2-6). If corrective actions by the reactor operators are not successful, then sequential trips of the main and feedwater turbines and, ultimately, complete isolation by closing the MSIVs and the bypass valves (opened with the main turbine trip), will occur.

A faster rate of loss of the condenser vacuum would shorten the time for the scram and reduce the overall effectiveness of the bypass valves since they would be closed more quickly.

Other uncertainties in these analyses involve protection system settings, system capacities, and system response characteristics.

In all cases, the most conservative values are used in the analyses. For example:

a. Slowest allowable control rod scram motion is assumed.

b. Scram worth shape for all rod-out conditions is assumed.

c. Minimum specified MSRV capacities are utilized for overpressure protection.

d. Setpoints of the MSRVs are assumed to be at the upper limit of Technical Specifications for all valves.

15.2.5.4 Barrier Performance

Peak nuclear system pressure is 1194 psig at the vessel bottom. The overpressure transient is below the RCPB transient pressure limit of 1375 psig. Vessel dome pressure does not exceed 1172 psig. A comparison of these values to those for turbine trip with bypass failure at high power shows the similarities between these two transients. The prime differences are the loss of feedwater and main steam line isolation, and the resulting low water level trips.

15.2.5.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.2.6 LOSS OF AC POWER

15.2.6.1 Identification of Causes and Frequency Classification

15.2.6.1.1 Identification of Causes

15.2.6.1.1.1 Loss of Auxiliary Power Transformers

The loss of all plant auxiliary buses due to transformer failure would require the simultaneous loss of three separate auxiliary transformers: the 1 Unit Auxiliary, the 10 Station Auxiliary, and the 20 Regulating transformers. The simultaneous loss of all three transformers is not considered credible without a common mode failure initiating event. Under this scenario, the plant sees a loss of all grid connections which is analyzed in the following sections.

15.2.6.1.1.2 Loss of All Grid Connections

Loss of all grid connections can result from major shifts in electrical loads, seismic events, loss of loads, lightning, storms, wind, etc., that contribute to electrical grid instabilities. These instabilities cause equipment damage if unchecked. Protective relay schemes automatically disconnect electrical sources and loads to mitigate damage and regain electrical grid stability.

15.2.6.1.2 Frequency Classification

15.2.6.1.2.1 Loss of All Grid Connections

This transient disturbance is categorized as an incident of moderate frequency.

15.2.6.2 Sequence of Events and System Operation

15.2.6.2.1 Sequence of Events

15.2.6.2.1.1 Loss of All Grid Connections

This is a non-limiting event that has not been reanalyzed for power rerate. The results of this event are based on Cycle 1 conditions. An analysis of this events for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Table 15.2-10 lists the sequence of events for Figure 15.2-8.

15.2.6.2.1.2 Identification of Operator Actions

The operator should maintain the reactor water level by use of the RCIC or HPCI system, control reactor pressure by use of the relief valves, and verify that the turbine dc oil pump is operating satisfactorily to prevent turbine bearing damage. The operator should also verify proper switching and loading of the emergency diesel generators.

The following is the sequence of operator actions expected during the course of the events when no immediate restart is assumed. The operator should:

a. Following the scram, verify all rods-in.

b. Check that diesel generators start and carry the vital loads.

c. Check that both RCIC and HPCI start when reactor vessel level drops to the initiation point after the relief valve opens.

d. Break vacuum before the loss of sealing steam occurs.

e. Check turbine-generator auxiliaries during coast-down.

f. When both the reactor pressure and level are under control, secure both HPCI and RCIC as necessary.

g. Continue cooldown following normal procedures.

15.2.6.2.2 System Operation

15.2.6.2.2.1 Loss of All Grid Connections

This transient analysis, unless otherwise stated, assumes and takes credit for normal functioning of plant instrumentation and controls, and plant protection and reactor protection systems.

The loss of all grid connections causes the loss of all auxiliary power. This transient consists of a generator load rejection and recirculation pump trip at time t=0. The load rejection immediately closes the turbine control valves and causes a scram.

15.2.6.2.3 The Effect of Single Failures and Operator Errors

Loss of all connections to the grid leads to a turbine trip due to load rejection and an immediate scram due to turbine control valve fast closure. Additional failures of other systems designed to protect the reactor would not result in effects different from those reported. Failures of the protective systems have been considered and satisfy single failure criteria, so no change in analyzed consequences is expected. See Section 15.9 for details on single failure analysis.

15.2.6.3 Core and System Performance

15.2.6.3.1 Mathematical Model

The computer model described in Section 15.1.1.3.1 was used to simulate this transient.

Operation of the RCIC or HPCI systems is not included in the simulation of this transient, since startup of these pumps does not permit flow in the time period of this simulation.

15.2.6.3.2 Input Parameters and Initial Conditions

15.2.6.3.2.1 Loss of All Grid Connections

These analyses have been performed, unless otherwise noted, with the plant conditions tabulated in Table 15.0-2, and under the assumed systems constraints described in Section 15.2.6.2.2.

15.2.6.3.3 Results

15.2.6.3.3.1 Loss of All Grid Connections

This is a non-limiting event that has not been reanalyzed for power rerate. The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Loss of all grid connections causes simultaneous generator load rejection and loss of all auxiliary power. It essentially takes on the characteristic response of the standard full load rejection discussed in Section 15.2.2. Figure 15.2-8 graphically shows the simulated transient. Peak neutron flux reaches 178.5% of NBR power while fuel surface heat flux peaks at 101.3% of initial value.

15.2.6.3.4 Consideration of Uncertainties

The most conservative characteristics of protection features are assumed. Any actual deviations in plant performance are expected to make the results of this transient less severe.

Operation of the RCIC or HPCI systems is not included in the simulation of the first 50 seconds of this transient. Startup of these pumps occurs in the latter part of this time period, but the systems have no significant effect on the results of this transient.

Following turbine control valve closure, the reactor pressure is expected to increase until the MSRV setpoints are reached. During this time the valves operate in a cyclic manner to discharge the decay heat to the suppression pool.

15.2.6.4 Barrier Performance

15.2.6.4.1 Loss of All Grid Connections

MSRVs open in the pressure relief mode of operation as the pressure increases beyond their setpoints. The vessel bottom peak pressure is well below the vessel pressure limit of 1375 psig.

15.2.6.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.2.7 LOSS OF FEEDWATER FLOW

The Loss of Feedwater Flow (LOFW) event represents the design basis for the performance of the reactor core isolation cooling (RCIC) system. The following criteria are applied to this event:

1) The RCIC system shall maintain sufficient water level inside the core shroud to assure that the top of active fuel remains covered throughout the event.

2) The RCIC system shall maintain wide range sensed reactor water level high enough that the very low level instrument trip setpoint (Level 1) for low pressure emergency core cooling system initiation and MSIV closure is not activated.

This transient event does not pose any direct challenge to the reactor vessel or core in terms of a power or pressure increase. All unacceptable safety results are avoided. However, it is included in the evaluation to provide assurance that sufficient makeup water capability is available to keep the core covered when all normal feedwater flow is lost.

15.2.7.1 Identification of Causes and Frequency Classification

15.2.7.1.1 Identification of Causes

A loss of feedwater flow could occur due to pump failures, feedwater controller failures, operator errors, or reactor system variables such as a high vessel water level (Level 8) trip signal.

15.2.7.1.2 Frequency Classification

This transient disturbance is categorized as an incident of moderate frequency.

15.2.7.2 Sequence of Events and System Operation

15.2.7.2.1 Sequence of Events

Table 15.2-11 lists the sequence of events for Figures 15.2-9A and 15.2-9B.

The operator should verify RCIC and HPCI actuation, so that water inventory is maintained in the reactor vessel. The operator should also monitor reactor water level, pressure control, and turbine-generator auxiliaries during shutdown.

The following is the sequence of operator actions expected during the course of the event when no immediate restart is assumed. The operator should:

a. Verify that all rods are in, following the scram.

b. Verify the initiation of HPCI and RCIC.

c. Verify that the recirculation pumps trip on reactor low level.

d. Secure HPCI when reactor level and pressure are under control.

e. Continue operation of the RCIC until decay heat diminishes to a point where the RHR system can be put into service.

f. Monitor the turbine coast-down, breaking vacuum as necessary.

15.2.7.2.2 System Operation

Loss of feedwater flow results in a proportional reduction of vessel inventory, causing the vessel water level to drop. The first corrective action is the low level (Level 3) trip actuation. RPS responds within 1.05 seconds after reaching this trip level to scram the reactor. The 1.05 second total response

time is equal to the level sensor response time (1.0 seconds) plus the RPS logic delay time (0.05 seconds). The low level (Level 3) trip function meets the single failure criterion.

Pressure control is maintained by the turbine bypass system, since the MSIVs remain open.

Because of an additional steam flow induced process measurement error in the Level 3 scram, the timing values in Table 15.2-11 following Low water level scram based on the L3 Analytical Limit are slightly different. However, as described in Reference 15.2-4, the impact of the change is not significant.

15.2.7.2.3 The Effect of Single Failures and Operator Errors

The nature of this transient, as explained above, results in a lowering of vessel water level. Key corrective actions to shut down the reactor are automatic, and designed to satisfy the single failure criterion.

15.2.7.3 Core and System Performance

15.2.7.3.1 Mathematical Model

The computer model described in Reference 6.3.7 was used to simulate this transient.

15.2.7.3.2 Input Parameters and Initial Conditions

This analysis has been performed, unless otherwise noted, with plant conditions as described in Section 6.3.3.

15.2.7.3.3 Results

Feedwater flow termination results in a decrease in subcooling, causing a reduction in core power level and pressure. As power level is lowered, the turbine steam flow starts to drop off because the pressure regulator is attempting to maintain pressure. Water level continues to drop until the vessel level (Level 3) scram trip setpoint is reached, whereupon the reactor is shut down. The trip of the recirc pumps occurs at approximately 13 seconds (after reactor scram) due to vessel water dropping to the Level 2 trip setpoint. Also at this time RCIC operation is initiated. For this analysis the HPCI system is assumed to be unavailable. MCPR remains considerably above the safety limit since increases in heat flux are not experienced.

The timing values in Table 15.2-11 following Low water level scram based on the L3 Analytical Limit are slightly different. However, as described in Reference 15.2-4, the impact of the change is not significant.

Water level in the annulus slowly decreases until the boil off from decay heat is matched by the RCIC makeup flow. The LOFW analysis (Reference 15.2.2) assumed 3622 MWt for an initial core thermal power. For these conditions the minimum water level in the annulus region is predicted to reach a minimum of 6.5 feet above the level 1 setpoint, occurring at approximately 800 seconds after the start of the event. Since natural recirculation flow continues through the core, the water level inside the shroud is maintained within the separator elevation.

15.2.7.3.4 Consideration of Uncertainties

EOC scram characteristics are assumed.

This transient is most severe from high power conditions, because the rate of level decrease is greatest, and the amounts of stored and decay heat to be dissipated are highest. As noted the LOFW analysis was conservatively performed at a power level of 3622 MWt. Furthermore, the HPCI systems was assumed to be unavailable. The RCIC system is assumed to inject at rated flow 55 seconds after the level 2 initiation signal.

An additional steam flow induced process measurement error in the Level 3 scram was accounted for in the Loss of Normal Feedwater event. A lowering in the Level 3 Analytical Limit (AL) setpoint was calculated in Reference 15.2-4. It was determined that adequate margin exists to Top of Active Fuel (TAF) uncovery while considering a bounding process measurement error applicable for this event. The consequences of lowering the AL is a bounding reduction in minimum water level in the upper plenum of 12 inches and a bounding reduction in minimum water level of 12 inches in the vessel downcomer region as discussed in Reference 15.2-4. The analysis also shows significant margin to the TAF. The results of the analysis are applicable for power levels up to extended (20%) Power Uprate (3952 MWt). The impact of the change is not significant, and no event descriptions or conclusions in the UFSAR need to be modified.

15.2.7.4 Barrier Performance

The consequences of this transient do not result in a temperature or pressure transient. Therefore, the RCPB is not threatened.

15.2.7.5 Radiological Consequences

Since this transient does not result in fuel failures or release of reactor coolant, there are no radiological consequences associated with the transient.

15.2.8 FEEDWATER LINE BREAK

Refer to Section 15.6.6

15.2.9 FAILURE OF RHR SHUTDOWN COOLING

Normally, in evaluating component failure considerations associated with the RHR shutdown cooling mode of operation, active pumps or instrumentation (all of which are redundant for safety system portions) would be assumed to be the likely failed equipment. For purposes of analysis, the single recirculation loop suction valve to the redundant RHR loops is assumed to fail. This failure would, of course, still leave four complete RHR loops for LPCI, or two RHR loops for LPCI and two loops for pool, and containment cooling minus the normal RHR shutdown cooling loop connection. Although the valve could be manually opened, it is assumed to be failed indefinitely. If it is now assumed that the single active failure criterion is applied, the plant operator has at least one complete RHR loop with a heat exchanger available.

Recent analytical evaluations of this transient have required additional worst case assumptions. These include:

a. Loss of all offsite ac power.

b. Utilization of safety shutdown equipment only.

c. Operator involvement only after 10 minutes after coincident assumptions.

Incorporation of these assumptions changes the initial incident (malfunction of RHR suction valve) from a moderate frequency incident to a classification in the design basis accident status. However, the transient is evaluated as a moderate frequency event with its subsequent limits.

During cold shutdown or refueling operation conditions, four subsystems of shutdown cooling exist, comprised of the A heat exchanger and A RHR pump, A heat exchanger and C RHR pump, B heat exchanger and B RHR pump, and B heat exchanger and D RHR pump. If two subsystems of shutdown cooling are required to be operable per Technical Specifications and both subsystems are associated with the same heat exchanger, a failure of the shutdown cooling discharge valve or discharge check valve associated with that heat exchanger may require use of the alternate vessel return flowpath, if manual repair of the valve can not be effected. This single failure is considered to be bounded by the single failure of the recirculation loop suction valve to the redundant RHR loops described above in that mitigating actions required to be taken in the event of a suction valve failure (ADS/relief valve with alternate shutdown cooling flowpath) exceed the required actions for a discharge valve failure. Further, a loss of electical power to the shutdown cooling discharge valve following the initial establishment of shutdown cooling would not require a change in cooling flowpath as the motor-operated valve fails in-place, and would be positioned for normal shutdown cooling return.

15.2.9.1 Identification of Causes and Frequency Classification

15.2.9.1.1 Identification of Causes

The plant is operating at 3528 MWt when a long-term LOOP occurs, causing multiple MSRV actuation (Section 15.2.6) and subsequent heatup of the suppression pool. Reactor vessel depressurization is initiated to bring the reactor pressure to approximately 75 psig. Concurrent with the LOOP, an additional single failure occurs which prevents the operator from establishing the normal shutdown cooling path through the RHR shutdown cooling lines. The operator then establishes a shutdown cooling path for the vessel through the ADS valves.

15.2.9.1.2 Frequency Classification

This transient is evaluated as a moderate frequency event. However, for the following reasons it could be considered an infrequent incident:

a. No RHR valves have failed in the shutdown cooling mode in BWR total operating experience.

b. The set of conditions evaluated is for multiple failure as described above and is only postulated (not expected) to occur.

15.2.9.2 Sequence of Events and System Operation

15.2.9.2.1 Sequence of Events

The sequence of events for this transient is shown in Table 15.2-12. Figures 15.2-10 and 15.2-11 show shutdown cooling paths.

For the early part of the transient, the operator actions are identical to those described in Section 15.2.6 (LOOP transient with isolation/scram).

The operator should do the following:

a. Within approximately 10 minutes of the isolation/scram, the operator should initiate RPV shutdown depressurization at 100°F/hr by manual actuation of the MSRVs.

b. At approximately 15 minutes into the transient, the operator should initiate suppression pool cooling (again for purposes of this analysis, it is assumed that only one RHR heat exchanger is available).

c. After the RPV is depressurized to approximately 75 psig, the operator should attempt to open the two RHR shutdown cooling suction valves. This attempt is assumed to be unsuccessful.

d. The operator then powers open the ADS relief valves to complete blowdown, and floods the RPV with LPCI or core spray to establish a closed cooling path as described in Figure 15.2-11.

15.2.9.2.2 System Operation

Plant instrumentation and control is assumed to be functioning normally except as noted. In this evaluation, credit is taken for the plant and reactor protection systems and/or the ESF is used.

15.2.9.2.3 The Effect of Single Failures and Operator Errors

The worst case single failure has already been analyzed in this transient. Therefore, no single failure or operator error can make the consequences of this event any worse. See Section 15.9 for a discussion of this subject.

15.2.9.3 Core and System Performance

15.2.9.3.1 Methods, Assumptions, and Conditions

A transient that can directly cause reactor vessel water temperature increase is one in which the energy removal rate is less than the decay heat rate. The applicable transient is loss of RHR shutdown cooling. This transient can occur only during the low pressure portion of a normal reactor shutdown and cooldown, when the RHR system is operating in the shutdown cooling mode. During this time, MCPR remains high and nucleate boiling heat transfer is not exceeded at any time. Therefore, the core thermal safety margin remains essentially unchanged. The 10 minute time period assumed for operator action is an estimate of how long it would take before the operator would initiate the necessary actions; it is not a time by which he must initiate action.

15.2.9.3.2 Mathematical Model

In evaluating this transient, the important parameters to consider are reactor depressurization rate and suppression pool temperature. Models used for this evaluation are described in Section 6.2.1.8.

15.2.9.3.3 Input Parameters and Initial Conditions

Table 15.2-13 shows the input parameters and initial conditions used in evaluation of this transient.

15.2.9.3.4 Results

For most single failures that could result in loss of shutdown cooling, no unique safety actions are required. In these cases, shutdown cooling is simply re-established using an alternate shutdown cooling flow path. In cases where either of the RHR shutdown cooling suction valves cannot be opened, alternate paths are available to accomplish the shutdown cooling function (Figure 15.2-10). An evaluation has been performed assuming the worst single failure that could disable the RHR shutdown cooling valves.

As a result of SIL 636, the failure of RHR cooling transient was re-evaluated to determine the impact of the increased decay heat and was performed at a reactor power of 3528 MWt and a revised K-factor for the RHR heat exchangers. This qualitative evaluation concludes that there no significant changes in the suppression pool temperature profile or shutdown cooling time, more information on the SIL 636 evaluation is provided in Section 6.2.1.8.

The analysis demonstrates the capability to safely transfer fission product decay heat, and other residual heat, from the reactor core so that specified acceptable fuel design limits and the design conditions of the RCPB are not exceeded. The evaluation assures that, for onsite electric power system operation (assuming offsite power is not available), and for offsite electric power system operation (assuming onsite power is not available), the safety function can be accomplished, assuming a worst case single failure.

The alternate cooldown path, chosen to accomplish the shutdown cooling function, utilizes the RHR pumps and heat exchangers, core spray pumps and ADS or normal relief valve systems (Reference 15.2-1 and Figure 15.2-11).

The alternate shutdown systems are capable of performing the function of transferring heat from the reactor to the environment using only safety-grade equipment. Even if it is additionally postulated that all of the ADS or relief valves discharge piping also fails, the shutdown cooling function would eventually be accomplished as the cooling water would run directly out of the ADS or MSRVs, flooding into the drywell and then to the suppression pool.

The systems have suitable redundancy in components so that, for onsite electrical power operation (assuming offsite power is not available), and for offsite electrical power operation (assuming onsite power is also not available), the systems' safety function can be accomplished, even assuming an additional single failure. The systems can be fully operated from the main control room.

The design evaluation is divided into two phases:

a. Full power operation to approximately 75 psig vessel pressure.

b. Approximately 75 psig vessel pressure to cold shutdown (200°F) conditions.

15.2.9.3.4.1 Full Power to Approximately 75 psig

Independent of the transient that initiated plant shutdown (whether it be a normal plant shutdown or a forced plant shutdown), the reactor is normally brought to approximately 75 psig using either the main condenser or, in the case where the main condenser is unavailable, the RCIC/HPCI systems, together with the nuclear boiler pressure relief system.

For evaluation purposes, however, it is assumed that plant shutdown is initiated by a transient event (LOOP) that results in reactor isolation/scram and subsequent relief valve actuation and suppression pool heatup. For this postulated condition, the reactor is shut down and the reactor vessel pressure and temperature are reduced to, and maintained at, saturated conditions at approximately 75 psig. The RPV is depressurized by manually opening selected MSRVs. Reactor vessel makeup water is automatically provided via the RCIC/HPCI systems. While in this condition, the RHR system (suppression pool cooling mode) is used to maintain the suppression pool temperature within design limits.

These systems are designed to routinely perform their functions for both normal and forced plant shutdown. Since the RCIC, HPCI, and RHR systems are divisionally separated, no single failure, together with the LOOP, can prevent reaching the 75 psig level.

For conservatism in the analysis of this event, it was assumed that the reactor vessel makeup water was provided by the feedwater system instead of the HPCI/RCIC system. While feedwater system is not a safety system, this assumption maximizes the energy addition to the vessel and containment due to the residual heat in the feedwater system. This results in a conservative calculation of the vessel depressurization and cooldown and conservative suppression pool temperature results.

15.2.9.3.4.2 Approximately 75 psig to Cold Shutdown

The following assumptions are used for the analyses of the procedures for attaining cold shutdown from a pressure of approximately 75 psig:

a. The vessel is at 75 psig and saturated conditions.

b. A worst case single failure is assumed to have occurred (i.e., loss of a division of emergency power).

c. There is no offsite power available.

In the event that the RHR shutdown suction line is not available because of single failure, the first action to be taken will be for personnel to gain access to the suction line and to attempt to effect repairs. For example, if a single electrical failure caused a suction valve to fail in the closed position, a hand wheel is provided on the valve to allow manual operation. If for some reason the normal shutdown cooling suction line cannot be repaired, the capabilities described below will satisfy the normal shutdown cooling requirements and comply with GDC 34.

The RHR shutdown cooling line valves are in two divisions (Division 1 = the outboard valve, and Division 2 = the inboard valve) to satisfy containment isolation criteria. For evaluation purposes, the worst case failure is assumed to be the loss of a division of emergency power, since this also prevents actuation of one shutdown cooling line valve. ESF equipment available for accomplishing the shutdown cooling function includes (for the selected path) the following:

a. ADS (dc Division 1 and dc Division 3)

b. RHR Loop A (Division 1)

c. RHR Loop B (Division 2)

d. HPCI (dc Division 2 and 4)

e. RCIC (dc Division 1 and 3)

f. Core Spray A (Division 1 and 3)

g. Core Spray B (Division 2 and 4).

For failures of Division 1 or 2, the following systems are assumed to be functional:

a. Division 1 fails, Divisions 2, 3, and 4 are functional:

Failed Systems	Functional Systems
RHR Pump A	HPCI
CS Loop A	ADS (one solenoid)
RCIC	RHR Loop B
	CS Loop B
	RHR Pumps B, C, and D

b. Division 2 fails, Divisions 1,3, and 4 are functional:

Failed Systems	Functional Systems
RHR Pump B	CS Loop A
CS Loop B	RCIC
HPCI	RHR Loop A
	ADS
	RHR Pumps A, C, and D

Assuming the single failure is the failure of Division 1, the safety function is accomplished by establishing one of the cooling loops described in Activity C1 of Figure 15.2-11. If the assumed single failure is Division 2, the safety function is accomplished by establishing one of the cooling loops described as Activity C2 of Figure 15.2-11.

Using the above assumptions, and following the depressurization transient shown in Figure 15.2-12A and 15.2-12B, the suppression pool temperature is shown in Figure 15.2-13.

The failure of RHR shutdown cooling event was evaluated for power rerate at an initial power level of 3694 MWt, ANS 5.1-1979 nominal decay heat values, and RHR heat exchanger K-value of 288.9 BTU/sec-F.

A qualitative evaluation was performed for this event considering the increased decay heat loads of SIL 636. Using an initial power level of 3528 MWt and an RHR heat exchanger K-value of 305

BTU/sec-F, the increase in decay values of SIL 636 with 2 sigma uncertainty is not expected to increase the shutdown cooling time beyond the 30 hours calculated for power rerate at 3694 MWt. (Ref. 15.2-3)

15.2.9.4 Barrier Performance

As noted above, the consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel, or containment are designed. Release of coolant to the containment occurs via MSRV actuation. Release of radiation to the environment is described below.

15.2.9.5 Radiological Consequences

While this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established technical specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.2.10 LOSS OF STATOR COOLING

15.2.10.1 Identification of Causes and Frequency Classification

15.2.10.1.1 Identification of Causes

A Loss of Stator Cooling (LOSC) event begins after a sustained Stator Coolant Trouble signal resulting from low coolant flow, low system discharge pressure, or high system return temperature.

15.2.10.1.2 Frequency Classification

A LOSC is a moderate frequency event and classified as an AOO.

15.2.10.2 Sequence of Events and System Operation

15.2.10.2.1 Sequence of Events

Table 15.2-15 lists the sequence of events for a LOSC event initiated at rated power. The sequence of events presented in Table 15.2-15 is for the analysis conditions. In the most recent analysis both recirculation pumps run back in tandem after a 10 second delay; however, in actuality the recirculation pump runbacks are separated by several seconds as discussed in the Table 15.2-15 footnotes.

15.2.10.2.2 System Operation

Once the LOSC signal is confirmed, both recirculation pumps will runback to 42% speed. Additionally a runback of the turbine-generator will initiate. The turbine-generator runback will cause the turbine control valves to close slowly. The turbine bypass valves will open in response to the closure of the turbine control valves. Once the available bypass capacity is exceeded, the system will begin to pressurize. The event is terminated when the reactor scrams on high pressure or high neutron flux. The analysis also considers the TBSOOS condition.

15.2.10.2.3 The Effect of Single Failures and Operator Errors

The single failure for the LOSC is the failure which initiates the event. No consideration for additional failures is required.

15.2.10.3 Core and System Performance

15.2.10.3.1 Mathematical Model

The computer models described in Section 15.1.2.3.1 are used to simulate this transient.

15.2.10.3.2 Input Parameters and Initial Conditions

The LOSC is assumed to occur at time zero, as shown in Table 15.2-15. At the same time, both recirculation pumps runback to 42% speed and the turbine-generator runback begins. The turbine-generator runback is assumed to reduce the load set from 105% to 20% over a period of 140 seconds which bounds actual plant response. The first LOSC analysis was done for Unit 1 Cycle 16 and is based on the rated power of 3,515 MWt (Reference 15.2-5).

15.2.10.3.3 Results

The LOSC event has the potential to be a limiting AOO and is therefore analyzed or confirmed to be bounded by other transients as part of each reload's safety analysis.

15.2.10.3.4 Consideration of Uncertainties

All systems utilized for protection in this transient were assumed to have the most conservative allowable response (e.g., pressure scram setpoint). Normal plant behavior is, therefore, expected to reduce the actual severity of the transient.

In actuality, the LOSC signal must be present for several seconds before any plant response is initiated. Additionally, the recirculation pump runbacks do not occur simultaneously but are separated by several seconds. This difference does not impact the results of the analysis because core flow reaches the reduced steady state flow well before the pressurization part of the event occurs. Finally, the actual turbine-generator runback times are greater than the assumed value. A shorter runback time results in a greater pressurization rate, increasing the severity of the event.

15.2.10.4 Barrier Performance

The consequences of this transient do not result in any temperature or pressure transient in excess of the criteria for which the fuel, pressure vessel or containment are designed. Therefore, these barriers maintain their integrity and function as designed.

15.2.10.5 Radiological Consequences

Because this transient does not result in any fuel failures, or any release of primary coolant to either the secondary containment or to the environment, there are no radiological consequences associated with this transient.

SEQUENCE OF EVENTS FOR
TURBINE-GENERATOR LOAD REJECTION WITHOUT BYPASS[1]

TIME (sec)	EVENT
-0.015 (approx.)	Turbine-generator detection of loss of electrical load.
0.0	Turbine-generator power load unbalance devices trip to initiate turbine control valve fast closure.
0.0	Turbine bypass valves fail to operate.
0.03	Fast control valve closure initiates scram trip.
0.05	Turbine control valve closure initiates a recirculation pump trip (RPT).
0.08 (approx.)	Turbine control valve closed.
0.175	Recirculation pump motor circuit breakers open causing the recirculation drive flow to begin to coast down.
1.9	MSRV actuation initiated.
> 6	MSRV closed.

(1) See Figure 15.2-2.

Table 15.2-3

SEQUENCE OF EVENTS FOR TURBINE TRIP WITH BYPASS[1]

TIME (sec)	EVENT
0.0	Turbine trip initiates closure of main stop valves.
0.0	Turbine trip initiates bypass operation.
0.01	Main turbine stop valves reach 90% open position and initiates reactor scram trip.
0.01	Main turbine stop valves reach 90% open position and initiates an RPT.
0.1	Turbine stop valves closed.
0.17	Turbine bypass valves start to open to regulate pressure.
2.5	Group 1 MSRVs actuated.
2.7	Group 2 MSRVs actuated.
2.9	Group 3 MSRVs actuated.
8.3	All MSRVs closed.

[1] See Figure 15.2-3.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.2-4

SEQUENCE OF EVENTS FOR TURBINE TRIP WITHOUT BYPASS[1]

TIME (sec)	EVENT
0.0	Turbine trip initiates closure of main stop valves.
0.0	Turbine bypass valves fail to operate.
0.01	Main turbine stop valves reach 90% open position and initiate reactor scram trip.
0.01	Main turbine stop valves reach 90% open position and initiate an RPT.
0.1	Turbine stop valves closed.
0.175	Recirculation pump motor circuit breakers open causing the recirculation drive flows to coast down.
≈ 1.8	MSRV actuation initiated.
> 6	MSRVs closed.

(1) See Figure 15.2-4.

Table 15.2-5

SEQUENCE OF EVENTS FOR MSIV CLOSURE[2]

TIME (sec)	EVENT
0.0	Initiate closure of all MSIV
0.3	MSIV position trip scram initiated[1]
2.9	Recirculation pump drive motors are tripped
3.1	MSRVs open 3 groups due to pressure relief setpoint action
14.6	All MSRVs closed
26.0	Initiate HPCI and RCIC systems on low-low water level (Level 2)

(1) The event was simulated with an MSIV position trip at the 90% open position. Using an analytical value of 85% has no significant impact on the ΔCPR and peak system pressure results.

(2) See Figure 15.2-5.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.2-6

TYPICAL RATES OF DECAY FOR CONDENSER VACUUM

CAUSE	ESTIMATED VACUUM DECAY RATE
a. Failure or isolation of steam jet air ejectors	<1 inch Hg/minute
b. Loss of sealing steam to shaft gland seals	1 to 2 inches Hg/minute (approx)
c. Opening of vacuum breaker valves	2 to 12 inches Hg/minute (approx)
d. Loss of one or more circulating water pumps	4 to 24 inches Hg/minute (approx)

Table 15.2-7

SEQUENCE OF EVENTS FOR LOSS OF CONDENSER VACUUM[1]

TIME (sec)	EVENT
-3.0	Initiate simulated loss of condenser vacuum at 2 inches of Hg per second.
0.0 (est)	Low condenser vacuum main turbine trip actuated.
0.0 (est)	Low condenser vacuum feedwater trip actuated.
0.01	Main turbine trip initiates reactor scram.
0.01	Main turbine trip initiates RPT.
0.1	Turbine stop valves closed.
0.1	Bypass valves begin to open.
2.5	Group 1 MSRV setpoints actuated.
2.7	Group 2 MSRV setpoints actuated.
2.9	Group 3 MSRV setpoints actuated.
5.0	Low condenser vacuum initiates MSIV closure.
5.0	Low condenser vacuum initiates bypass valve closure.
13.3	All MSRVs close.
16.9	MSRV cyclic actuation on pressure demand.
50.6	HPCI/RCIC system initiation on low level (Level 2) (not included in simulation)

(1) See Figure 15.2-6.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.2-8

TRIP SIGNALS ASSOCIATED WITH LOSS OF CONDENSER VACUUM

	Condenser Vacuum (Inches of Hg) Transient Analysis (Table 15.2-7)
a. Normal Operating Range	-
b. Main Turbine Trip	20
c. Feedwater Trip	20
d. MSIV Closure Initiated	10
e. Bypass Valve Closure Initiated	10

(1) In the plant, the spread between the turbine trip (b) and bypass valve closure (e) conservatively exceeds the analyzed condition. The transient analysis ΔCPR and peak system pressure results remain bounding.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.2-9

SEQUENCE OF EVENTS FOR LOSS OF AUXILIARY POWER TRANSFORMER[1]

REFER TO TABLE 15.2-10

[1] See Figure 15.2-7.

Table 15.2-10

SEQUENCE OF EVENTS FOR LOSS OF ALL GRID CONNECTIONS[1]

TIME (sec)	EVENT
-0.015 (approx.)	Loss of grid causes turbine-generator to detect a loss of electrical load.
0.0	Turbine control valve fast closure is initiated.
0.0	Turbine-generator power load unbalance trip initiates main turbine bypass system operation.
0.0	Recirculation system pump motors are tripped.
0.0	Turbine control valve fast closure initiates a reactor scram trip.
0.07	Turbine control valves closed.
0.10	Turbine bypass valves begin to open.
2.0	Feedwater pumps trip on low suction pressure.
2.4	MSRVs open and cycle.
7.2	Initial SRVs closure.
49	Low water Level 2 setpoint reached, HPCI/RCIC initiated (not simulated).

(1) See Figure 15.2-8.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.2-11

SEQUENCE OF EVENTS FOR LOSS OF FEEDWATER FLOW

TIME (sec)[2]	EVENT
0.0	Trip of all feedwater pumps initiated.
~6	Vessel water level (Level 3)[1] trip initiates scram trip.
~19	Vessel water level (Level 2)* trip initiates RCIC (and HPCI) operation.
~19	Vessel water level (Level 2) trip initiates containment isolation.
~19	Vessel water level (Level 2) trip initiates recirculation pump trip.
~74	Rated RCIC flow is achieved. **
~800	Minimum Level is reached (444 inches above vessel zero), approx. 45.5 inches above Level 1 trip.***

Note:

(1) **Because of an additional steam flow induced process measurement error in the Level 3 scram, the timing values following Low water level scram based on the L3 Analytical Limit are slightly different. However, as described in Reference 15.2-4, the impact of the change is not significant.**

(2) Results presented above are taken from historical analyses but continue to be generally representative and applicable to modern fuel designs.

* Level 2 (Analytical Limit) is assumed to be at 457.5 inches above vessel zero.

** A system response time of 55 seconds is assumed.

*** Level 1 (NTSP) is 398.5 inches above vessel zero.

Table 15.2-12

SEQUENCE OF EVENTS FOR FAILURE OF RHR SHUTDOWN COOLING

TIME (min)	EVENT
0	Reactor is operating at 3528 MWt when LOOP occurs initiating plant shutdown.
0	Concurrently, loss of one division of power occurs.
10	Controlled depressurization initiated (100%) using selected MSRVs.
15	Suppression pool cooling initiated to prevent overheating from MSRV actuation(1).
157	Blowdown to approximately 75.0 psig completed.
157	Personnel are sent in to open RHR shutdown cooling suction valve; this fails.
187	Actuate core spray into vessel and reopen ADS valves to establish alternate cooling path.

(1) See Table 15.2-9 for detailed sequence of events for loss of ac power transient.

Table 15.2-13

INPUT PARAMETERS FOR EVALUATION OF FAILURE
OF RHR SHUTDOWN COOLING

Initial power level (MWt)	3528
Suppression pool mass (lb_m)	7.364×10^{6}
RHR (KHX value) (Btu/sec/°F)	305
Initial vessel condition	
Pressure (psia)	1068
Temperature (°F)	553
Initial primary fluid inventory (lb_m)	6.253×10^{5}
Initial pool temperature, (°F)	$9.500 \times 10^{+1}$
Service water temperature, (°F)	$9.500 \times 10^{+1}$
Vessel heat capacity (Btu/lb_m/°F)	1.230×10^{-1}
Core spray flow rate, (lb_m/sec)	$8.690 \times 10^{+2}$
RHR pool cooling flow rate (lb_m/sec)	$1.390 \times 10^{+3}$

TABLE 15.2-14

SIGNIFICANT INITIAL CONDITIONS AND RESULTS
FOR THE GENERATOR LOAD REJECTION WITHOUT BYPASS AND RPT

INITIAL CONDITIONS	
Initiating Event:	Generator Load Rejection
Failed Systems	Recirculation Pump Trip[1] Turbine Bypass Valves
First Functioning Scram Signal	Turbine Control Valve Fast Closure
RESULTS	
Maximum Vessel Pressure (psig)	1276
Time of Maximum Pressure (sec)	2.1
Delta Critical Power Ratio (ΔCPR)	0.22/0.32/0.32[2]
Time of MCPR (sec)	1.19/1.22/1.19[2]

(1) Initiated by Turbine Control Valve Fast Closure.

(2) GE8X8NB/GE11/GNF3

Table 15.2-15

SEQUENCE OF EVENTS FOR
LOSS OF STATOR COOLING

TIME (sec)	EVENT
0.0	Loss of Stator Cooling occurs.
0.0[a]	Dual Recirculation Pump to 42% Speed is initiated[b].
0.0	Turbine-Generator Load Set Runback begins from 105% going to 20% over 140 seconds.
45 (approx.)[a][c]	Turbine-Generator Load Set reaches Turbine Control Valve (TCV) position and starts causing the TCVs to close. Turbine Bypass Valves (TBV) begin to open in response to the TCV Closure.
75 (approx.)[a][c]	TBVs open to their available capacity. Pressurization begins due to mismatch between steam flow coming from the vessel and the available TCV/TBV capacity.
95 (approx.)[a][c]	Reactor scrams on high pressure or neutron flux.

(a) This timeline assumes the feedwater flow interlock does not inhibit recirculation runback.

(b) In the original LOSC analysis both recirculation pumps runback immediately at time 0. In subsequent cycle-specific analyses the pumps are conservatively modeled as running back together after an approximately 10 second delay. In reality, Recirculation Pump 'A' runback is initiated at 1 second and Recirculation Pump 'B' runback is initiated at 10 seconds after event start.

(c) If recirculation runback is inhibited, this time will increase by approximately 45 seconds.

15.3 DECREASE IN REACTOR COOLANT SYSTEM FLOW RATE

15.3.1 RECIRCULATION PUMP TRIP

15.3.1.1 Identification of Causes and Frequency Classification

15.3.1.1.1 Identification of Causes

Recirculation pump motor operation can be tripped off either by design for the reduction of other core and RCPB transient effects or by random unpredictable operational failures. Intentional tripping will occur in response to the following:

a. Reactor vessel water level Level 2 setpoint trip

b. Turbine control valve fast closure or stop valve closure

c. Reactor vessel high pressure setpoint trip

d. Motor branch circuit overcurrent protection

e. Motor overload protection

f. Suction block valve not fully open (Unit 2 only)

g. Discharge valve not fully open (Unit 2 only)

h. Deleted

i. Low lube oil pressure

j. Main unit lockout

k. Deleted

l. Deleted

m. Bus undervoltage

n. High oil temperature

o. Manual trip

Random tripping will occur in response to the following:

a. Operator error

b. Loss of electrical power source to the pumps

c. Equipment or sensor failures and malfunctions which initiate the above trips.

15.3.1.1.2 Frequency Classification

15.3.1.1.2.1 Trip of One Recirculation Pump

This transient is categorized as one of moderate frequency.

15.3.1.1.2.2 Trip of Two Recirculation Pumps

This transient is categorized as one of moderate frequency.

15.3.1.2 Sequence of Events and System Operation

15.3.1.2.1 Sequence of Events

15.3.1.2.1.1 Trip of One Recirculation Pump

Table 15.3-1 lists the sequence of events for Figure 15.3-1.

15.3.1.2.1.2 Trip of Two Recirculation Pumps

Table 15.3-2 lists the sequence of events for Figure 15.3-2.

15.3.1.2.1.3 Identification of Operator Actions

15.3.1.2.1.3.1 Trip of One Recirculation Pump

Since no scram occurs for trip of one recirculation pump, no immediate operator action is required. As soon as possible, the operator should first verify that no operating limits are being exceeded and then reduce the flow of the operating pump to conform to the single pump flow criteria. Also, the operator must determine the cause of failure before following the restart procedure and returning the system to normal.

15.3.1.2.1.3.2 Trip of Two Recirculation Pumps

Tripping of two recirculation pumps will cause a reactor water level swell that will trip the main turbine. This in turn will cause a reactor scram. The operator should ascertain that the reactor has been scrammed by the turbine trip resulting from reactor water level swell. The operator should regain control of reactor water level through RCIC operation, monitoring reactor water level and pressure control after shutdown. When both reactor pressure and level are under control, the operator may secure both HPCI and RCIC as necessary. The operator should also determine the cause of the trip before returning the system to normal.

15.3.1.2.2 System Operation

15.3.1.2.2.1 Trip of One Recirculation Pump

Tripping a single recirculation pump requires no protection system or safeguard system operation. This analysis assumes normal functioning of plant instrumentation and controls.

15.3.1.2.2.2 Trip of Two Recirculation Pumps

Analysis of this transient assumes normal functioning of plant instrumentation and controls as well as plant and reactor protection systems.

Specifically, this transient takes credit for vessel level (Level 8) instrumentation that closes the turbine stop valves. Reactor shutdown relies on scram trips from the turbine stop valves. High system pressure is limited by MSRV operation.

15.3.1.2.3 The Effect of Single Failures and Operator Errors

15.3.1.2.3.1 Trip of One Recirculation Pump

Since no corrective action is required, no additional effects of single failures need be discussed. If additional single active failure or single operator error are assumed (for envelope purposes the other pump is assumed tripped), then the following two-pump trip analysis is provided (Section 15.9.6.3.3.g, Table 15.9-2).

15.3.1.2.3.2 Trip of Two Recirculation Pumps

Table 15.3-2 lists the vessel level (Level 8) trip event as the first response to initiate corrective action in this transient. The level (Level 8) is intended to prohibit moisture carryover to the main turbine. Multiple level sensors are used to sense and detect when the water level reaches the Level 8 setpoint. At this point, a single failure will neither initiate nor impede a turbine trip signal. However, turbine trip signal transmission circuitry is not built to the single failure criterion. The result of a failure at this point would have the effect of delaying the pressurization "signature." However, high moisture levels entering the turbine can trip the turbine via turbine supervisory instrumentation.

Scram trip signals from the turbine are designed so that a single failure will neither initiate nor impede a reactor scram trip initiation (Section 15.9.6.3.3.g, Table 15.9-2).

15.3.1.3 Core and System Performance

15.3.1.3.1 Mathematical Model

The nonlinear dynamic model used to simulate this transient is discussed in Reference 15.1-1.

15.3.1.3.2 Input Parameters and Initial Conditions

Unless otherwise noted, these analyses have been performed using Cycle 1 plant conditions.

Pump motors and pump rotors are simulated with minimum specified rotating inertias.

15.3.1.3.3 Results

The results of these events are based on Cycle 1 conditions. However, with the development of new analysis methodologies and the introduction of new fuel types, a recirculation pump trip does not have as significant of a level response and the Level 8 setpoint is not expected to be reached. In this scenario, a two recirculation pump trip remains non-limiting. Additionally, other transient events which result in a two recirculation pump trip model the recirculation pump trip as part of the event, and the resulting level response may be different than the historic Cycle 1 response due to the introduction of new fuel types and the use of newer analysis methodologies.

15.3.1.3.3.1 Trip of One Recirculation Pump

Figure 15.3-l shows the results of losing one recirculation pump. The tripped loop diffuser flow reverses in approximately 2.7 seconds. However, the ratio of diffuser mass flow to pump mass flow in the active jet pumps increases considerably and produces approximately 154% of normal diffuser flow and 58% of rated core flow. MCPR remains well above the safety limit; thus, the fuel thermal limits are not violated. During this transient, level swell is not sufficient to cause turbine trip and scram.

15.3.1.3.3.2 Trip of Two Recirculation Pumps

Figure 15.3-2 shows this transient, with minimum specified rotating inertia, in graph form. MCPR remains unchanged. No scram is initiated directly by pump trip. The vessel water level swell due to rapid flow coast-down is expected to reach the high level trip, thereby shutting down the main turbine and feed pump turbines and scramming the reactor. Subsequent events, such as main steam line isolation and initiation of RCIC and HPCI systems occurring later in this transient, have no significant effect on the results.

15.3.1.3.4 Consideration of Uncertainties

Initial conditions chosen for these analyses are conservative and tend to force analytical results to be more severe than those expected under actual plant conditions.

Actual pump and pump motor driveline rotating inertias are expected to be somewhat greater than the minimum design values assumed in this simulation. Actual plant deviations regarding inertia are expected to lessen the severity of the results indicated by this analysis. Minimum design inertias were used as well as the least negative void coefficient, because the primary concern here is flow reduction.

15.3.1.4 Barrier Performance

15.3.1.4.1 Trip of One Recirculation Pump

Figure 15.3-1 results indicate a basic reduction in system pressures from the initial conditions. Therefore, the RCPB barrier is not threatened.

15.3.1.4.2 Trip of Two Recirculation Pumps

The results shown in Figure 15.3-2 indicate that peak pressures stay well below the 1375 psig limit allowed by the applicable code. Therefore, the barrier pressure boundary is not threatened.

15.3.1.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there is no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established technical specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.3.2 RECIRCULATION FLOW CONTROL FAILURE - DECREASING FLOW

15.3.2.1 Identification of Causes and Frequency Classification

15.3.2.1.1 Identification of Causes

Some causes of recirculation flow control failure are malfunction of the active ASD controller (one of two redundant controllers), malfunction of the PLC supplying command signals to the controllers, or corruption to the communication between these devices (one of two redundant channels). These malfunctions can result in a rapid flow decrease in only one recirculation loop.

15.3.2.1.2 Frequency Classification

This transient is categorized as an incident of moderate frequency.

15.3.2.2 Sequence of Events and System Operation

15.3.2.2.1 Sequence of Events

15.3.2.2.1.1 Failure of One Controller - Closed

The sequence of events for this transient is similar to, and can never be more severe than, that listed in Table 15.3-1 for the trip of one recirculation pump.

15.3.2.2.1.2 Deleted

15.3.2.2.1.3 Identification of Operator Actions

As soon as possible, the operator should verify that no operating limits are being exceeded. If limits are exceeded, corrective action must be initiated. The operator must also determine the cause of the trip before returning the system to normal.

15.3.2.2.2 System Operation

Normal plant instrumentation and control is assumed to function. Credit is taken for scram in response to vessel high water level (Level 8) turbine trip if it occurs.

15.3.2.2.3 The Effect of Single Failures and Operator Errors

The single failure and operator error considerations for these events are the same as those discussed in Section 15.3.1.2.3 on the RPT. Failure of an ASD and thus an RPT, would be the envelope case for additional single action failure or single operator error (Section 15.9.6.3.3.f, Table 15.9-2).

15.3.2.3 Core and System Performance

15.3.2.3.1 Mathematical Model

The nonlinear dynamic model used to simulate these transients is discussed in Reference 15.1-1.

15.3.2.3.2 Input Parameters and Initial Conditions

These analyses have been performed, unless otherwise noted, with Cycle 1 plant conditions. The lowest negative void coefficient in Table 15.0-2 was used for these analyses.

15.3.2.3.3 Results

The results of these events are based on Cycle 1 conditions. An analysis of these events for current conditions is not expected to result in a change in the general trends and characteristics as shown.

In the case of zero demand to both controllers each individual ASD speed controller has internal limits established in its system operating program (SOP) that limits the maximum rate of change of speed in each loop. Thus, the results of these transients can never be more severe than those of the simultaneous trip of both recirculation pumps, as evaluated in Section 15.3.1.3.3.2.

The failure of one controller has two possible outcomes. A detectable failure of the active primary controller will cause swap-over to the back-up controller, resulting in maintaining pump speed at a lower fixed (speed-hold) value. An undetectable malfunction of the primary active controller or malfunction of an active back-up controller (with primary controller inactive) can result in a speed decrease at an uncontrolled rate (step change) to 0% speed. This case is similar to the trip of one recirculation pump, described in Section 15.3.1.3.3.1, and is less severe than the transient that results from the simultaneous trip of both recirculation pumps.

15.3.2.3.4 Consideration of Uncertainties

Initial conditions chosen for these analyses are conservative and tend to force the analytical results to be more severe than would otherwise be expected. These analyses, unlike the pump trip series, will be unaffected by deviations in pump/pump motor and driveline inertias because the flow controllers are what cause rapid recirculation decreases.

15.3.2.4 Barrier Performance

The barrier performance considerations for these events are the same as those discussed in Section 15.3.1.4.

15.3.2.5 Radiological Consequences

While the consequence of this transient does not result in fuel failure, it does result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there will be no exposure to operating personnel. This transient does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment, or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.3.3 RECIRCULATION PUMP SEIZURE

15.3.3.1 Identification of Causes and Frequency Classification

The seizure of a recirculation pump is considered as a DBA. It has been evaluated as being a very mild accident in relation to other DBAs such as the LOCA. The analysis has been conducted with

consideration to both single-loop and two-loop operations. A discussion is given in GESTAR II (Reference 4.1-1).

15.3.3.1.1 Identification of Causes

The case of recirculation pump seizure represents the extremely unlikely event of instantaneous stoppage of the pump motor shaft of one recirculation pump. This accident produces a very rapid decrease of core flow as the result of the large hydraulic resistance introduced by the stopped rotor.

15.3.3.1.2 Frequency Classification

This accident is considered a limiting fault but results in effects that are comparable to those of an accident of greater probability (i.e. infrequent incident classification).

15.3.3.2 Sequence of Events and System Operation

15.3.3.2.1 Sequence of Events

Table 15.3-3 lists the sequence of events for Figure 15.3-3. Appropriate operator actions must be taken for recovery after the recirculation pump seizure event.

15.3.3.2.2 System Operation

In order to properly simulate the expected sequence of events, the analysis of this accident assumes normal functioning of plant instrumentation and controls, plant protection, and reactor protection systems.

Operation of safe shutdown features, though not included in this simulation, is expected to be utilized in order to maintain adequate water level.

15.3.3.2.3 The Effect of Single Failures and Operator Errors

Corrective action by the level control is expected to establish a new stable operating state. The effect of a single failure in the level control system has rather straightforward consequences, including level rise or fall by improper control of the feedwater system. Increasing level will trip the main and feedwater turbines. This trip signal is described in Section 15.1.2.2.3. Decreasing level will automatically initiate scram at the low level (Level 3) trip which is designed to single failure criteria (Section 15.9.6.4.3.e, Table 15.9-2).

15.3.3.3 Core and System Performance

15.3.3.3.1 Mathematical Model

The nonlinear dynamic model used to simulate this accident is discussed in Reference 15.1-1.

15.3.3.3.2 Input Parameters and Initial Conditions

This analysis has been performed, unless otherwise noted, with the plant conditions tabulated in Table 15.0-2A.

For the purpose of evaluating consequences to the fuel thermal limits, this accident is assumed to occur as the result of an unspecified, instantaneous stoppage of one recirculation pump shaft while the reactor is operating at 102% rated power. The reactor is also assumed to be operating at thermally limited conditions.

15.3.3.3.3 Results

Figure 15.3-3 presents the results of the accident while operating in two-loop mode. Core coolant flow drops rapidly, reaching its minimum value in approximately 1.7 seconds. The vessel water level rises and feedwater flow reduces to compensate. The reactor stabilizes at a new steady-state operating condition. The peak neutron flux and average surface heat flux did not increase significantly above the initial conditions, therefore no impact on the fuel thermal margins is postulated to occur.

A specific analysis has been performed to model the recirculation pump seizure transient while in single-loop mode and is used to establish a MCPR requirement for single-loop operation. See Reference 15.3-1.

15.3.3.3.4 Consideration of Uncertainties

This transient is predicted to result in a reactor vessel water level increase to slightly below the high level (Level 8) turbine trip setpoint. Slightly different nuclear boiler system operational parameters might result in the level swell causing a turbine trip. Should the vessel water level reach the high water level setpoint (Level 8), main turbine trip, resulting from stop valve closure, and feedwater pump trip would be initiated. Subsequently, reactor scram and the remaining recirculation pump trip would be initiated due to the turbine trip. The vessel water level would eventually be controlled by HPCI and RCIC flow.

Further uncertainties are considered in the GETAB (Reference 15.0-2) analysis.

15.3.3.4 Barrier Performance

The bypass valves, and possible momentary opening of some of the MSRVs, limit the pressure well within the range allowed by the ASME vessel code. Therefore, the RCPB is not threatened by overpressure.

15.3.3.5 Radiological Consequences

While the consequence of this accident does not result in fuel failure, it could result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there would be no exposure to operating personnel. This accident does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment or discharge it to the environment under controlled release conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

15.3.4 RECIRCULATION PUMP SHAFT BREAK

15.3.4.1 Identification of Causes and Frequency Classification

The breaking of the shaft of a recirculation pump is considered an accident. It has been evaluated as a very mild accident in relation to other DBAs such as the LOCA. The analysis has been conducted with consideration to both single-loop and two-loop operation.

This postulated accident is bounded by the more limiting case of recirculation pump seizure. Quantitative results for this more limiting case are presented in Section 15.3.3.

15.3.4.1.1 Identification of Causes

Recirculation pump shaft breakage represents the extremely unlikely event of instantaneous stoppage of one recirculation pump motor. This accident produces a very rapid decrease of core flow as a result of the broken pump shaft.

15.3.4.1.2 Frequency Classification

This accident is considered a limiting fault, but results in effects that are comparable to those of an accident of greater probability (i.e., infrequent incident classification).

15.3.4.2 Sequence of Events and System Operation

15.3.4.2.1 Sequence of Events

A postulated instantaneous break of the motor shaft of one recirculation pump, as discussed in Section 15.3.4.1.1, will cause the core flow to decrease rapidly and result in water level swell in the reactor vessel but no scram. The core flow and power will stabilize at new equilibrium conditions. Appropriate operator actions must be taken for recovery after the recirculation pump shaft break event.

15.3.4.2.2 System Operation

Normal operation of plant instrumentation and control is assumed. Operation of HPCI and RCIC systems during shutdown is expected in order to maintain adequate water level control.

15.3.4.2.3 The Effect of Single Failures and Operator Errors

Effects of single failures are similar to those considered in Section 15.3.3.2.3 .

Refer to Section 15.9.6.4.3.f and Table 15.9-3 for more details.

15.3.4.3 Core and System Performance

The severity of this pump shaft break accident is bounded by the pump seizure accident as described in Section 15.3.3. This can be easily demonstrated by consideration of these two accidents as discussed in the section below. Since the shaft break accident is less limiting than the accident discussed in Section 15.3.3 only a qualitative evaluation is provided. Therefore, no discussion of mathematical model, input parameters, and consideration of uncertainties, etc., is necessary.

15.3.4.4 Qualitative Results

If this extremely unlikely accident occurs, core coolant flow will drop rapidly. The vessel level increases but remains below the trip level (Level 8) of the main and feedwater turbines. The flow in the recirculation loop with the failed pump decreases rapidly. The core flow and then the reactor power stabilize at lower values within less than a minute of the failure.

The severity of this pump shaft break accident is bounded by the pump seizure accident (Section 15.3.3). This can be demonstrated easily by consideration of the two types of accidents. In both accidents, the recirculation drive flow of the affected loop decreases rapidly. In the case of the pump seizure accident, the loop flow decreases faster than the normal flow coast-down as a result of the large hydraulic resistance introduced by the stopped rotor. In the case of the pump shaft break accident, the hydraulic resistance caused by the broken pump shaft is less than that of the stopped rotor for the pump seizure accident. Therefore, the core flow decrease following a pump shaft break effect is slower than the pump seizure accident. Thus, it can be concluded that the potential effects of the hypothetical pump shaft break accident are bounded by the effects of the pump seizure accident.

15.3.4.5 Barrier Performance

The bypass valves, and possible momentary opening of some of the MSRVs, limit the pressure well within the range allowed by the ASME vessel code. Therefore, the RCPB is not threatened by overpressure.

15.3.4.6 Radiological Consequences

While the consequence of this accident does not result in fuel failure, it could result in the discharge of normal coolant activity to the suppression pool via MSRV operation. Because this activity is contained in the primary containment, there would be no exposure to operating personnel. This accident does not result in an uncontrolled release to the environment, so the plant operator can choose to leave the activity bottled up in the containment, or discharge it to the environment under controlled conditions. If purging of the containment is chosen, the release will be in accordance with established Technical Specifications and, at the worst, would only result in a small increase in the yearly integrated exposure level.

Table 15.3-1

SEQUENCE OF EVENTS FOR TRIP OF ONE RECIRCULATION PUMP[1]

TIME (sec)	EVENT
0.0	Trip of one recirculation pump initiated.
2.7	Diffuser flow decreases significantly in the tripped loop.
20.0	Core flow stabilizes at new equilibrium conditions.
40.0	Power level stabilizes at new equilibrium conditions.

[1] See Figure 15.3-1.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.3-2

SEQUENCE OF EVENTS FOR TRIP OF BOTH RECIRCULATION PUMPS[2]

TIME (sec)	EVENT[1]
0.0	Trip of both recirculation pumps initiated.
5.2	Vessel water level (Level 8) trip initiates turbine trip and feedwater pumps trip.
5.2	Turbine trip initiates bypass operation.
5.2	Turbine trip initiates reactor scram trip.
9.9	Group 1 MSRVs open.
12.9	Group 1 MSRVs close.
43.5	Level 2 vessel level setpoint initiates steam line isolation and HPCI/RCIC start.

(1) For these events, MSIV closure was simulated at Level 2. Subsequent design modifications have lowered the closure setpoint to Level 1. However, HPCI and RCIC initiation at Level 2 will prevent the water level from dropping to Level 1 and no MSIV closure will occur. Because no safety limits are approached during this event, reanalysis for the setpoint change is not required.

(2) See Figure 15.3-2.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.3-3

SEQUENCE OF EVENTS FOR RECIRCULATION PUMP SEIZURE[1]

TIME (sec)	EVENT
0.0	Single pump seizure was initiated.
0.7	Jet pump diffuser flow reverses in seized loop.
4.0	Core flow stabilizes at new equilibrium conditions.
40.0	Power stabilizes at new equilibrium conditions.

15.4 REACTIVITY AND POWER DISTRIBUTION ANOMALIES

15.4.1 ROD WITHDRAWAL ERROR - LOW POWER

15.4.1.1 Control Rod Removal Error During Refueling

15.4.1.1.1 Identification of Causes and Frequency Classification

The transient considered here is inadvertent criticality due to the complete withdrawal or removal of the highest worth control rod during refueling. The probability of the initial causes alone is considered low enough to warrant its being categorized as an infrequent incident, since there is no postulated set of circumstances that results in an inadvertent rod withdrawal error while in the refueling mode.

15.4.1.1.2 Sequence of Events and System Operation

15.4.1.1.2.1 Initial Control Rod Removal or Withdrawal

During refueling operations system interlocks provide assurance that inadvertent criticality does not occur because two control rods have been removed or withdrawn together.

When fuel is being moved from the core to the spent fuel pool during refueling, the refueling interlocks may be disabled for core cells from which the four fuel assemblies have been removed if the conditions contained in technical specification 3.9.10.2 are met and compensating administrative controls are established.

15.4.1.1.2.2 Fuel Insertion With Control Rod Withdrawn

To minimize the possibility of loading fuel into a cell containing no control rod, all control rods must be fully inserted when fuel is being loaded into the core. This requirement is backed up by refueling interlocks on rod withdrawal and movement of the refueling platform. When the mode switch is in the REFUEL position, the interlocks prevent the platform from being moved over the core if a control rod is withdrawn and fuel is on the hoist. Likewise, if the refueling platform is over the core and fuel is on the hoist, control rod motion is blocked by the interlocks.

When fuel is being moved from the core to the spent fuel pool during refueling, the refueling interlocks may be disabled for core cells from which the four fuel assemblies have been removed if the conditions contained in technical specification 3.9.10.2 are met and compensating administrative controls are established.

15.4.1.1.2.3 Second Control Rod Removal or Withdrawal

When the platform is not over the core (or fuel is not on the hoist) and the mode switch is in the REFUEL position, only one control rod can be withdrawn. Any attempt to withdraw a second rod results in a rod block by the refueling interlocks. Since the core is designed to meet shutdown requirements with the highest worth rod withdrawn, the core remains subcritical even with one rod withdrawn.

15.4.1.1.2.4 Control Rod Removal Without Fuel Removal

Finally, the design of the control rod, incorporating the velocity limiter, does not physically permit the upward removal of the control rod without prior or simultaneous removal of the four adjacent fuel bundles. This precludes any hazardous condition.

15.4.1.1.2.5 Identification of Operator Actions

No operator actions are required to preclude this transient since the plant design, as discussed above, prevents its occurrence.

15.4.1.1.2.6 Effect of Single Failure and Operator Errors

If any one of the operations involved in initial failure or error is followed by any other single active failure or single operator error, the necessary safety actions (e.g., rod block or scram) are taken automatically prior to limit violation (Section 15.9).

15.4.1.1.3 Core and System Performances

Since the probability of inadvertent criticality during refueling is precluded, the core and system performances were not analyzed. The withdrawal of the highest worth control rod during refueling will not result in criticality. This is determined analytically during the core design process. Shutdown Margin is verified experimentally during the first startup following refueling operations. (See Section 4.3.2 for a description of the methods and results of the shutdown margin analysis.) Additional reactivity insertion is precluded by interlocks (Section 7.7). As a result, no radioactive material is ever released from the fuel making it unnecessary to assess any radiological consequences.

No mathematical models are involved in this transient. The need for input parameters or initial conditions is not required as there are no results to report. Consideration of uncertainties is not appropriate.

15.4.1.1.4 Barrier Performance

An evaluation of the barrier performance was not made for this transient, since there is not a postulated set of circumstances for which this transient could occur.

15.4.1.1.5 Radiological Consequences

An evaluation of the radiological consequences was not made for this transient, since no radioactive material is released from the fuel.

15.4.1.2 Continuous Rod Withdrawal During Reactor Startup

15.4.1.2.1 Identification of Causes and Frequency Classification

The probability of initial causes or errors of this transient alone is considered low enough to warrant its being categorized as an infrequent incident. The probability of further development of this transient is extremely low because it is contingent upon the failure of the RWM system, together with a high worth out-of-sequence rod selection contrary to procedures, and operator failure to acknowledge continuous alarm annunciations prior to safety system actuation.

15.4.1.2.2 Sequence of Events and System Operation

15.4.1.2.2.1 Sequence of Events

Control rod withdrawal errors are not considered credible in the startup and low power ranges. The RWM system prevents the operator from selecting and withdrawing an out-of-sequence control rod.

15.4.1.2.2.2 Identification of Operator Actions

No operator actions are required to preclude this transient since the plant design, as discussed above, prevents its occurrence.

15.4.1.2.2.3 The Effect of Single Failures and Operator Errors

If any one of the operations involved the initial failure or error is followed by another single active failure or single operator error, the necessary safety actions (e.g., rod blocks) are automatically taken prior to any limit violation (Section 15.9). Further development of this event is contingent upon simultaneous failure of two systems as described in Appendix 15A.

15.4.1.2.3 Core and System Performance

The performance of the RWM system prevents erroneous selection and withdrawal of an out-of-sequence rod. The core and system performance is not affected by such an operator error.

No mathematical models are involved in this transient. The need for input parameters, or initial conditions, is not required as there are no results to report. Consideration of uncertainties is not appropriate.

15.4.1.2.4 Barrier Performance

An evaluation of the barrier performance was not made for this transient, since there is no postulated set of circumstances for which this error could occur.

15.4.1.2.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this transient, since no radioactive material is released from the fuel.

15.4.2 ROD WITHDRAWAL ERROR - AT POWER

15.4.2.1 Identification of Causes and Frequency Classification

15.4.2.1.1 Identification of Causes

While operating in the power range in a normal mode of operation, the reactor operator makes a procedural error and continuously withdraws a high worth control rod until the RBM system inhibits further withdrawal.

15.4.2.1.2 Frequency Classification

This transient is classified as an incident of moderate frequency.

15.4.2.2 Sequence of Events and System Operation

15.4.2.2.1 Sequence of Events

The sequence of events for this transient, as calculated with conservative assumptions, is presented in Table 15.4-1. No operator actions are required during this transient. However, operator procedural actions expected to occur are shown in the above referenced table.

15.4.2.2.2 System Operation

The focal point of this transient is localized to a small portion of the core. Therefore, although reactor controls and instrumentation are assumed to function normally, credit is taken only for the RBM system. A discussion of the transient follows below.

While operating in the power range in a normal mode of operation, the reactor operator withdraws high worth control rod until the RBM system inhibits further withdrawal.

Under most normal operating conditions, no operator action is required since the transient which would occur would be very mild.

If the rod withdrawal error is severe enough, the RBM system would sound alarms, at which time the operator would acknowledge the alarm and take corrective action. Even assuming that the operator ignores all alarms and warnings and continues to withdraw the control rod, the RBM system will block further withdrawal of the control rod before the fuel reaches the point of boiling transition or the 1% strain limit imposed on the cladding.

15.4.2.2.3 The Effect of Single Failures and Operator Errors

The effect of operator errors has been discussed above. It was shown that operator errors (which initiated this transient) cannot impact the consequences of this transient due to the highly reliable RBM system (Section 15.9).

15.4.2.3 Core and System Performance

The Rod withdrawal Error (RWE) event has been analyzed generically to support the Rod Block Monitor (RBM) set points established by the ARTS program. The RWE analysis and the ARTS program for Limerick are discussed in Reference 15.0-10. The generic RWE analysis provides a relationship between ΔCPR and Rod Block Monitor set points.

Reference 15.4-21 concludes that the generic ARTS rated RWE ΔCPR can be eliminated for Limerick Generating Station for all RBM setpoints. Sufficient off-rated analyses are performed for the first cycle with GNF3 as fresh fuel for Limerick Unit 1 and Limerick Unit 2 to confirm that the conclusion is applicable to GNF3 reload cores. A cycle-specific generic ARTS RWE Kp validation is performed for all RBM high power trip setpoints (HTSPs) to ensure that the calculated rated RWE ΔCPR, combined with the generic ARTS RWE Kp limits, provide adequate RWE protection for the cycle. Limits are documented in the Supplemental Reload Licensing Report and incorporated in the Core Operating Limits Report for the cycle. If necessary, new RBM set points are established. The generic and

cycle specific RWE analyses also verify conformance to the fuel thermal-mechanic limit of 1 % strain.

15.4.2.4 Barrier Performance

An evaluation of the barrier performance was not made for this transient, since this is a localized transient with very little change in the gross core characteristics. Typically, the increase in total core power is less than 5% and the changes in pressure are negligible.

15.4.2.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this transient, since no radioactive material is released from the fuel.

15.4.3 CONTROL ROD MALOPERATION (SYSTEM MALFUNCTION OR OPERATOR ERROR)

This transient is covered by the evaluations cited in Sections 15.4.1 and 15.4.2.

15.4.4 ABNORMAL STARTUP OF IDLE RECIRCULATION PUMP

15.4.4.1 Identification of Causes and Frequency Classification

15.4.4.1.1 Identification of Causes

This action results directly from the operator's manual action to initiate pump operation. It assumes that the remaining loop is already operating.

15.4.4.1.1.1 Normal Restart of Recirculation Pump at Power

This transient is categorized as an incident of moderate frequency.

15.4.4.1.1.2 Abnormal Startup of Idle Recirculation Pump

This transient is categorized as an incident of moderate frequency.

15.4.4.2 Sequence of Events and System Operation

15.4.4.2.1 Sequence of Events

Table 15.4-3 lists the sequence of events.

The normal sequence of operator actions expected in starting the idle loop is as follows. The operator should:

a. Adjust rod pattern as necessary for new power level following idle loop start.

b. Determine that the idle recirculation pump suction valve is open, the discharge valve is closed, and the coupler in the idle loop is in the starting position. If they are not, the operator must place them in these configurations.

c. Readjust flow of the running loop downward to less than one-half of rated flow.

d. Determine that the temperature differential between the reactor pressure vessel steam space coolant and the bottom head drain line coolant is no more than 145°F.

e. Determine that the temperature difference between the two loops is no more than 50°F.

f. Start the idle loop pump and open the discharge valve by jogging manual circuitry.

g. Adjust flow to match the adjacent loop flow. Monitor reactor power.

h. Readjust power, as necessary, to satisfy plant requirements per standard procedure.

The time required to do the above work is approximately ½ hour.

15.4.4.2.2 System Operation

This transient assumes and takes credit for normal functioning of plant instrumentation and controls, plant protection, and RPS. In particular, credit is taken for high flux scram to terminate the transient. No ESF action occurs as a result of the transient.

15.4.4.2.3 The Effect of Single Failures and Operator Errors

This transient leads to a quick rise in reactor power level. Corrective action first occurs in the APRM neutron flux upscale trip and, being part of the RPS, it is designed to the single failure criterion. Therefore, shutdown is assured. Operator errors are not of concern here in view of the fact that automatic shutdown transients follow so quickly after the postulated failure (Section 15.9).

15.4.4.3 Core and System Performance

15.4.4.3.1 Mathematical Model

The nonlinear dynamic model described briefly in Section 15.1.1.3.1 is used to simulate this transient.

15.4.4.3.2 Input Parameters and Initial Conditions

This analysis has been performed, unless otherwise noted, with plant conditions as tabulated in Table 15.0-2.

One recirculation loop is idle and filled with cold water at 100°F. (Normal procedure when starting an idle loop with one pump already running requires heating the idle recirculation loop to within 50°F of core inlet temperature prior to loop startup.)

The active recirculation loop is operating with about 84% of normal rated diffuser flow going across the active jet pumps.

The core is receiving 38% of its normal rated flow. The remainder of the coolant flows in the reverse direction through the inactive jet pumps.

Reactor power is 55% of NBR power conditions. (Normal procedures require startup of an idle loop at a lower power.)

The idle recirculation pump suction valve is open, but the pump discharge valve is closed.

The idle pump fluid coupler is at a setting that approximates 50% generator speed demand.

15.4.4.3.3 Results

The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Shortly after the pump begins to move, a surge in flow from the jet pump diffusers causes the core inlet flow to rise sharply.

When the neutron flux peak reaches the APRM neutron flux upscale scram setpoint, reactor scram is initiated. The neutron flux peaks at 454.9% of NBR. Surface heat flux follows the slower response of the fuel and peaks at 90% NBR. Nuclear system pressures do not increase significantly above the initial pressures. The water level does not reach either the high or low level setpoints.

15.4.4.3.4 Consideration of Uncertainties

This particular transient is analyzed for an initial power level that is much higher than that expected for the actual transient. The much slower thermal response of the fuel mitigates the effects of the rather sharp neutron flux spike and, even in this high range of power, no threat to thermal limits is possible.

15.4.4.4 Barrier Performance

No evaluation of barrier performance is required for this transient, since no significant pressure increases are incurred.

15.4.4.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this transient, since no radioactive material is released from the fuel.

15.4.5 RECIRCULATION FLOW CONTROL FAILURE WITH INCREASING FLOW

15.4.5.1 Identification of Causes and Frequency Classification

15.4.5.1.1 Identification of Causes

Failure of an individual flow controller can cause a speed increase for its associated recirculation pump. The failure of one ASD controller has two possible outcomes. A detectable failure of the active primary controller will cause swap-over to the back-up controller, resulting in maintaining pump speed at a lower fixed (speed-hold) value. An undetectable malfunction of the primary active controller or malfunction of the active back-up controller (with primary controller inactive) can result in a speed decrease at an uncontrolled rate (step change) to 0% speed.

15.4.5.1.2 Frequency Classification

This transient is classified as an incident of moderate frequency.

15.4.5.2 Sequence of Events and System Operation

15.4.5.2.1 Sequence of Events

Table 15.4-4 lists the sequence of transients for Figure 15.4-3.

Initial actions by the operator include:

a. Reducing recirculation flow to minimum

b. Identifying the cause of the failure.

Reactor pressure will be controlled as required, depending upon whether a restart or cooldown is planned. In general, the corrective action would be to hold reactor pressure and condenser vacuum for restart after the malfunctioning flow controller has been repaired. The following is the sequence of operator actions expected during the course of the transient. The operator should:

a. Observe that all rods are in.

b. Check the reactor water level and maintain it above low level (Level 1) trip to prevent MSIVs from isolating.

c. Switch the reactor mode switch to the STARTUP position.

d. Continue to maintain vacuum and turbine seals.

e. Reduce seep demand to 28% or less.

f. Monitor the turbine coast-down and auxiliary systems.

The time required from first alarm to restart would be approximately one hour.

15.4.5.2.2 System Operation

The analysis of this transient assumes and takes credit for normal functioning of plant instrumentation and controls, and the RPS. Operation of engineered safeguards is not expected.

15.4.5.2.3 The Effect of Single Failures and Operator Errors

This transient leads to a quick rise in reactor power level. Corrective action first occurs in the APRM neutron flux upscale trip and, being part of the RPS, it is designed to the single failure criterion. Therefore, shutdown is assured (Section 15.9). Operator errors are not of concern here in view of the fact that automatic shutdown transients follow so quickly after the postulated failure.

15.4.5.3 Core and System Performance

15.4.5.3.1 Mathematical Model

The nonlinear dynamic model described briefly in Section 15.1.1.3.1 is used to simulate this transient.

15.4.5.3.2 Input Parameters and Initial Conditions

This analysis has been performed, unless otherwise noted, with Cycle 1 plant conditions.

In each of these transients, the most severe transient results when initial conditions are established for operation at the low end of the rated flow control rod line. Specifically, at 57% NBR power and 39.6% core flow.

Maximum change in speed control occurs with a malfunction of one of the two redundant ASD controllers that results in an instantaneous step change to maximum output speed.

15.4.5.3.3 Results

The results of this event are based on Cycle 1 conditions. An analysis of this event for current conditions is not expected to result in a change in the general trends and characteristics as shown.

Figure 15.4-3 shows the results of the transient. The changes in nuclear system pressure are not significant with regard to overpressure. Pressure decreases over most of the transient. The rapid increase in core coolant flow causes an increase in neutron flux, which initiates a reactor APRM neutron flux upscale scram.

The peak neutron flux rise reaches 382.3% of NBR flux, and the accompanying transient fuel surface heat flux reaches 82.7% of rated. The MCPR remains above the safety limit, and fuel center temperature increases only 383°F. Therefore, the design basis is satisfied.

15.4.5.3.4 Consideration of Uncertainties

Some uncertainties in void reactivity characteristics, scram time, and worth are expected to be more optimistic and will therefore produce less severe consequences than those simulated here.

15.4.5.4 Barrier Performance

This transient results in a very slight increase in reactor vessel pressure, as shown in Figure 15.4-3, and therefore represents no threat to the RCPB.

15.4.5.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this transient, since no radioactive material is released from the fuel.

15.4.6 CHEMICAL AND VOLUME CONTROL SYSTEM MALFUNCTIONS

These are not applicable to BWRs. This is a PWR transient.

15.4.7 MISPLACED BUNDLE ACCIDENT

15.4.7.1 Identification of Causes and Frequency Classification

15.4.7.1.1 Identification of Causes

The accident discussed in this section is the improper loading of a fuel bundle and subsequent operation of the core. Three errors must occur for this accident to take place in the initial core loading. First, a bundle must be loaded into a wrong location in the core. Second, the bundle which was supposed to be loaded where the mislocation occurred would have to be overlooked and also put in an incorrect location. Third, the misplaced bundles would have to be overlooked during the core verification performed following initial core loading.

15.4.7.1.2 Frequency Classification

This accident occurs when a fuel bundle is loaded into the wrong location in the core. It is assumed the bundle is misplaced in the worst possible location, and the plant is operated with the mislocated bundle. This accident is categorized as an infrequent incident based upon the following data:

Expected Frequency: 0.004 events/operating cycle

The above number is based upon past experience. The only misloading accidents that have occurred in the past were in reload cores where only two errors are necessary. Therefore, the frequency of occurrence for initial cores is even lower since three errors must occur concurrently.

15.4.7.2 Sequence of Events and System Operation

The postulated sequence of transients for the misplaced bundle accident is presented in Table 15.4-5.

Fuel loading errors, undetected by incore instrumentation following fueling operations, may result in undetected reductions in thermal margins during power operations. No detection is assumed and, therefore, no corrective operator action or automatic protection system functioning occurs.

15.4.7.2.1 The Effect of Single Failures and Operator Errors

This analysis already represents the worst case (i.e., operation of a misplaced bundle with three single active failures or single operator errors) and there are no further operator errors which can make the accident results any worse. It is felt that this section is not applicable to this accident (Section 15.9).

15.4.7.3 Core and System Performance

This event is discussed in the corresponding section of GESTAR II (Reference 4.1-1).

Results of analyzing the worst fuel bundle loading error are reported in Table 15.4-6. As can be seen, MCPR remains well above the point where boiling transition would be expected to occur, and the MLHGR does not exceed the 1% strain limit for the cladding. Therefore, no fuel damage occurs as a result of this accident.

15.4.7.4 Barrier Performance

An evaluation of the barrier performance was not made for this accident since it is very mild and highly localized. No perceptible change in the core pressure would be observed.

15.4.7.5 Radiological Consequences

An evaluation of the radiological consequences is not required for this accident since no radioactive material is released from the fuel.

15.4.8 SPECTRUM OF ROD EJECTION ACCIDENTS

This is not applicable to BWRs since the BWR has precluded this transient by incorporating into its design mechanical equipment which restricts any movement of the CRD system assemblies. The CRD housing support assemblies are described in Chapter 4.

15.4.9 CONTROL ROD-DROP ACCIDENT

15.4.9.1 Identification of Causes and Frequency Classification

Causes and frequency of the control rod-drop accident are described in the corresponding section of GESTAR II (Reference 4.1-1).

15.4.9.2 Sequence of Events and System Operation

A description of the sequence of events and the operation of the system during a control rod-drop accident is provided in the corresponding Section of GESTAR II (Reference 4.1-1).

15.4.9.3 Core and System Performance

15.4.9.3.1 Mathematical Model

The analytical methods, assumptions and conditions for evaluating the excursion aspects of the control rod-drop accident originally presented in the UFSAR are described in detail in GESTAR II (Reference 4.1-1). In support of the deletion of the MSLRM trip and valve closure functions, a new analysis was performed as described in NEDO-31400A, Reference 15.4-7.

15.4.9.3.2 Input Parameters and Initial Conditions

The input parameters and conditions for the control rod-drop accident originally presented in the UFSAR are described in GESTAR II (Reference 4.1-1). In support of the deletion of the MSLRM trip and valve closure functions, a new analysis was performed, with slightly different input parameters, as described in NEDO-31400A, Reference 15.4-7.

15.4.9.3.3 Results

The radiological consequences of the control rod drop accident are based on the methodology of Regulatory Guide 1.183 and the assumed failure of 1200 fuel rods of GNF2 and GNF3 10x10 fuel in an equivalent pin array of 85.6 and 88.3, respectively, and with a radial peaking factor of 2.0.

Two cases were evaluated. One with a release pathway through the main condenser where the condenser is assumed to leak radioactivity into the turbine enclosure and then released to the environment. The second pathway is through the Steam Jet Air Ejectors which discharge to the

off-gas system. In all cases, the dose for the main condenser leakage pathway bound the off-gas pathway dose.

The offsite dose limits established by Regulatory Guide 1.183 are 6.3 rem TEDE at the exclusion area boundary and 6.3 rem TEDE at the low population zone. The calculated dose at the exclusion area boundary is 0.054 rem TEDE and at the low population zone is 0.038 rem TEDE and are well within the prescribed limits.

The control room dose limit established by 10 CFR 50.67 is 5 rem TEDE. The calculated dose in the control room for the control rod drop accident is 1.85 rem TEDE and is within the prescribed limit.

15.4.9.4 Barrier Performance

An evaluation of the barrier performance was not made for this accident, since this is a highly localized accident with no significant change in the gross core temperature or pressure.

15.4.9.5 Radiological Consequences for the CRDA

Regulation 10 CFR 50.67, "Accident Source Term," provides a mechanism for power reactor licensees to voluntarily replace the traditional TID-14844 (Ref. 15.4-9) accident source term used in design-basis accident analyses with an "Alternative Source Term" (AST). The methodology of approach to this replacement is given in USNRC Regulatory Guide 1.183 (Ref. 15.4-10) and its associated Standard Review Plan 15.0.1 (Ref. 15.4-11).

Accordingly, Limerick Generating Station, Units 1 and 2, have applied the AST methodology for several areas of operational relief in the event of a Design Basis Accident (DBA), without fully crediting the use of previously assumed safety systems. Amongst these systems are the Control Room Emergency Fresh Air Supply System (CREFAS) and the Standby Gas Treatment System (SGTS).

In support of a full-scope implementation of AST as described in and in accordance with the guidance of Ref. 15.4-10, AST radiological consequence analyses are performed for the four DBAs that result in offsite exposure (i.e., Loss of Coolant Accident (LOCA), Main Steam Line Break (MSLB), Fuel Handling Accident (FHA), and Control Rod Drop Accident (CRDA)).

Implementation consisted of the following steps:

- Identification of the AST based on plant-specific analysis of core fission product inventory,
- Calculation of the release fractions for the four DBAs that could potentially result in control room and offsite doses (i.e., LOCA, MSLB, FHA, and CRDA),
- Analysis of the atmospheric dispersion for the radiological propagation pathways,
- Calculation of fission product deposition rates and removal mechanisms,
- Calculation of offsite and control room personnel Total Effective Dose Equivalent (TEDE) doses.

15.4.9.5.1 Regulatory Approach

The analyses are prepared in accordance with the guidance provided by Regulatory Guide 1.183 (Ref. 15.4-10).

15.4.9.5.2 Dose Acceptance Criteria

The AST acceptance criteria for Control Room dose for postulated major credible accident scenarios such as those resulting in substantial meltdown of the core with release of appreciable quantities of fission products is provided by 10 CFR 50.67, which requires:

> "Adequate radiation protection is provided to permit access to and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 0.05 Sv (5 rem) total effective dose equivalent (TEDE) for the duration of the accident."

This limit is applied by Regulatory Guide 1.183 to all of the accidents considered with AST.

The AST acceptance criteria for an individual located at any point on the boundary of the exclusion area (the Exclusion Area Boundary or EAB) are provided by 10 CFR 50.67 as 25 rem TEDE for any 2-hour period following the onset of the postulated fission product release.

The AST acceptance criteria for an individual located at any point on the outer boundary of the low population zone (LPZ) are provided by 10 CFR 50.67 as 25 rem TEDE during the entire period of passage of the radioactive cloud resulting from the postulated fission product release.
These limits are applied by Regulatory Guide 1.183 to events with a higher probability of occurrence (including CRDA, MSLB, and FHA considered herein) to provide the following acceptance criteria:

- For the BWR MSLB for the case of an accident assuming fuel damage or a pre-incident Iodine spike, doses at the EAB and LPZ should not exceed 25 rem TEDE for the accident duration (2 hour dose for EAB and 30 day dose for LPZ). For MSLB accidents assuming normal equilibrium Iodine activity, doses should not exceed 2.5 rem TEDE for the accident duration.
- For the BWR CRDA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2 hour dose for EAB and 24 hour dose for LPZ).
- For the FHA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2 hour dose for EAB and 30 day dose for LPZ).

15.4.9.5.3 Computer Codes

New AST calculations for the CRDA were prepared to simulate the radionuclide release, transport, removal, and dose estimates associated with the postulated accident scenarios.

The RADTRAD computer code (Ref. 15.4-13) endorsed by the NRC for AST analyses was used in the calculations for the CRDA. The RADTRAD program is a radiological consequence analysis code used to estimate post-accident doses at plant offsite locations and in the control room. The

CRDA assessment takes no credit for control room isolation, emergency ventilation or filtration of intake air for the duration of the accident event.

Offsite X/Qs were calculated with the PAVAN computer code (Ref. 15.4-14), using the guidance of Regulatory Guide 1.145 (Ref. 15.4-15); control room X/Qs were calculated with the ARCON96 computer code (Ref. 15.4-16). The PAVAN and ARCON96 codes generally calculate relative concentrations in plumes from nuclear power plants at offsite locations and control room air intakes, respectively.

All of these computer codes have been used by the NRC staff in their safety reviews.

15.4.9.5.4 Source Terms

Core Inventory

The inventory of reactor core fission products used in RADTRAD for the AST CRDA analysis is based on maximum full power operation at a power level of 3527 MWth, which includes a 2% instrument error per Reg. Guide 1.49 (Ref. 15.4-17). The fission products used for the accidents are the 60 isotopes of the standard RADTRAD input library, determined by the code developer as significant in dose consequences. These were extracted from Attachment A of the LGS Design Analysis LM-0645 (Ref. 15.4-18), and correspond to 24 month cycle burnup parameters, conservatively calculated using the ORIGEN-ARP code.

Reactor Coolant Inventory

The reactor coolant fission product inventory for CRDA analysis is based on the Technical Specification concentration limits.

Release Fraction

Current design basis accident evaluations as modified by Regulatory Guide 1.183 (Ref. 15.4-10) were used to determine the specific releases of radioactive isotopes at the given stages of fuel pin failure and provide these releases as a percentage of the total release for each accident, as summarized below.

15.4.9.5.5 Methodology

Dose Calculations

As per Regulatory Guide 1.183 {Ref. 15.4-10), Total Effective Dose Equivalent (TEDE) doses are determined as the sum of the CEDE and the Effective Dose Equivalent (EDE) using dose conversion factors for inhalation CEDE from Federal Guidance Report No. 11 (Ref. 15.4-19) and for external exposure EDE from Federal Guidance Report No. 12 (Ref. 15.4-20).

Table 15.4-11 lists key assumptions and inputs used in the CRDA analysis. The design basis CRDA involves the rapid removal of a highest worth control rod resulting in a reactivity excursion that encompasses the consequences of any other postulated CRDA. The core performance analysis shows that the energy deposition that results from this event is inadequate to damage fuel pellets or cladding. However, for the dose consequence analysis, it was assumed that 1200 fuel pins in the full core were damaged, with melting occurring in 0.77 percent of the damaged

rods. This is applicable to the currently limiting assumption of a core loaded solely with 10x10 GNF2 or GNF3 fuel. A core average radial peaking factor of 2.0 was also assumed in the analysis, consistent with core operating limit report bases, as suggested in Regulatory Guide 1.183.

Releases to the environment are possible via two pathways. The first is through the Main Condenser. The main condenser is assumed to leak activity into the Turbine Building (TB) at a rate of 1% per day. This activity is then released, unfiltered, to the environment by way of the North Vent Stack, taking no credit for holdup in the TB. The north vent stack is the most conservative release point with respect to the Control Room intake, as the normal release pathway via the South Stack is further from the intake, with lower X/Q's.

The second pathway is through the Steam Jet Air Ejectors. When in operation, the Steam Jet Air Ejectors (SJAE) discharge to the augmented off-gas system. The augmented off-gas system charcoal delay beds in this scenario substantially delay noble gas release and essentially eliminate iodine release.

Both were evaluated in Ref. 15.4-12, and the first release scenario, through the main condenser, was found to clearly be the bounding DBA.

The analysis assumptions for the transport, reduction, and release of the radioactive material from the fuel and the reactor coolant are consistent with the guidance provided in Appendix C of Regulatory Guide 1.183, and are provided in the design analysis of Ref. 15.4-12.

15.4.9.5.6 Atmospheric Dispersion Factors (X/Qs)

Table 15.4-12 lists *X/Q* values used for the control room dose assessments, as derived in UFSAR Chapter 2 and applied for release points applicable to the CRDA.

Table 15.4-12 lists *X/Q* values for the EAB and LPZ boundaries, as also derived in UFSAR Chapter 2 and applied for release points applicable to the CRDA.

15.4.9.5.7 Summary and Conclusions

The radiological consequences of the postulated CRDA are given in Table 15.4-13. As indicated, the control room, EAB, and LPZ calculated doses are within regulatory limits after AST implementation.

Table 15.4-1

SEQUENCE OF EVENTS FOR CONTROL ROD
WITHDRAWAL ERROR IN POWER RANGE

- Operator selects (the RBM is automatically normalized) and withdraws high worth control rod.

- The RBM system indicates excessive local peaking. Operator ignores the alarm and continues to withdraw control rod.

- The RBM system initiates a rod block, inhibiting further withdrawal.

- Operator verifies fuel thermal limits are satisfied before renormalizing RBM to further withdraw control rod.

Table 15.4-3

SEQUENCE OF EVENTS FOR ABNORMAL STARTUP OF
IDLE RECIRCULATION PUMP

TIME (sec)	EVENT
0	Start pump motor.
9.0	Startup loop flow starts to increase significantly.
10.4	APRM neutron flux upscale scram initiated.
>50.0	Vessel level returning to normal and will stabilize quickly.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.4-4

SEQUENCE OF EVENTS FOR RECIRCULATION FLOW CONTROL FAILURE WITH INCREASING FLOW[1]

TIME (sec)	EVENT
0	Simulate failure of single-loop control.
1.7	APRM neutron flux upscale scram trip initiated.
5.5	Turbine control valves start to close upon falling turbine pressure.
20.2	Feedwater decreases upon rising water level.
>100.0	Reactor variables settle into new steady-state.

[1] See Figure 15.4-3.

NOTE: The results presented here are based on original plant conditions. Because this is not a limiting transient, this event was not reanalyzed for rerated conditions. However, the general trends and characteristics as shown here are not expected to change.

Table 15.4-5

SEQUENCE OF EVENTS FOR MISPLACED BUNDLE ACCIDENT

a. During core loading operation, bundle is placed in the wrong location.

b. Subsequently, the bundle intended for this location is placed in the location of the previous bundle.

c. During core verification procedure, error is not observed.

d. Plant is brought to full power operation without detecting misplaced bundle.

e. Plant continues to operate.

Table 15.4-6

INITIAL CONDITIONS AND RESULTS
OF FUEL BUNDLE LOADING ERROR[1]

Reactor Power, % rated	100
Core Flow, % rated	100
For Largest ΔCPR:	
Core Exposure, MWD/ST	7810
Location of Error	(29, 32)
Initial CPR without Fuel Loading Error	1.40
Minimum CPR with Fuel Loading Error	1.29
ΔCPR	0.11
For Largest ΔMLHGR:	
Core Exposure, MWD/ST	5000
Location of Error	(21, 54)
Initial LHGR (Assumed at Operating Limit), kW/ft	13.4
LHGR with Fuel Loading Error, kW/ft	16.97
Core Conditions	
Minimum CPR Operating Limit	1.22
Minimum CPR Safety Limit	1.06

(1) Core conditions are assumed to be normal for a hot, operating core.

NOTE: This is a non-limiting event that has not been reanalyzed for power rerate. The results of this event are based on Cycle 1 conditions. This event is analyzed for the initial core and for each reload to confirm the CPR is non-limiting. See current SRLR for cycle-specific values.

15.5 INCREASE IN REACTOR COOLANT INVENTORY

15.5.1 INADVERTENT HPCI STARTUP

15.5.1.1 Identification of Causes and Frequency Classification

15.5.1.1.1 Identification of Causes

Manual startup of the HPCI system is postulated for this analysis, i.e., operator error.

15.5.1.1.2 Frequency Classification

This transient is categorized as an incident of moderate frequency.

15.5.1.2 Sequence of Events and System Operation

15.5.1.2.1 Sequence of Events

Table 15.5-1 lists the sequence of events for Figure 15.5-1.

15.5.1.2.1.1 Identification of Operator Actions

Relatively small changes would be experienced in plant conditions as a result of inadvertent HPCI start-up. The operator should, after hearing the alarm that the HPCI has commenced operation, check reactor water level and drywell pressure. If conditions are normal, the operator should shut down the system.

15.5.1.2.2 System Operation

In order to properly simulate the expected sequence of events, the analysis of this transient assumes normal functioning of plant instrumentation and controls; specifically, the pressure regulator and the vessel level control which respond directly to this event.

The Inadvertent HPCI injection results in a mild depressurization followed by increasing reactor water level. It is probable that feedwater control systems will appropriately adjust downscale to account for the rising water level; however, for conservatism the water level is modeled to rise until the high level (L8) trip setpoint is reached, resulting in a turbine trip. At this point the event largely proceeds as the Turbine Bypass transient.

Required operation of engineered safeguards other than what is described is not expected for this transient event.

The system is assumed to be in the manual flow control mode of operation.

15.5.1.2.3 The Effect of Single Failures and Operator Errors

The effect of a single failure in the pressure regulator will aggravate the transient depending upon the nature of the failure. Pressure regulator failures are discussed in Sections 15.1.3 and 15.2.1.

The effect of a single failure in the level control system has rather straightforward consequences including level rise or fall by improper control of the feedwater system. Increasing level will trip the

turbine and automatically trip the HPCI system off. This trip signature is already described in the failure of feedwater controller with increasing flow. Decreasing level will automatically initiate scram at the Level 3 level trip and will have a signature similar to loss of feedwater control - decreasing flow.

15.5.1.3 Core and System Performance

15.5.1.3.1 Mathematical Model

The detailed nonlinear dynamic models described briefly in Section 15.1.2.3.1 are used to simulate this transient.

15.5.1.3.2 Input Parameter and Initial Conditions

The original analysis was performed with the conditions in Table 15.0-2. Subsequent analyses utilize reload specific parameters shown in the reload transient analyses documents (e.g., FRED Form, OPL-3, WILMA).

The water temperature of the HPCI system was assumed to be 40°F with an enthalpy of 11.0 Btu/lb.

Inadvertent startup of the HPCI system was chosen for analysis since it provides the greatest auxiliary source of cold water for the vessel.

15.5.1.3.3 Results

Figure 15.5-1 shows the simulated transient. It begins with the introduction of cold water into the vessel through the core spray nozzles and the feedwater injection spargers. Within one second the full HPCI flow is established (2,000 gpm through the core spray and 3,600 gpm through the feedwater). The HPCI flow split event is conservative because it maximizes the decrease in the core inlet. No delays were considered because they are not relevant to the analysis.

Addition of cooler water through the feedwater sparger increases core inlet subcooling, causing power to go up. The effect of the cool water through the core sprays, however, is some small condensation of steam in the upper plenum, resulting in a mild depressurization. The loss of steam flow through the condensation process is small when compared to the gain in steam flow that is due to subcooling change. The combined effect is a decrease in reactor pressure, along with some increase in reactor power. The water level begins to rise until the high vessel water level (Level 8) setpoint trip initiates main turbine and feedwater turbine trips. The event is bounded by FWCF or LRNBP/TTNBP, and MCPR remains well above the safety limit.

15.5.1.3.4 Consideration of Uncertainties

Important analytical factors, including reactivity coefficient and feedwater temperature change, have been assumed to be at the worst conditions so that any deviations in the actual plant parameters will produce a less severe transient.

15.5.1.4 Barrier Performance

Figure 15.5-1 indicates a slight pressure reduction from initial conditions, therefore, no further evaluation is required as RCPB pressure margins are maintained.

15.5.1.5 Radiological Consequences

Since no activity is released during this transient, a detailed evaluation is not required.

15.5.2 CHEMICAL VOLUME CONTROL SYSTEM MALFUNCTION (OR OPERATOR ERROR)

Not applicable to BWR. This is a PWR transient.

15.5.3 OTHER BWR TRANSIENTS WHICH INCREASE REACTOR COOLANT INVENTORY

These transients are discussed and considered in Sections 15.1 and 15.2.

Table 15.5-1

SEQUENCE OF EVENTS: INADVERTENT HPCI STARTUP[1]

TIME (sec)	EVENT
0	Simulate HPCI cold water injection.
2.0	Full Flow for HPCI reached, reactor water level increasing for remainder of event
5.0	Feedwater Control System begins reducing coolant flow
8.0	Dome Pressure equalizes at slightly lower value
8.0	Steam Flow to turbine equalized at slightly lower value
34.0	Reactor water level reaches high trip value, turbine trip initiated[2]
34.01	Main Turbine stop valves reach 90% open and initiate RPS scram and RPT
34.17	Turbine Stop valves fully close, causing pressurization and cessation of steam flow
35	Turbine Bypass valves open. MSRVs are available for additional pressure relief (cycling as needed)

(1) See Figure 15.5-1.

(2) Assumes single failure of level control or FW control

Note: All timing values are approximate and generally representative; see current SRLR for cycle-specific values.

15.6 DECREASE IN REACTOR COOLANT INVENTORY

15.6.1 INADVERTENT MAIN STEAM RELIEF VALVE OPENING

This transient is discussed and analyzed in Section 15.1.4.

15.6.2 INSTRUMENT LINE PIPE BREAK

This accident involves the postulation of a small steam or liquid line pipe break inside or outside primary containment but within a controlled release structure. In order to bound the accident, it is assumed that a small instrument line, instantaneously and circumferentially, breaks at a location where it may not be able to be isolated and where immediate detection is not automatic or apparent.

Obviously, this accident is far less limiting than the postulated events in Sections 15.6.4, 15.6.5, and 15.6.6.

This postulated accident represents the envelope evaluation for small line failure inside and outside primary containment, relative to sensitivity to detection. It is summarized in Tables 15.6-1 through 15.6-7 and Figure 15.6-1.

15.6.2.1 Identification of Causes and Frequency Classification

15.6.2.1.1 Identification of Causes and Event Description

There is no specific event or circumstance identified that results in the failure of an instrument line. These lines are designed to high quality engineering codes and standards, and seismic and environmental requirements. However, for the purpose of evaluating the consequences of a small line rupture, the failure of an instrument line is assumed to occur.

A circumferential rupture of an instrument line connected to the primary coolant system is postulated to occur outside primary containment but inside secondary containment. This failure results in the release of primary system coolant to the secondary containment until the reactor is depressurized. This accident could conceivably occur also in the drywell. However, the associated effects would not be as significant as those from a failure in the secondary containment.

15.6.2.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.6.2.2 Sequence of Events and System Operation

15.6.2.2.1 Sequence of Events

The sequence of events for this accident is shown in Table 15.6-1.

The operator should isolate the affected instrument line. Depending on which line is broken, the operator should determine whether to continue plant operation until a scheduled shutdown can be made or to proceed with an immediate, orderly plant shutdown and initiate the SGTS or other ventilation effluent treatment systems.

As a result of increased radiation, temperature, humidity, fluid, and noise levels within the secondary containment, operator action can be initiated by any one or any combination of the following:

a. Operator comparing the readings of several instruments monitoring the same process variable, such as reactor level, jet pump flow, steam flow, and steam pressure.

b. By alarm, either high or low in the control room, from the instrument served by the failed line.

c. By a half-channel scram if rupture occurred on an RPS instrument line.

d. By a general increase in the area radiation monitor readings.

e. By an increase in the ventilation process radiation monitor readings.

f. By leak detection system actuation.

Upon receiving one or more of the above signals and having made an unsuccessful attempt to isolate the break, the operator should proceed to shutdown the plant in an orderly manner.

15.6.2.2.2 System Operation

Normal plant instrumentation and controls are assumed to be fully operational during the entire plant transient to ensure positive identification of the break and safe shutdown of the plant. Minimum reactor and plant protection system operations are assumed for the analysis, e.g., minimum ECCS flow, and pool cooling capability. As a consequence of the accident, the reactor is scrammed and the reactor vessel cooled and depressurized over a 5 hour period.

15.6.2.2.3 The Effect of Single Failures and Operator Errors

The initiating event is handled by a protection sequence that can accommodate additional single failures. See Section 15.9 for a more detailed discussion of this subject.

15.6.2.3 Core and System Performance

15.6.2.3.1 Qualitative Summary

Instrument line breaks, because of their small size, are substantially less limiting from a core and systems performance standpoint than the accidents examined in Sections 15.6.4, 15.6.5, and 15.6.6. Consequently, instrument line breaks are considered to be bounded specifically by the steam line break (Section 15.6.4). Details of this calculation, including those pertinent to core and system performance, are discussed in detail in Section 15.6.4.3.

Since instrument line breaks result in a slower rate of coolant loss and are bounded by the calculations referenced above, the results presented here are qualitative rather than quantitative. Since the rate of coolant loss is slow, an orderly reactor system depressurization follows reactor scram, and the primary system is cooled down and maintained without ECCS actuation. No fuel damage or core uncovering occurs as a result of this accident.

15.6.2.3.2 Quantitative Results

Instrument line breaks, because of their small size, are substantially less limiting from a core and system performance standpoint than the steam line break outside primary containment. Similarly, instrument line breaks are considered within the spectrum considered in ECCS performance calculations discussed in detail in Section 6.3.3.

Therefore, all information concerning ECCS models employed, input parameters, and detailed results for a more limiting (steam line break) event may be found in Section 6.3.

15.6.2.3.3 Consideration of Uncertainties

The approach toward conservatively analyzing this accident is discussed in detail for a more limiting case in Section 6.3.

15.6.2.4 Barrier Performance

15.6.2.4.1 General

The release of primary coolant through the orificed instrument line could result in an increase in secondary containment pressure and the potential for isolation of the normal ventilation system.

The following assumptions and conditions are the basis for the mass loss during the 5 hour reactor shutdown period of this accident:

a. Shutdown and depressurization initiated 10 minutes after break occurs.

b. Normal depressurization and cooldown of RPV.

c. Line contains a ¼ inch diameter flow restricting orifice inside the drywell.

d. Moody critical blowdown flow model (Reference 15.6-1) is applicable, and flow is critical at the orifice.

The total integrated mass of fluid released into the secondary containment via the break during the blowdown is 25,000 pounds. Of this total, 6000 pounds flash to steam. Release of this mass of coolant results in a secondary containment pressure that is well below the design pressure.

Using the assumptions and methods discussed above, analysis shows that following the break of an instrument line installed with a ¼ inch orifice, the vessel inventory mass loss during the first two hours is 14,500 pounds; of this total, 4200 pounds flash to steam.

Small lines connected to the primary reactor coolant system and penetrating the containment that do not have a ¼ inch orifice upstream of the primary containment are listed below:

System	Containment Penetration No.
Recirculation Loop Sample	X-28A-1
CRD Insert	X-37A-D
CRD Withdraw	X-38A-D
SLCS	X-42
Main Steam Sample	X-43B

As identified in Table 6.2-17, these lines have redundant containment isolation barriers, except for the CRD withdraw lines. An estimate of the primary coolant released from the CRD withdraw lines in the event of a break is provided in NUREG-0803, "Generic Safety Evaluation Report Regarding Integrity of BWR Scram System Piping." Analyses to determine the amount of primary coolant released from the other lines have not been performed because the offsite radiological consequences of breaks in these lines would be bounded by those of a large steam line break outside primary containment (Section 15.6.4).

15.6.2.5 Radiological Consequences

Two separate radiological analyses are provided for this accident:

a. The first is based on conservative assumptions considered to be acceptable to the NRC for the purpose of determining adequacy of the plant design to meet 10CFR100. This analysis is referred to as the "design basis analysis."

b. The second is based on assumptions considered to provide a realistic conservative estimate of the radiological consequences. This analysis is referred to as the "realistic analysis."

A schematic of the release path is shown in Figure 15.6-1.

15.6.2.5.1 Design Basis Analysis

The design basis analysis is based on SRP 15.6.2 and Regulatory Guide 1.5. The specific models, assumptions, and the program used for computer evaluation are described in Section 15.10. Specific values of parameters used in the evaluation are presented in Table 15.6-2.

The assumptions and calculation methodology used are as follows:

a. Spiking factor

The activity released from the fuel to the coolant as a consequence of reactor scram and vessel depression was based on measurements during plant shutdowns (Reference 15.6-2). It was shown that for a 95 percentile probability, a total of 7 Ci of I-131 is released to the coolant for every 1 μCi/sec of prespike I-131 release. This conservative ratio was applied for all the iodine isotopes for the dose analysis. The

prespike iodine releases were those that correspond to a 0.35 Ci/sec noble gases release, a DBA assumption.

b. Iodine concentration in coolant

The total iodine released from the fuel to the coolant was assumed to take place in a span of 5 hours, resulting in continued buildup of coolant activity during that period. The coolant activity during 0-2 hours was assumed to be constant and equal to that at the end of the first hour. The coolant activity during 2-5 hours was assumed to be equal to that at the end of 3½ hours. This is a conservative assumption, since the rate of increase in coolant activity decreases with time.

c. Partition factor

It was assumed that 100% of the activity in the coolant that flashed into steam remains airborne and that 10% of the activity carried by the coolant water into the secondary containment becomes airborne (corresponding to a conservative partition factor of 0.1).

d. Activity in secondary containment and released to the environment

The secondary containment volume was assumed to consist of one reactor enclosure, as discussed in Section 15.6.5.5.1.2. The activity airborne in the secondary containment was assumed to be uniformly mixed by the RERS with an air flow rate of 60,000 cfm and a 95% efficient filter. Secondary containment air is released to the environment via the SGTS at the rate of two secondary containment volumes change per day. The SGTS filter has an efficiency of 99%. The SGTS draws air from the RERS exhaust. The activity airborne in the secondary containment and the activity released to the environment are presented in Tables 15.6-3 and 15.6-4, respectively.

The calculated exposure at the EAB and LPZ are presented in Table 15.6-7.

15.6.2.5.2 Realistic Analysis

The realistic analysis was based on a realistic but still conservative assessment of this accident. The specific models, assumptions, and the program used for computer evaluation are described in Reference 15.6-3. Specific values of parameters used in the evaluation are presented in Table 15.6.2. The leakage path used in these calculations is shown in Figure 15.6-1.

Assumptions and calculations for the realistic analysis were identical to that of the design basis except for the following:

a. Total iodine released from the fuel to the coolant was assumed to be 2 Ci for every 1 μCi/sec prespike release. This is an estimated ratio for a 50 percentile probability spiking release during plant shutdowns (Reference 15.6-2).

b. The 50% X/Qs were used instead of the 5% X/Qs used for the design basis analysis.

The activity airborne in the secondary containment is presented in Table 15.6-5. The activity released to the environment is presented in Table 15.6-6. The calculated exposure at the EAB and the LPZ are presented in Table 15.6-7.

15.6.3 STEAM GENERATOR TUBE FAILURE

This section is not applicable to the direct cycle BWR; this is a PWR-related event.

15.6.4 STEAM SYSTEM PIPING BREAK OUTSIDE PRIMARY CONTAINMENT

This accident involves the postulation of a large steam line pipe break outside primary containment. It is assumed that the largest steam line instantaneously and circumferentially breaks at a location downstream of the outermost isolation valve. The plant is designed to immediately detect such an occurrence, initiate isolation of the broken line, and actuate the necessary protective features. This postulated accident represents the envelope evaluation of steam line failures outside primary containment.

This accident is summarized in Tables 15.6-8 through 15.6-11 and the leakage path used in these calculations is shown in Figure 15.6-2.

15.6.4.1 Identification of Causes and Frequency Classification

15.6.4.1.1 Identification of Causes

A main steam line break is postulated without the cause being identified. These lines are designed to high quality engineering codes and standards, and seismic and environmental requirements. However, for the purpose of evaluating the consequences of a postulated large steam line rupture, the failure of a main steam line is assumed to occur.

15.6.4.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.6.4.2 Sequence of Events and System Operation

15.6.4.2.1 Sequence of Events

Accidents that result in the release of radioactive materials directly outside primary containment are primary results of postulated breaches in the RCPB or the steam power conversion system boundary. A break spectrum analysis for the complete range of reactor conditions indicates that the limiting fault accident for breaks outside primary containment is a complete severance of one of the four main steam lines. The sequence of events and approximate time required to respond to the accident is given in Table 15.6-8.

Normally, the reactor operator will maintain reactor vessel water inventory and, therefore, core cooling with the RCIC system. Without operator action, the RCIC would initiate automatically on low water level following isolation of the main steam supply system (i.e., MSIV closure). The core would be covered throughout the accident and there would be no fuel damage. Without taking credit for the RCIC water makeup capability and assuming HPCI failure, the termination of the accident without fuel damage is assured because the ADS will actuate at low water level (Level 1). This will permit the low pressure ECCS to re-establish water level above the core.

15.6.4.2.2 System Operation

A postulated guillotine break of one of the four main steam lines outside primary containment results in mass loss from both ends of the break. The flow from the upstream side is initially limited by the flow restrictor upstream of the inboard isolation valve. Flow from the downstream side is initially limited by the total area of the flow restrictors in the three unbroken lines. Subsequent closure of the MSIVs further limits the flow when the valve area becomes less than the limiter area and finally terminates the mass loss when the full closure is reached.

A discussion of plant and reactor protection system action and ESF action is given in Sections 6.3, 7.3, and 7.6.

15.6.4.2.3 The Effect of Single Failures and Operator Errors

The effect of single failures has been considered in analyzing this accident. The ECCS aspects are covered in Section 6.3. The break detection and isolation considerations are defined in Sections 7.3 and 7.6. All of the protective sequences for this accident are capable of single failure accommodation and yet completion of the necessary safety action (Section 15.9).

15.6.4.3 Core and System Performance

Quantitative results (including mathematical models, input parameters, and consideration of uncertainties) for this accident are given in Section 6.3. The temperature and pressure transients resulting as a consequence of this accident are insufficient to cause fuel damage.

15.6.4.3.1 Input Parameters and Initial Conditions

Refer to Section 6.3 for initial conditions.

15.6.4.3.2 Results

There is no fuel damage as a consequence of this accident. Refer to Section 6.3 for ECCS analysis.

15.6.4.3.3 Consideration of Uncertainties

Sections 6.3 and 7.3 contain discussions of the uncertainties associated with the ECCS performance and the containment isolation systems, respectively.

15.6.4.4 Barrier Performance

Since this break occurs outside primary containment, barrier performance within the primary containment envelope is not applicable. Details of the results of this accident can be found in Section 6.2.3.

The following assumptions and conditions are used in determining the mass loss from the primary system from the inception of the break to full closure of the MSIVs:

a. The reactor is operating at the power level associated with maximum mass release (4% Reactor Power, 35% Core Flow).

b. Nuclear system pressure is initially 1060 psia.

c. An instantaneous circumferential break of the main steam line occurs.

d. Isolation valves start to close at 1.0 second on high flow signal and are fully closed at 6.0 seconds.

e. The Moody critical flow model (Reference 15.6-1) is applicable.

f. The SAFER Code (Ref. 15.6-10) is used to calculate the time varying two-phase flow and system pressure during the accident.

Initially, only steam will issue from the broken end of the steam line. The flow in each line is limited by critical flow at the limiter to a maximum of 200% of rated flow for each line. Rapid depressurization of the RPV causes the water level to rise, resulting in a steam/water mixture flowing from the break until the valves are closed. The total integrated mass leaving the RPV through the steam line break is 115,700 lbm of which 101,562 lbm is liquid and 14,138 lbm is steam (Ref. 15.6-26). For the radiological consequence evaluation, a total mass of 140,000 lbm is assumed.

15.6.4.5 Radiological Consequences for the MSLB

Regulation 10CFR50.67, "Accident Source Term," provides a mechanism for power reactor licensees to voluntarily replace the traditional TID-14844 (Ref. 15.6-11) accident source term used in design-basis accident analyses with an "Alternative Source Term" (AST). The methodology of approach to this replacement is given in USNRC Regulatory Guide 1.183 (Ref. 15.6-12) and its associated Standard Review Plan 15.0.1 (Ref. 15.6-13).

Accordingly, Limerick Generating Station, Units 1 and 2, have applied the AST methodology for several areas of operational relief in the event of a Design Basis Accident (DBA), without fully crediting the use of previously assumed safety systems. Amongst these systems are the Control Room Emergency Fresh Air Supply System (CREFAS) and the Standby Gas Treatment System (SGTS).

In support of a full-scope implementation of AST as described in and in accordance with the guidance of Ref. 15.6-12, AST radiological consequence analyses are performed for the four DBAs that result in offsite exposure (i.e., Loss of Coolant Accident (LOCA), Main Steam Line Break (MSLB), Fuel Handling Accident (FHA), and Control Rod Drop Accident (CRDA).

Implementation consisted of the following steps:

- Identification of the AST based on plant-specific analysis of core fission product inventory,
- Calculation of the release fractions for the four DBAs that could potentially result in control room and offsite doses (i.e., LOCA, MSLB, FHA, and CRDA),
- Analysis of the atmospheric dispersion for the radiological propagation pathways,
- Calculation of fission product deposition rates and removal mechanisms,

- Calculation of offsite and control room personnel Total Effective Dose Equivalent (TEDE) doses.

15.6.4.5.1 Regulatory Approach

The analyses are prepared in accordance with the guidance provided by Regulatory Guide 1.183 (Ref. 15.6-12).

15.6.4.5.2 Dose Acceptance Criteria

The AST acceptance criteria for Control Room dose for postulated major credible accident scenarios such as those resulting in substantial meltdown of the core with release of appreciable quantities of fission products is provided by 10CFR50.67, which requires:

> "Adequate radiation protection is provided to permit access to and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 0.05 Sv (5 rem) total effective dose equivalent (TEDE) for the duration of the accident."

This limit is applied by Regulatory Guide 1.183 to all of the accidents considered with AST.

The AST acceptance criteria for an individual located at any point on the boundary of the exclusion area (the Exclusion Area Boundary or EAB) are provided by 10 CFR 50.67 as 25 rem TEDE for any 2-hour period following the onset of the postulated fission product release.

The AST acceptance criteria for an individual located at any point on the outer boundary of the low population zone (LPZ) are provided by 10CFR50.67 as 25 rem TEDE during the entire period of passage of the radioactive cloud resulting from the postulated fission product release.

These limits are applied by Regulatory Guide 1.183 to events with a higher probability of occurrence (including CRDA, MSLB, and FHA considered herein) to provide the following acceptance criteria:

- For the BWR MSLB for the case of an accident assuming fuel damage or a pre-incident Iodine spike, doses at the EAB and LPZ should not exceed *25* rem TEDE for the accident duration (2 hour dose for EAB and 30 day dose for LPZ). For MSLB accidents assuming normal equilibrium Iodine activity, doses should not exceed 2.5 rem TEDE for the accident duration.
- For the BWR CRDA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2 hour dose for EAB and 24 hour dose for LPZ).
- For the FHA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2 hour dose for EAB and 30 day dose for LPZ).

15.6.4.5.3 Computer Codes

New AST calculations for the MSLB were prepared to simulate the radionuclide release, transport, removal, and dose estimates associated with the postulated accidents.

While the RADTRAD computer code (Ref. 15.6-15) endorsed by the NRC for AST analyses was used in the calculations for the LOCA, CRDA and FHA, the MSLB was analyzed using the

Regulatory Guide 1.183 methodology. The MSLB assessment takes no credit for control room isolation, emergency ventilation or filtration of intake air for the duration of the accident event.

15.6.4.5.4 Source Terms

Reactor Coolant Inventory

The reactor coolant fission product inventory for MSLB analysis is based on the Technical Specification limits in terms of Dose Equivalent I-131 (the concentration of I-131 that alone would produce the same dose as the quantity and isotopic mixture of I-131, I-132, I-133, I-134, and I-135 actually present), using inhalation Committed Effective Dose Equivalent (CEDE) dose conversion factors from Federal Guidance Report No. 11 (Ref. 15.6-20). Cesium, as Cesium Iodide, and Noble Gas releases are also considered, but the iodine isotopes are the only significant dose contributors.

15.6.4.5.5 Methodology

Dose Calculations

As per Regulatory Guide 1.183 (Ref. 15.6-12), Total Effective Dose Equivalent (TEDE) doses are determined as the sum of the CEDE and the Effective Dose Equivalent (EDE) using dose conversion factors for inhalation CEDE from Federal Guidance Report No. 11 (Ref. 15.6-20) and for external exposure EDE from Federal Guidance Report No. 12 (Ref. 15.6-21).

Main Steam Line Break (MSLB)

Table 15.6-9 lists the key assumptions and inputs used in the analysis. The postulated MSLB accident assumes a double-ended break of one main steam line outside the primary containment with displacement of the pipe ends that permits maximum blowdown rates. However, the break mass released is taken for the dose calculations as a bounding maximized value for all current Boiling Water reactor plants of 140,000 pounds of water, as provided in Standard Review Plan 15.6.4 for a GESSAR-251 plant. This value bounds for dose calculation purposes the historic UFSAR values, ensuring that the dose consequences are maximized and that the releases bound any other credible pipe break. Two activity release cases corresponding to the pre-accident spike and maximum equilibrium concentration allowed by Technical Specifications of 4.0 μCi/gm and 0.2 μCi/gm dose equivalent I-131 respectively were assumed, with inhalation CEDE dose conversion factors from Federal Guidance Report 11 conservatively used for normalized Dose Equivalent I-131 determination. The released activity assumptions are consistent with the guidance provided in Appendix D of Regulatory Guide 1.183.

The analysis assumes an instantaneous ground level release. For the control room dose calculations, the released reactor coolant and steam is assumed to expand to a hemispheric volume at atmospheric pressure and temperature (consistent with an assumption of no Turbine Building credit). This hemisphere is then assumed to move at a speed of 1 meter per second downwind past the control room intake. No credit is taken for buoyant rise of the steam cloud or for decay, and dispersion of the activity of the plume was conservatively ignored. For offsite locations, the buoyant rise of the steam cloud is similarly ignored, and the ground level dispersion is based on the conservative and simplified Regulatory Guide 1.5 (Ref. 5.6-22) methodology.

The radiological consequences following an MSLB accident were determined using a spreadsheet. The following significant assumptions were made and are detailed in the applicable MSLB design analysis (Ref. 15.6-14):

- Iodine activity distribution in the coolant as follows:

Iodine Isotope	Activity (μCi/cc)
I-131	0.039
I-132	0.360
I-133	0.267
I-134	0.720
I-135	0.390

- Release from the break to the environment is assumed instantaneous. No holdup in the Turbine Building or dilution by mixing with Turbine Building air volume is credited.

- The steam cloud is assumed to consist of the portion of the liquid reactor coolant release that flashed to steam.

- The activity of the cloud is based on the total mass of water released from the break. This assumption is conservative because it considers the maximum release of fission products.

- Flashing fraction of liquid water released was assumed as 40%. However, all activity in the water is assumed to be released.

15.6.4.5.6 Atmospheric Dispersion Factors (X/Qs)

For the control room dose calculations, the released reactor coolant and resultant flashed steam is assumed to expand to a hemispheric volume at atmospheric pressure and temperature (consistent with an assumption of no Turbine Building credit). This hemisphere is then assumed to move at a speed of 1 meter per second downwind past the control room intake. No credit is taken for buoyant rise of the steam cloud or for decay, and dispersion of the activity of the plume was conservatively ignored.

For offsite locations, the buoyant rise of the steam cloud is similarly ignored, and the ground level dispersion is based on the conservative and simplified Regulatory Guide 1.5 (Ref. 15.6-22) methodology. Table 15.6-10 lists X/Q values for the EAB and LPZ boundaries.

15.6.4.5.7 Summary and Conclusions

The radiological consequences of the postulated MSLB are given in Table 15.6-11. As indicated, the control room, EAB, and LPZ calculated doses are within regulatory limits after AST implementation.

15.6.5 LOSS-OF-COOLANT ACCIDENTS (RESULTING FROM SPECTRUM OF POSTULATED PIPING BREAKS WITHIN THE REACTOR COOLANT PRESSURE BOUNDARY) INSIDE PRIMARY CONTAINMENT

This accident involves the postulation of a spectrum of piping breaks inside containment varying in size, type, and location. The break type includes steam and/or liquid process system lines.

The accident is analyzed quantitatively in Sections 6.3, 6.2, 7.3, 7.6, and 8.3. Therefore, the following discussion provides only new information not presented in the subject sections. All other information is covered by cross-referencing.

The postulated accident represents the envelope evaluation for liquid or steam line failures inside primary containment. It is summarized in Tables 15.6-13 through 15.6-20 and the leakage path used in these calculations is shown in Figure 15.6-3.

15.6.5.1 Identification of Causes and Frequency Classification

15.6.5.1.1 Identification of Causes

There are no realistic, identifiable events that would result in a pipe break inside primary containment of the magnitude required to constitute a LOCA coincident with a single active failure. The subject piping is designed to high quality engineering codes and standards, and seismic and environmental requirements. However, for estimating the resultant effects of this category of pipe breaks, a LOCA plus single active failure are assumed to occur without the causes being identified.

15.6.5.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.6.5.2 Sequence of Events and System Operation

15.6.5.2.1 Sequence of Events

The sequence of events associated with this accident is shown in Table 6.3-2 for core system performance and Table 6.2-8 for barrier (containment) performance.

Following the pipe break and scram, the low-low water level (Level 2) trip or the high drywell pressure trip will start the HPCI system. The MSIVs will begin to close on the low-low-low water level (Level 1) trip. Either the Level 1 trip or the high drywell pressure coincident with low reactor pressure trip will start the CS and LPCI systems. From time zero, the CS system will start at less than or equal to 54 seconds, the HPCI system will start at approximately 60 seconds and the LPCI system will start at less than or equal to 70 seconds..

Since automatic actuation and operation of the ECCS is a system design basis, no credit for immediate operator actions are assumed in the evaluation of the accident. However, in accordance with procedural requirements, the operator should perform the following described actions.

The operator should, after ensuring that all rods have been inserted at time 0 plus approximately 10 seconds, determine plant condition by observing the annunciators. After observing that the ECCS flows are initiated, the operator should check that the diesel generators have started and are on standby condition, and that the ESW system has started. Based on plant conditions, the operator should initiate operation of the RHRSW system and the RHR system heat exchangers in the suppression pool cooling mode. After the RHR system and other auxiliary systems are in proper operation, the operator should monitor the hydrogen concentration in the drywell for proper activation of the post-LOCA recombiners, if necessary.

15.6.5.2.2 System Operation

Accidents that could result in the release of radioactive fission products directly into the containment are the result of postulated nuclear system RCPB pipe breaks. A spectrum of pipe break sizes and locations are examined in Sections 6.2 and 6.3, including the severance of small process system lines, the main steam lines upstream of the flow restrictors, and the recirculation loop pipelines. The most severe nuclear system effects and the greatest release of radioactive material to the containment result from a complete circumferential break of one of the two recirculation loops. The minimum required functions of any reactor and plant protection system are discussed in Sections 6.2, 6.3, 7.3, 7.6, 8.3, and 15.9.

15.6.5.2.3 The Effect of Single Failures and Operator Errors

Single failures and operator errors have been considered in the analysis of the entire spectrum of primary system breaks. The consequences of a LOCA with considerations for single failures are shown to be fully accommodated without the loss of any required safety function (Section 15.9).

15.6.5.3 Core and System Performance

15.6.5.3.1 Mathematical Model

The analytical methods and associated assumptions used in evaluating the consequences of this accident are considered to provide a conservative assessment of the expected consequences of this very improbable event.

The details of these calculations, their justification, and bases for the models are developed in Sections 6.3, 7.3, 7.6, 8.3, and 15.9.

15.6.5.3.2 Input Parameters and Initial Conditions

Input parameters and initial conditions used for the analysis of this event are given in Table 6.3-1.

15.6.5.3.3 Results

Results of this accident are given in detail in Section 6.3. Even though some swelling may have occurred, the temperature and pressure transients resulting as a consequence of this accident are insufficient to cause perforation of the fuel cladding. Postaccident tracking instrumentation and control are assured. Continued long-term core cooling is demonstrated. Radiological input is minimized and within limits. Continued operator control and surveillance are examined and guaranteed.

15.6.5.3.4 Consideration of Uncertainties

This event was conservatively analyzed (Sections 6.3, 7.3, 7.6, 8.3, and 15.9).

15.6.5.4 Barrier Performance

The primary containment is designed to maintain pressure integrity in the event of an instantaneous rupture of the largest single primary system piping within the structure while also accommodating the dynamic effects of the pipe break. Therefore, any postulated LOCA would not

exceed the containment design limit. For details and results of the analyses, see Sections 3.8, 3.9, and 6.2.

15.6.5.5 Radiological Consequences for the LOCA

Regulation 10CFR50.67, "Accident Source Term," provides a mechanism for power reactor licensees to voluntarily replace the traditional TID-14844 (Ref. 15.6-11) accident source term used in design-basis accident analyses with an "Alternative Source Term" (AST). The methodology of approach to this replacement is given in USNRC Regulatory Guide 1.183 (Ref. 15.6-12) and its associated Standard Review Plan 15.0.1 (Ref. 15.6-13).

The AST methodology has been applied to justify that a Design Basis Accident (DBA) can be accommodated without fully crediting the use of previously assumed safety systems. Amongst these systems are the Control Room Emergency Fresh Air Supply System (CREFAS) and the Standby Gas Treatment System (SGTS).

In support of a full-scope implementation of AST as described in and in accordance with the guidance of Ref. 15.6-12, AST radiological consequence analyses are performed for the four DBAs that result in offsite exposure (i.e., Loss of Coolant Accident (LOCA), Main Steam Line Break (MSLB), Fuel Handling Accident (FHA), and Control Rod Drop Accident (CRDA)).

Implementation consisted of the following steps:

- Identification of the AST based on plant-specific analysis of core fission product inventory,
- Calculation of the release fractions for the four DBAs that could potentially result in control room and offsite doses (i.e., LOCA, MSLB, FHA, and CRDA),
- Analysis of the atmospheric dispersion for the radiological propagation pathways,
- Calculation of fission product deposition rates and removal mechanisms,
- Calculation of offsite and control room personnel Total Effective Dose Equivalent (TEDE) doses,
- Evaluation of suppression pool pH to ensure that the particulate iodine deposited into the pool during a DBA LOCA does not re-evolve and become airborne as elemental iodine.

15.6.5.5.1 Regulatory Approach

The analyses are prepared in accordance with the guidance provided by Regulatory Guide 1.183 (Ref. 15.6-12).

15.6.5.5.2 Dose Acceptance Criteria

The AST acceptance criteria for Control Room dose for postulated major credible accident scenarios such as those resulting in substantial meltdown of the core with release of appreciable quantities of fission products is provided by 10 CFR 50.67, which requires:

> "Adequate radiation protection is provided to permit access to and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 0.05 Sv (5 rem) total effective dose equivalent (TEDE) for the duration of the accident."

This limit is applied by Regulatory Guide 1.183 to all of the accidents considered with AST.

The AST acceptance criteria for an individual located at any point on the boundary of the exclusion area (the Exclusion Area Boundary or EAB) are provided by 10 CFR 50.67 as 25 rem TEDE for any 2-hour period following the onset of the postulated fission product release.

The AST acceptance criteria for an individual located at any point on the outer boundary of the low population zone (LPZ) are provided by 10 CFR 50.67 as 25 rem TEDE during the entire period of passage of the radioactive cloud resulting from the postulated fission product release.

These limits are applied by Regulatory Guide 1.183 to events with a higher probability of occurrence (including CRDA, MSLB, and FHA considered herein) to provide the following acceptance criteria:

- For the BWR MSLB for the case of an accident assuming fuel damage or a pre-incident Iodine spike, doses at the EAB and LPZ should not exceed 25 rem TEDE for the accident duration (2 hour dose for EAB and 30 day dose for LPZ). For MSLB accidents assuming normal equilibrium Iodine activity, doses should not exceed 2.5 rem TEDE for the accident duration.
- For the BWR CRDA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2 hour dose for EAB and 24 hour dose for LPZ).
- For the FHA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2 hour dose for EAB and 30 day dose for LPZ).

15.6.5.5.3 Computer Codes

New AST calculations for the LOCA were prepared to simulate the radionuclide release, transport, removal, and dose estimates associated with the postulated accident scenario.

The RADTRAD computer code (Ref. 15.6-15) endorsed by the NRC for AST analyses was used in the calculations for the LOCA. The RADTRAD program is a radiological consequence analysis code used to estimate post-accident doses at plant offsite locations and in the control room.

Offsite X/Qs were calculated using the guidance of Regulatory Guide 1.145 (Ref. 15.6-17); control room X/Qs were calculated with the ARCON96 computer code (Ref. 15.6-18).

All of these computer codes and methodologies have been used by the NRC staff in their safety reviews.

15.6.5.5.4 Source Terms

Core Inventory

The inventory of reactor core fission products used in RADTRAD for the AST LOCA analysis is based on maximum full power operation at a power level of 3527 MWth, which includes a 2%

instrument error per Reg. Guide 1.49 (Ref: 15.6-19) (See Section 15.0.4, Regulatory Guide 1.49). The fission products used for the accidents are the 60 isotopes of the standard RADTRAD input library, determined by the code developer as significant in dose consequences. These were extracted from Attachment A of the LGS Design Analysis LM-0645 (Ref: 15.6-24), and correspond to 24 month cycle burnup parameters, conservatively calculated using the ORIGEN-ARP code.

Release Fraction

Current design basis accident evaluations as modified by Regulatory Guide 1.183 (Ref: 15.6-12) were used to determine the specific releases of radioactive isotopes at the given stages of fuel pin failure and provide these releases as a percentage of the total release for the accident, as summarized below.

15.6.5.5.5 Methodology

Dose Calculations

As per Regulatory Guide 1.183 (Ref. 15.6-12), Total Effective Dose Equivalent (TEDE) doses are determined as the sum of the CEDE and the Effective Dose Equivalent (EDE) using dose conversion factors for inhalation CEDE from Federal Guidance Report No. 11 (Ref: 15.6-20) and for external exposure EDE from Federal Guidance Report No. 12 (Ref. 15.6-21). Breathing rates and occupancy factors are given in Table 15.6-13.

Loss of Coolant Accident (LOCA)

The LOCA radiological assessment was performed in accordance with the guidance of Regulatory Guide 1.183. The key inputs used in this analysis are included in Tables 15.6-14 through Table 15.6-17. These inputs and assumptions are grouped into three main categories (i.e., release, transport, and removal). The initial source term parameters are given in Table 15.6-14.

LOCA Release Inputs

Key parameters used in the release pathway modeling for the LOCA analysis are given in Table 15.6-15. The primary containment is assumed to leak at 0.5 v%/day for the first 24 hours, then at a reduced rate of 0.25 v%/day for the remaining 30-day duration of the accident. Separately, the MSIVs are assumed to leak at a combined total of 200 scfh for the first 24 hours, then at a reduced rate of 110.20 scfh for the remaining accident duration, due to reductions in containment pressure. No primary containment leakage, with the exception of MSIV leakage, has been identified to bypass the secondary containment to be released unfiltered to the atmosphere.

The analysis assumes that the leak rate through the MSIVs to the environment is 200 scfh at a test pressure of 22 psig for the first 24 hours of the accident. This rate is then assumed to be reduced to 110.20 scfh after 24 hours and for the duration of the accident, due to containment pressure reductions. The maximum allowable per line is 100 scfh(*).

(*) For Unit 1 Cycle 19 only. The 1B outboard main steam isolation valve (28B) exceeded the 100 scfh leakage by 4.88 scfh. TS Amendment 245 approved a one-time allowable leakage limit of 105 scfh for a single MSIV (UFSAR Reference 15.6-27).

The analysis assumes an emergency core cooling system (ECCS) liquid leakage rate outside of containment of 5 gpm (Table 15.6-15). Ten percent of the activity in the leakage is assumed to become airborne. This is consistent with Regulatory Guide 1.183. Although the ECCS leakage rate may realistically be assumed to begin approximately 15 minutes following the accident, with the actuation of the drywell sprays, the present analysis conservatively assumes leakage to begin at the onset of the accident and to continue throughout the 30-day duration of the postulated accident.

The Regulatory Guide 1.183 accident isotopic release specification allows deposition of iodine in the suppression pool. Essentially all of the iodine is assumed to remain in solution as long as the pool pH is maintained at or above a level of 7. Station procedures will direct operators, upon detection of symptoms indicating that core damage is occurring to manually initiate the SLC System. The calculation results demonstrate the buffering effect of the boron solution maintains the suppression pool pH above 7 for the 30-day duration of the postulated LOCA.

LOCA Transport Inputs

Prior to the LOCA, the reactor enclosure is mechanically maintained at a negative pressure. At the beginning of the LOCA event, the reactor enclosure exhaust fans are tripped and the reactor enclosure (i.e., secondary containment) is then exhausted by the SGTS continuing the building's negative pressure thus precluding unfiltered exfiltration.

In the analysis, the control room is assumed to be automatically isolated upon a high radiation signal, and therefore in Radiation Mode prior to activity infiltration. Flow rates are given in Table 15.6-16.

LOCA Removal Inputs

Key parameters identifying radionuclide removal processes are given in Table 15.6-17. The activity of elemental iodine and aerosols released from the core into the drywell is reduced by deposition (i.e., plate-out) and settling in the drywell utilizing the natural deposition values identified in the RADTRAD code. No credit is assumed for natural deposition of elemental or organic iodine, or for suppression pool scrubbing.

Containment leakage into the reactor building is collected by the SGTS, which exhausts the reactor building, via filters, and reduces releases. The deposition removal mechanisms are characteristics of the AST methodology and represent a change in the plant design and licensing basis.

Main steam line pipe and main steam condenser particulate and chemical iodine deposition was modeled using the RADTRAD code with removal coefficients based on gravitational settling and chemical plateout. Two-node treatment is used for each steam line in which flow occurs. The first node is from the reactor vessel to the inboard MSIV. The second node is from the inboard MSIV to the outboard MSIV. No credit is taken for holdup or plate-out in the main steam lines beyond the outboard MSIV. However, additional credit is taken for plate-out in the main condenser. Main steam line deposition was based on using the shortest line (i.e., most rapid transport) for the worst case line (i.e., the one with the assumed failed inboard isolation valve).

Removal efficiencies for the standby gas treatment system (SGTS), reactor enclosure recirculation system, and the control room emergency filtration system (CREFAS) filters are given in Table 15.6-17.

The analysis assumptions for the transport, reduction, and release of the radioactive material from the fuel and the reactor coolant are consistent with the guidance provided in Appendix C of Regulatory Guide 1.183, and are provided in the design analysis of Ref. 15.6-23.

15.6.5.5.6 Atmospheric Dispersion Factors (X/Qs)

The station release points and control room intake are shown in Figure 15.6-3. Table 15.6-19 lists X/Q values used for the control room dose assessments. For release points applicable to the LOCA, the zero velocity vent release X/Q values were calculated with the ARCON96 computer code, as derived in UFSAR Chapter 2.

Table 15.6-20 lists X/Q values for the EAB and LPZ boundaries. These X/Q values are calculated using Regulatory Guide 1.145 methodology, as derived in UFSAR Chapter 2.

15.6.5.5.7 Summary and Conclusions

The radiological consequences of the postulated LOCA are given in Table 15.6-18. As indicated, the control room, EAB, and LPZ calculated doses are within regulatory limits after AST implementation.

15.6.6 FEEDWATER LINE BREAK OUTSIDE PRIMARY CONTAINMENT

The postulated break of the feedwater line, representing the largest liquid line outside primary containment, provides the envelope evaluation relative to this type of occurrence. The break is assumed to be instantaneous, circumferential, and upstream of the outermost isolation valve.

A more limiting accident from a core performance evaluation standpoint (feedwater line break inside primary containment) has been quantitatively analyzed in Section 6.3. Therefore, the following discussion provides only new information not presented in Section 6.3. All other information is covered by cross- referencing.

15.6.6.1 Identification of Causes and Frequency Classification

15.6.6.1.1 Identification of Causes

A feedwater line break is assumed without the cause being identified. The subject piping is designed to high quality engineering codes and standards, and seismic and environmental requirements.

15.6.6.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.6.6.2 Sequence of Events and System Operation

15.6.6.2.1 Sequence of Events

The sequence of events is shown in Table 15.6-23.

Since automatic actuation and operation of the ECCS is a system design basis, no credit for immediate operator actions are assumed in the evaluation for this accident. However, in accordance with procedural requirements the operator should perform the following actions, which are shown below for informational purposes:

a. The operator should determine that a line break has occurred and evacuate the area of the turbine enclosure.

b. The operator is not required to take any action to prevent primary reactor system mass loss, but should ensure that the reactor is shut down and that RCIC and/or HPCI are operating normally.

c. The operator should implement appropriate radiation incident procedures.

d. If possible, the operator should shut down the feedwater system and de-energize any electrical equipment that may be damaged by water from the feedwater system in the turbine enclosure.

e. The operator should continue to monitor reactor water level and the performance of the ECCS while the radiation incident procedure is being implemented and should begin normal reactor cooldown measures.

f. When the reactor pressure has decreased below 75 psig, operator should initiate RHR in the shutdown cooling mode to continue cooling down the reactor.

The operator procedures above occur over an elapsed time of 3-4 hours.

15.6.6.2.2 System Operation

It is assumed that the normally operating plant instrumentation and controls are functioning. Credit is taken for the actuation of the reactor isolation system and ECCS. The RPS (MSRVs, ECCS, and CRD) and plant protection system (RHR heat exchangers) are assumed to function properly to assure a safe shutdown.

The ESF and RCIC/HPCI systems are assumed to operate normally.

15.6.6.2.3 The Effect of Single Failures and Operator Errors

The feedwater line break outside of primary containment is a high energy line break as described in paragraph 3.6.1.2.1.3. For purposes of plant transient analysis, it is considered as a special case of the general LOCA break spectrum considered in detail in Section 6.3. The general single failure analysis for LOCAs is discussed in detail in Section 6.3.3.3. For the feedwater line break outside primary containment, since the break can be isolated, either the RCIC or HPCI can provide adequate flow to the vessel to maintain core cooling and prevent fuel clad failure. A single failure of either the HPCI or the RCIC would still provide sufficient flow to keep the core covered with water. See Sections 6.3 and 15.9 for detailed description of the analysis.

15.6.6.3 Core and System Performance

15.6.6.3.1 Qualitative Summary

The accident evaluation qualitatively considered in this section is considered to be a conservative and envelope assessment of the consequences of the postulated failure (i.e., severance) of one of the feedwater piping lines outside primary containment. The accident is postulated to occur at the input parameters and initial conditions given in Table 6.3-1.

15.6.6.3.2 Qualitative Results

The feedwater line break outside the containment is less limiting than either of the steam line breaks outside primary containment (analysis presented in Section 6.3 and/or in Section 15.6.4) or the feedwater line break inside primary containment (analysis presented in Sections 6.3.3 and 15.6.5). It is far less limiting than the DBA (the recirculation line break analysis presented in Sections 6.3.3 and 15.6.5).

The RCIC and the HPCI initiate on low-low (Level 2) water level and together restore the reactor water level to the normal elevation. MSIV isolation will occur upon receipt of a low-low-low (Level 1) water level signal, but it is unlikely that this level will be reached during this event. The fuel is covered throughout the accident and there are no pressure or temperature transients sufficient to cause fuel damage.

15.6.6.3.3 Consideration of Uncertainties

This accident was conservatively analyzed, and uncertainties were adequately considered (Section 6.3).

15.6.6.4 Barrier Performance

Accidents that result in the release of radioactive materials outside primary containment are the results of postulated breaches in the RCPB or the steam power conversion system boundary. A break spectrum analysis for the complete range of reactor conditions indicates that the limiting fault event for breaks outside primary containment is a complete severance of one of the main steam lines as described in Section 15.6.4. The feedwater system piping break is less severe than the main steam line break. Results of analysis of this accident can be found in Sections 6.2.3 or 6.2.4.

15.6.6.5 Radiological Consequences

15.6.6.5.1 Design Basis Analysis

No design basis analysis is presented.

15.6.6.5.2 Realistic Analysis

The realistic analysis is based on a conservative assessment of this accident. The specific models and assumptions, and the program used for computer evaluation, are described in Reference 15.6-3. Specific values of parameters used in the evaluation are presented in Table 15.6-24. A schematic diagram of the leakage path for this accident is shown in Figure 15.6-4.

15.6.6.5.2.1 Fission Product Release

There is no fuel damage as a consequence of this accident. In addition, an insignificant quantity of activity (compared to that existing in the main condenser hotwell prior to occurrence of the break) is released from the contained piping system prior to isolation closure.

The iodine concentration in the main condenser hotwell is consistent with an offgas release rate of 0.10 Ci/sec at 30 minutes delay and is 0.02 (2% carryover) times the concentration in the reactor coolant. Noble gas activity in the condensate is negligible, since the air ejector removes practically all noble gas from the condenser.

15.6.6.5.2.2 Fission Product Transport to the Environment

Two breaks were postulated for release of liquid coolant: a break just outside primary containment, and a break on the 30 inch header manifolding the discharge of three condensate pumps.

If a break just outside primary containment is considered, reverse flow would release 650 gallons of feedwater before the check valve inside primary containment fully closes. During this time no reactor water would be discharged through the break. On the pump side, either the turbine drive protection equipment would sense overspeed, or the pump itself would see low suction pressure. Very rapid trip would result in either case, minimizing spillage.

For the break on the 30 inch header, the condensate from the hotwell would be released along with the makeup from the CST. Backflow from upstream of the condensate filter/demineralizer would again close the check valves, but condensate in the feedwater heaters would be spilled. Since more coolant would be discharged by this break than by the break just outside primary containment, it was used for the analysis.

The fission transport pathway consists of liquid release from the break, carryover to the turbine enclosure atmosphere due to flashing and partitioning, and unfiltered release to the environment through the turbine enclosure ventilation system.

From the hotwell, 967,000 lb of condensate is released, of which 64,800 lb flashes to steam. Also released is 150,000 lb of condensate that was in the pipes from the break to the filter/demineralizers. Of this condensate, 10,100 lb flashes to steam. Low level in the condenser will send a signal for makeup to the CST; thus, 542,000 lb will be released, of which 36,300 lb will flash to steam. Upstream of the filter/demineralizers, 584,000 lb of condensate will backflow, with 146,000 lb flashing into steam. The condensate is assumed to be at a reactor steam concentrations. Of the activity remaining in the unflashed liquid, 10% is assumed to become airborne. Liquid that was upstream of the filter/demineralizers has passed through the condensate cleanup system, which have a 90% iodine removal efficiency. The CST is assumed to be 99% free of iodine.

Taking no credit for holdup, decay, or plateout during transport through the turbine enclosure, the release of activity to the environment is presented in Table 15.6-25. The release is assumed to take place within two hours of the occurrence of the break.

15.6.6.5.2.3 Results

The calculated exposures for the realistic analysis are presented in Table 15.6-26 and are a small fraction of 10CFR100 limits.

LOSS OF COOLANT ACCIDENT: CONTAINMENT PARAMETERS

Key LOCA Analysis Inputs and Assumptions	
Release Inputs - Primary and Secondary Containment Parameters	
Input/Assumption	**Value**
Containment Free Volume	3.79E+05 cubic feet
Suppression Pool Water Volume	118,655 cubic feet
Primary Containment Leak Rate	0.5% per day for 0 – 24 hours 0.25% per day for 24 – 720 hours
Total MSIV leak rate @ 22 psig test pressure	200 scfh total for 0 – 24 hours (100 scfh max per line)(*) 110.20 scfh for 24 – 720 hours
Secondary Containment Volume	1.8E+06 cubic feet
SGTS Flow Rate (maximum)	3,000 cfm (during drawdown) 2,500 cfm (post-drawdown)
RERS Flow Rate (minimum)	54,000 cfm
Secondary Containment Drawdown Time	15.5 minutes
ECCS Systems Leak Rate Outside of Primary Containment (includes factor of 2 margin)	5 gpm
ECCS Leakage Duration	0-30 days
Release Location ECCS/Containment Leakage MSIV Leakage	 North Vent Stack North Vent Stack
Release Duration ECCS/Containment Leakage MSIV Leakage	 0-30 days 0-30 days

(*) For Unit 1 Cycle 19 only. The 1B outboard main steam isolation valve (28B) exceeded the 100 scfh leakage by 4.88 scfh. TS Amendment 245 approved a one-time allowable leakage limit of 105 scfh for a single MSIV (UFSAR Reference 15.6-27).

LOSS OF COOLANT ACCIDENT: REMOVAL INPUTS

Key LOCA Analysis Inputs and Assumptions	
Removal Inputs	
Input/Assumption	**Value**
Aerosol Natural Deposition Coefficients Used in the Drywell	Credit is taken for natural deposition of aerosols based on equations for the Power's model in NUREG/CR 6189 and input directly into RADTRAD as natural deposition time dependent lambdas.
Main Steam Lines Deposition	Two-node treatment, each well-mixed, is used for each steam line in which flow occurs. The first node is from the reactor vessel to the inboard MSIV. The second node is from the inboard MSIV to the turbine stop valve. Gravitational settling applied to aerosols on horizontal pipe projected areas, based on a 20 group probability distribution as a function of particle velocities and characteristics. For Elemental Iodine, deposition velocities are calculated based on the pipe wall temperatures, and because elemental iodine deposition is not gravity dependant, all interior pipe surface is credited.
Main Steam Condenser Credit	Only the deposition area of the horizontal surface of the wetwell of the HP Condenser is credited. Aerosol and Elemental Iodine removal efficiencies are calculated in a manner similar to that used for the main steam lines, as discussed in the applicable design analysis.

SEQUENCE OF EVENTS FOR FEEDWATER LINE BREAK
OUTSIDE PRIMARY CONTAINMENT

TIME (min)[2]	EVENT
0	One feedwater line breaks.
0+	Feedwater line check valves isolate the reactor from the break.
<0.5	At low water level (Level 3), reactor scram would initiate. At low-low water (Level 2), HPCI would initiate, RCIC would initiate, and recirculation pumps would trip. If low-low-low water level (Level 1) is reached, MSIV closure begins, and CS and LPCI receive initiation signals but will not inject due to high reactor pressure.[1]
2 (approx)	The MSRVs would open and close and maintain the reactor vessel pressure at approximately 1170 psig.
60 - 120	Normal reactor cooldown procedure established.

Note:

(1) **Because of an additional steam flow induced process measurement error in the Level 3 scram, the timing values following Low water level scram based on the L3 Analytical Limit are slightly different. However, as described in Reference 15.6-25, the impact of the change is not significant.**

(2) The timetable for this case is representative of the general scenario. This case is bounded by the Steam Line Break Outside Containment scenario in Table 15.6-8.

LOSS OF COOLANT ACCIDENT: SEQUENCE OF EVENTS FOR RADIOLOGICAL CONSEQUENCE ANALYSIS

Time	Events and Assumptions
0	DBA LOCA is initiated. - Instantaneous Regulatory Guide 1.183 source term assumed. - Activity release from Reactor Enclosure taken at design basis SGTS flow of 3000 cfm per Reactor enclosure, to simulate exfiltration.
18 sec	SGTS is initiated. - No credit is taken for filtration during drawdown period. - Exfiltration of 3000 cfm per Reactor Enclosure continues to be assumed.
3 min	RERS is initiated. - No credit is taken for filtration during drawdown period.
15.5 min.	Reactor enclosure reaches -¼ inch wg. [Drawdown Period Ends(1).] - Unfiltered exfiltration ceases. - Reactor Enclosure exhausts at 2500 cfm [TS inleakage limit] throughout SGTS with 99% iodine removal eff. - RERS filtration of recirculation flow with iodine removal eff. of 95% for organic / elemental and 99% for particulate.

(1) Drawdown period determined based on a more conservative 2800 cfm SGTS flow, to allow for flow balancing margin.

15.7 RADIOACTIVE RELEASES FROM SUBSYSTEMS AND COMPONENTS

15.7.1 RADIOACTIVE GAS WASTE SYSTEM LEAK OR FAILURE

The following radioactive gas waste system components are examined under severe failure mode conditions for effects on plant safety:

a. Main condenser offgas treatment system failure

b. Malfunction of main turbine gland sealing system

c. Failure of SJAE lines.

15.7.1.1 Main Condenser Offgas Treatment System Failure

15.7.1.1.1 Identification of Causes and Frequency Classification

15.7.1.1.1.1 Identification of Causes

Those events which could cause a failure in the offgas treatment system are:

a. A seismic occurrence greater than the equipment can withstand.

b. A fire in the filter assemblies.

c. Failure of spacially related equipment.

The equipment and piping are designed to resist any hydrogen/oxygen detonation that has a reasonable probability of occurring. Consequently, a detonation is not considered as a possible failure mode.

The decay heat on the filters is handled inherently by the system and by the available air flows.

The system is reasonably isolated from other systems or components that could cause any serious interaction or failure. The only credible event that could result in the release of significant activity to the environment is an earthquake.

Even though the offgas system is designed to the requirements of Regulatory Guide 1.143 as discussed in Section 11.3, an event resulting in the failure of the offgas system is assumed to occur.

The design basis, description, and performance evaluation of the subject system is given in Section 11.3.

15.7.1.1.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.7.1.1.2 Sequence of Events and System Operation

15.7.1.1.2.1 Sequence of Events

The sequence of events following this failure is shown in Table 15.7-1.

15.7.1.1.2.2 Identification of Operator Actions

Gross failure of this system may require manual isolation of this system from the main condenser. This isolation results in high condenser pressure and a reactor scram. The operator should monitor the turbine-generator auxiliaries and break vacuum as soon as possible. The operator should notify personnel to evacuate the area immediately and notify radiation protection personnel to survey the area and determine requirements for re-entry. The time to perform these actions is estimated to be about two minutes.

15.7.1.1.2.3 System Operation

In analyzing the postulated offgas system failure, credit is taken for functioning of normally operating plant instrumentation and controls and other systems only in assuming the following:

a. Capability to detect the failure itself, indicated by an alarmed increase in radioactivity levels seen by the area radiation monitoring system, in a loss of flow in the offgas system, and in an alarmed increase in activity at the ventilation release.

b. Capability to isolate the system and shut down the reactor.

c. Operational indicators and annunciators in the control room.

15.7.1.1.2.4 The Effect of Single Failures and Operator Errors

After the initial system gross failure, the inability of the operator to actuate a system isolation could affect the analysis. However, a seismic event greater than design basis will cause the tripping of the turbine, or will lead to a load rejection. This will result in a scram and negate a need for the operator to initiate a reactor shutdown via system isolation.

See Section 15.9 for a further detailed discussion of this subject.

15.7.1.1.3 Core and System Performance

The postulated failure results in a system isolation necessitating reactor shutdown because of loss of vacuum in the main condenser. This transient is analyzed in Section 15.2.5.

15.7.1.1.4 Barrier Performance

The postulated failure is the rupture of the offgas treatment system pressure boundary. No credit is taken for performance of secondary barriers, except to the extent inherent in the assumed equipment release fractions discussed in Section 15.7.1.1.5, below.

15.7.1.1.5 Radiological Consequences

15.7.1.1.5.1 General

Two separate radiological analyses are provided for this accident:

a. The first is based upon conservative assumptions considered to be acceptable to the NRC for the purpose of determining adequacy of the plant design to meet 10CFR100. This analysis is referred to as the "design basis analysis."

b. The second is based upon assumptions considered to provide a realistic conservative estimate of radiological consequences. This analysis is referred to as the "realistic analysis."

15.7.1.1.5.2 Design Basis Analysis

Regulatory Guide 1.98 contains specific quantitative regulatory guidelines upon which a design basis analysis can be performed. The primary differences between this analysis and the realistic analysis are in the basic source terms and atmospheric dilution factors. The same analytical techniques used for the realistic analysis are used for this evaluation. Specific parametric values used in this evaluation are presented in Table 15.7-2.

15.7.1.1.5.2.1 Fission Product Release

15.7.1.1.5.2.1.1 Initial Conditions

The activity in the offgas system was based upon the following conditions:

a. 6 scfm air inleakage.

b. 0.35 Ci/sec noble gas after 30 minutes delay for a period of one month, preceding the accident and 0.1 Ci/sec (at 30 minutes delay) for a time earlier than 30 days.

c. The total mass of charcoal in the system is 321,790 lbs. The adsorption coefficients for Xe and Kr are 1000 cc/g and 65 cc/g, respectively.

d. The uncontrolled releases from the SJAE occur for a period of 1 hour following the accident. The delay time between the SJAE and the break is five minutes.

15.7.1.1.5.2.1.2 Assumptions

Depending upon assumptions as to radionuclide release fractions, various equipment pieces may be controlling with respect to dose consequences. The assumed release fractions are shown in Table 15.7-3. All other release sources are negligible. Iodine and activation gases are neglected per Regulatory Guide 1.98.

15.7.1.1.5.2.2 Fission Product Transport to the Environment

The transport pathway consists of direct release from the failed component to the environment through the radwaste enclosure ventilation system. The activity released to the environment is presented in Tables 15.7-4 and 15.7-8.

15.7.1.1.5.2.3 Results

The dose contributions due to releases from the charcoal tanks and SJAE are presented in Tables 15.7-6 and 15.7-9(a) respectively. The total offsite doses due to failure of the system are summarized in Table 15.7-9(b).

15.7.1.1.5.3 Realistic Analysis

The realistic analysis is based upon an engineered but still conservative assessment of this accident. Specific values of parameters used in the evaluation are presented in Table 15.7-2.

15.7.1.1.5.3.1 Fission Product Release

15.7.1.1.5.3.1.1 Initial Conditions

The activity in the offgas system is based upon the following conditions:

a. 20 scfm air inleakage.

b. 0.06 Ci/sec noble gas after 30 minutes delay.

c. The total mass of charcoal in the system is 321,790 lbs. The adsorption coefficients for Xe and Kr are 733 cc/g and 31.8 cc/g, respectively.

d. The uncontrolled releases from the SJAE occur for a period of 1 hour following the accident. The delay time between the SJAE and the break is five minutes.

15.7.1.1.5.3.2 Fission Product Transport to the Environment

The activity released to the environment is presented in Table 15.7-5 and 15.7-8.

15.7.1.1.5.3.3 Results

The dose contributions due to releases from the charcoal tanks and SJAE are presented in Tables 15.7-6 and 15.7-9(a) respectively. The total offsite doses due to failure of the system are summarized in Table 15.7-9(b).

15.7.1.2 Malfunction of Main Turbine Gland Sealing System

15.7.1.2.1 Identification of Causes and Frequency Classification

15.7.1.2.1.1 Identification of Causes

Those events that could cause a malfunction failure in the main turbine gland sealing system are:

a. Failure of the gland steam evaporator and its backup supply.

b. Failure of the gland steam condenser exhausters.

c. Excessive pressure in the steam seal header.

15.7.1.2.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.7.1.2.2 Sequence of Events and System Operation

It is assumed that the system fails near the condenser. This results in activity normally processed by the offgas treatment system being discharged directly to the turbine enclosure and subsequently through the ventilation system to the environment.

The operator initiates a normal shutdown of the reactor to reduce the gaseous activity being discharged. A loss of main condenser vacuum will result in a turbine trip and reactor shutdown.

Failure of the gland steam evaporator and its backup steam supply would result in the discharge of a small amount of contaminated steam from the high pressure and low pressure shaft seals to the gland steam condenser exhauster.

Failure of both of the gland steam condenser exhausters results in the escape of clean steam from the high pressure and low pressure shaft seals.

Excessive pressure in the steam seal header as a result of a malfunction of the gland steam evaporator or the backup steam supply valve is prevented by a relief valve, so that there is no detrimental effect on the operation of the seals.

15.7.1.2.3 Core and System Performance

The failure of this power conversion system does not directly affect the NSSS. It will, of course, lead to the decoupling of the NSSS from the power conversion system.

This failure has no applicable effect on the core or the NSSS safety performance.

15.7.1.2.4 Barrier Analysis

This release occurs outside primary containment; therefore, the primary containment barrier integrity is not involved.

15.7.1.2.5 Radiological Consequences

Each of the assumed malfunctions results in negligible releases of activity. Therefore, the doses that result from these failures are inconsequential.

15.7.1.3 Failure of Steam Jet Air Ejector Lines

15.7.1.3.1 Identification of Causes and Frequency Classification

15.7.1.3.1.1 Identification of Causes

An evaluation of events that could cause a failure of the SJAE line indicates that a seismic event or hydrogen detonation more serious than the system is able to withstand are the only events that could rupture the lines.

15.7.1.3.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.7.1.3.2 Sequence of Events and System Operation

It is assumed that the line leading from the SJAE to the offgas treatment system fails. This results in activity normally processed by the offgas treatment system being discharged directly to the turbine enclosure and subsequently through the ventilation system to the environment.

The operator will initiate a normal shutdown of the reactor to reduce the gaseous activity being discharged. The operator will isolate the main condenser, which results in high condenser pressure and a reactor scram. The operator will notify personnel to evacuate the area immediately and notify radiation protection personnel to survey the area and determine requirements for re-entry.

15.7.1.3.3 Core and System Performance

The failure of this power conversion system does not directly affect the NSSS. It will, of course, lead to the decoupling of the NSSS with power conversion system.

This failure has no applicable effect on the core or the NSSS safety performance.

15.7.1.3.4 Barrier Analysis

This release occurs outside primary containment; therefore, the primary containment barrier integrity is not involved.

15.7.1.3.5 Radiological Consequences

The offgas release rates at the SJAE are assumed for the design basis and the realistic case to be 0.35 Ci/Sec and 0.06 Ci/Sec at 30 minutes decay, respectively. The delay between the SJAE and the break is assumed to be five minutes. It is conservatively assumed that activities are released directly to the environment and that the uncontrolled release period is one hour before the plant operator initiates a plant shutdown. Iodines are neglected per Regulatory Guide 1.98. Specific parametric values in this evaluation are presented in Table 15.7-7.

The activity released to the environment and the calculated exposures are presented in Tables 15.7-8 and 15.7-9, respectively.

15.7.2 LIQUID RADIOACTIVE WASTE SYSTEM FAILURE

15.7.2.1 Identification of Causes and Frequency Classification

15.7.2.1.1 Identification of Causes

It was assumed that an unspecified event causes the complete release of the average radioactivity inventory in the tank containing the largest quantities of significant radionuclides in the liquid radwaste system. This is the RWCU phase separator in the radwaste enclosure. The airborne radioactivity released during this accident passes directly to the environment via the ventilation stack.

Postulated events that could cause release of the radioactive inventory of the RWCU phase separator are cracks in the vessel and operator error. The possibility of small cracks and consequent low-level release rates receives primary consideration in system and component design. The RWCU phase separator is designed to operate at atmospheric pressure and 212°F, so the possibility of failure is considered small. A liquid radwaste release caused by operator error

is also considered a remote possibility. Operating techniques and administrative procedures emphasize detailed system and equipment operating instruction. Should a release of liquid radioactive wastes occur, floor drain sump pumps in the floor of the radwaste enclosure will receive a high-water level signal, activate automatically, and remove the spilled liquid.

15.7.2.1.2 Frequency Classification

Much of the discussion concerning the remote likelihood of a leakage or malfunction accident of a RWCU phase separator applies equally to a complete release accident. The probability of a complete rupture or complete malfunction accident is, however, considered even lower.

Although not analyzed for the requirements of seismic Category I equipment, the liquid radwaste tanks are constructed in accordance with sound engineering principles. Therefore, simultaneous failure of all the tanks is not considered credible.

This accident is expected to occur with the frequency of a limiting fault.

15.7.2.2 Sequence of Events and System Operation

The sequence of events following this accident is shown in Table 15.7-10.

The rupture of a RWCU phase separator would leave little recourse to the operator. No method of recontaining the gaseous phase discharge is available.

15.7.2.3 Core and System Performance

Failure of a RWCU phase separator does not directly affect the NSSS. It will, of course, lead to the decoupling of the NSSS from the liquid radioactive waste system.

This failure is not expected to have any applicable effect on the core or NSSS safety performance.

15.7.2.4 Barrier Performance

This release occurs outside primary containment; therefore, barrier integrity is not involved.

15.7.2.5 Radiological Consequences

15.7.2.5.1 Design Basis Analysis

It is assumed that a RWCU phase separator contains the inventory of radioactive material as presented in Section 12.2. A RWCU phase separator, which contains the greatest amount of iodine inventory that could be released, is assumed to fail releasing the entire contents of this tank (equal to 80% of the tank capacity) to the radwaste enclosure. An iodine partitioning factor of 100 is assumed for the spilled liquid. The airborne iodine activity is exhausted through the radwaste ventilation system over a two-hour period. Specific parametric values used in this evaluation are presented in Table 15.7-11.

Table 15.7-12 lists the iodine activity released to the environment.

The offsite radiological doses for a RWCU phase separator rupture accident are given in Table 15.7-14.

15.7.2.5.2 Realistic Analysis

It is assumed that the inventory in a RWCU phase separator corresponds to 0.05 Ci/sec offgas release under normal operation. Other assumptions are the same as that of the design basis analysis. Activities released to the environment and offsite doses are presented in Tables 15.7-13 and 15.7-14, respectively.

15.7.3 POSTULATED RADIOACTIVE RELEASES DUE TO LIQUID RADWASTE TANK FAILURE

Refer to Section 2.4.12 for a discussion of tank failures.

15.7.4 FUEL HANDLING ACCIDENT

The material presented in Section 15.7.4 is historical and based on an 8x8 fuel design. However, the material presented in Section 15.7.4.5 is updated for Alternative Source Terms and represents the current licensing basis for the FHA. The analytical methodology and licensing bases for the Fuel Handling Accident are provided in GESTAR II (Reference 4.1-1). Compliance with these bases is verified in Amendment 22 of GESTAR II for each new fuel design. The analysis in this Section generally follows the methodology described in GESTAR II, however, it applies additional conservative assumptions. The GE RCWP jib cranes are permitted to extend into the boundary zone during fuel handling based on a determination in a GE analysis that a collision between a loaded fuel grapple and the GE RCWP would not result in dropping the fuel bundle or mast fuel grapple assembly onto the core; and therefore the original FHA remains bounding.

15.7.4.1 Identification of Causes and Frequency Classification

15.7.4.1.1 Identification of Causes

The fuel handling accident is assumed to occur as a consequence of a failure of the fuel assembly lifting mechanism resulting in the dropping of a raised fuel assembly onto other fuel bundles. A variety of events that qualify for the class of accidents termed "fuel handling accidents" has been investigated. The accident that produces the largest number of failed spent fuel rods is the drop of a spent fuel bundle and the fuel grapple assembly of the refueling platform into the reactor core when the reactor vessel head is off. The fuel grapple assembly consists of a telescopic mast and head assembly.

15.7.4.1.2 Frequency Classification

This accident is categorized as a limiting fault.

15.7.4.2 Sequence of Events and System Operation

15.7.4.2.1 Sequence of Events

The sequence of events following this failure is shown in Table 15.7-15.

15.7.4.2.2 Identification of Operator Actions

The operator actions are as follows:

a. Initiate the evacuation of the refueling area.

b. Notify Health Physics

c. The supervisor in charge of fuel handling will alert the control room operator to the accident.

d. Determine if the normal ventilation system has isolated and the SGTS is in operation.

e. Initiate action to determine the extent of potential radiation doses by measuring the radiation levels in the vicinity of or close to the refueling area.

f. Appropriate radiological control methods should be implemented at the entrance of the refueling area.

g. Before entering the refueling area, a careful study of conditions, radiation levels, etc., will be performed.

15.7.4.2.3 System Operation

Normally, operating plant instrumentation and controls are assumed to function, although credit is taken only for the isolation of the normal ventilation system and the operation of the SGTS. Operation of other plant or RPS or ESF systems is not expected.

15.7.4.2.4 The Effect of Single Failures and Operator Errors

The automatic ventilation isolation system includes the radiation monitoring detectors and isolation valves. The SGTS is designed to the single failure criterion and safety requirements. Refer to Sections 7.6, 9.4 and 15.10 for further details.

15.7.4.3 Core and System Performance

15.7.4.3.1 Mathematical Model

The analytical methods and associated assumptions used to evaluate the consequences of this accident are considered to provide a realistic yet conservative assessment of the consequences.

Calculations were performed to evaluate the consequences of a variety of drop scenarios. The worst-case scenario that produced the greatest number of failed fuel rods is represented by the fuel bundle and grapple assembly falling as two separate and independent units from their respective fully raised heights.

The consequences of a drop scenario consisting of a fuel bundle and grapple assembly falling as a single unit are bounded by the above worst-case scenario, mainly because twice as many fuel rods are struck (and consequently fail due to bending) by the drop of two independent units.

The calculated results of the worst case scenario are conservative because both of the following unlikely events would have to occur:

a. The fuel bundle becomes detached from the grapple by either a break of the bail handle or grapple.

b. The grapple assembly becomes detached from the refueling platform by either a break of the cables or a break of the cable support eye bracket.

To estimate the expected number of failed fuel rods in each impact, an energy approach is used.

The fuel assembly and grapple assembly are expected to impact on the reactor core at a small angle from the vertical, possibly inducing a bending mode of failure on the fuel rods of the dropped assembly. It is assumed that each fuel rod resists the imposed bending load by a couple consisting of two equal, opposite concentrated forces. Therefore, fuel rods are expected to absorb little energy prior to failure as a result of bending. Actual bending tests with concentrated point loads show that each fuel rod absorbs approximately 1 ft-lb prior to cladding failure. Each rod that fails as a result of gross compression distortion is expected to absorb approximately 250 ft-lb before cladding failure (based upon 1% uniform plastic deformation of the rods). The energy of the dropped assemblies is conservatively assumed to be absorbed by only the cladding and other core structures. Because a typical 8x8 fuel assembly consists of 72% fuel, 11% cladding, and 17% other structural material by weight, the assumption that no energy is absorbed by the fuel material results in considerable conservatism in the mass-energy calculations that follow.

It should be noted that the energy required to cause cladding failure due to compression and weight percentages of fuel, cladding, and other structural material are fuel type specific. The values given here are historical as discussed in Section 15.7.4.

The energy absorption on successive impacts is estimated by considering a plastic impact. Conservation of momentum under a plastic impact shows that the fractional kinetic energy absorbed during impact is:

$$1 - \frac{M_1}{M_1 + M_2}$$

where M_1 is the impacting mass and M_2 is the struck mass.

15.7.4.3.2 Input Parameters and Initial Conditions

The assumptions used in the analysis of this accident are listed below:

a. The fuel assembly and grapple assembly are dropped from the maximum height allowed by the refueling platform (32 feet and 47 feet, respectively, when handling fuel) as two separate and independent units.

b. The entire amount of potential energy, referenced to the top of the reactor core, is available for application to the fuel assemblies involved in the accident. This assumption neglects the dissipation of some of the mechanical energy of the falling fuel assembly and grapple assembly in the water above the core.

c. None of the energy associated with the dropped assemblies is absorbed by the fuel material (uranium dioxide).

d. The minimum water depth between the top of the fuel rods and the fuel pool surface is 22 feet.

e. Maximum fuel rod pressurization is 2072 psia.

f. The peak linear power density for the highest power assembly discharged is 13.4 kW/ft and the corresponding maximum centerline operating fuel temperature is 3412°F.

g. Because the weights of the fuel assembly and grapple assembly are similar, the fractional energy losses are assumed to be the same for both assemblies.

15.7.4.3.3 Results

15.7.4.3.3.1 Energy Available

Dropping a fuel assembly onto the reactor core from the maximum height allowed by the refueling platform (32 feet) results in an impact velocity of 45.4 fps. Dropping the fuel grapple assembly onto the reactor core from the maximum height allowed by the refueling platform (47 feet) results in an impact velocity of 55.0 fps.

The total kinetic energy acquired by the falling assemblies is approximately 45,900 ft-lb and is dissipated in one or more impacts. The total kinetic energy equals the sum of the kinetic energy of the dropped fuel assembly (32 ft x 700 lb = 22,400 ft-lb) and the dropped fuel grapple assembly (47 ft x 500 lb = 23,500 ft-lb).

A review has been made to determine whether there are any potential drops of loads lighter than a fuel bundle and full grapple assembly (i.e., 1200 lb) that could have a higher kinetic energy due to a higher carrying height. The following conclusions have been reached:

No load that weighs less than 540 lb can develop a higher kinetic energy than a fuel bundle and full grapple assembly if dropped over spent fuel. This value is based on a potential energy of 45,900 ft-lb with the load at the maximum lift height of the reactor enclosure crane and relative to the reactor core (worst case). The majority of light loads carried over spent fuel weigh less than 540 lb.

As listed in Table 15.7-22, the potential energy of the remaining few light loads which will be handled over spent fuel and which weigh more than 540 lb is less than 45,900 ft-lb because their maximum drop heights are less than the worst case. Infrequent or unexpected movement of light loads (i.e., weighing greater than 540 lb but less than 1200 lb) over spent fuel which are not identified in Table 15.7-22 are administratively controlled on a case-by-case basis. These infrequent or unexpected load handling situations use the load handling guidelines to ensure that the probability of a load drop is extremely small or that the consequences are acceptable.

Based on the above review, the maximum kinetic energy resulting from the drop of each object weighing less than a fuel bundle and grapple assembly that could be handled over spent fuel will not exceed the effects of the fuel handling accident described above.

15.7.4.3.3.2 Energy Loss Per Impact

Based on the fuel geometry in the reactor core and the long narrow shape of both dropped assemblies, four fuel assemblies are struck by each dropped assembly. The fractional energy loss on the first impact is approximately 80%.

The second impact is expected to be less direct. The broadside of each dropped assembly impacts approximately 24 more fuel assemblies, so that after the second impact less than 240 ft-lb (approximately 1% of the original kinetic energy) is available for a third impact. Because a single fuel rod is capable of absorbing 250 ft-lb in compression before cladding failure, it is unlikely that any fuel rod will fail on a third impact.

If each dropped assembly strikes only one or two fuel assemblies on its first impact, the energy absorption by the core support structure results in approximately the same energy dissipation on the first impact as in the case where four fuel assemblies are struck. The energy relations on the second and third impacts remain approximately the same as in the original case. Thus, the calculated energy dissipation is as follows:

First impact	80%
Second impact	19%
Third impact	1% (no cladding failures)

15.7.4.3.3.3 Fuel Rod Failures

15.7.4.3.3.3.1 First Impact Failures

The first impacts dissipate 0.80 x 45,900 or 36,720 ft-lb of energy. It is assumed that 50% of this energy is absorbed by the dropped fuel assembly and that the remaining 50% is absorbed by the struck fuel assemblies in the core. In addition, it is conservatively assumed that 0% of this energy is absorbed by the dropped grapple assembly and 100% is absorbed by the struck fuel assemblies. Because the fuel rods of the dropped fuel assembly are susceptible to the bending mode of failure and because 1 ft-lb of energy is sufficient to cause cladding failure as a result of bending, all 62 rods of the dropped fuel assembly are assumed to fail.

Each assembly, fuel and grapple, hits four fuel assemblies in the reactor core. This results in 64 tie rod failures as follows: 2 dropped assemblies (fuel and grapple) x 4 struck fuel assemblies per dropped assembly x 8 tie rods per struck fuel assembly.

Because the remaining fuel rods of the struck assemblies are held rigidly in place in the core, they are susceptible only to the compression mode of failure. To cause cladding failure of one fuel rod as a result of compression, 250 ft-lb of energy is required. To cause failure of all the remaining rods of each group of four struck assemblies, 250 x 54 x 4 or 54,000 ft-lb of energy would have to be absorbed in cladding alone. Thus, it is clear that not all the remaining fuel rods of the struck assemblies can fail on the first impact. The number of fuel rod failures caused by compression is computed as follows:

Dropped fuel assembly:

$$\frac{0.5 \times 0.8 \times 22{,}400 \times \frac{11}{11 + 17}}{250} = 14$$

Dropped fuel grapple assembly:

$$\frac{11}{}$$

$$\frac{1.0 \times 0.8 \times 23{,}500 \times 11 + 17}{250} = \frac{30}{44}$$

Thus, during the first impact, fuel rod failures are as follows:

Dropped fuel assembly	62 rods (bending)
Struck assemblies	64 tie rods (bending)
Struck assemblies	44 rods (compression)
	170 failed rods

15.7.4.3.3.3.2 Second Impact Failures

Because of the less severe nature of the second impact and the distorted shape of each dropped assembly, it is assumed that the tie rods in only two of the 24 struck assemblies are subjected to bending failure. Because each dropped assembly strikes 24 fuel assemblies, 2 x 2 x 8 = 32 tie rods are assumed to fail. The number of fuel rod failures caused by compression on the second impact is computed as follows:

Dropped fuel assembly:

$$\frac{0.19}{\frac{2 \times 22{,}400 \times \overline{11 + 17}}{250}} = 3$$

Dropped fuel grapple assembly:

$$\frac{1.0 \times 0.19 \times 23{,}500 \times \overline{11 + 17}}{250} = \frac{7}{10}$$

Thus, during the second impact, the fuel rod failures are as follows:

Struck assemblies	32 tie rods (bending)
Struck assemblies	10 rods (compression)
	42 failed rods

15.7.4.3.3.3.3 Total Failures

The total number of failed rods resulting from the accident is as follows:

First impact	170 rods
Second impact	42 rods
Third impact	0 rods
	212 total failed rods

15.7.4.4 Barrier Performance

The RCPB and primary containment are assumed to be open. The transport of fission products from the refueling area is discussed in Sections 15.7.4.5.2.1 and 15.7.4.5.2.2.

15.7.4.5 Radiological Consequences for the FHA

Regulation 10CFR50.67, "Accident Source Term," provides a mechanism for power reactor licensees to voluntarily replace the traditional TID-14844 (Ref. 15.7-4A) accident source term used in design-basis accident analyses with an "Alternative Source Term" (AST). The methodology of approach to this replacement is given in USNRC Regulatory Guide 1.183 (Ref. 15.7-5) and its associated Standard Review Plan 15.0.1 (Ref. 15.7-6).

Accordingly, Limerick Generating Station, Units 1 and 2, have applied the AST methodology for several areas of operational relief in the event of a Design Basis Accident (DBA), without fully crediting the use of previously assumed safety systems. Amongst these systems are the Control Room Emergency Fresh Air Supply System (CREFAS) and the Standby Gas Treatment System (SGTS).

In support of a full-scope implementation of AST as described in and in accordance with the guidance of Ref. 15.7-5, AST radiological consequence analyses are performed for the four DBAs that result in offsite exposure (i.e., Loss of Coolant Accident (LOCA), Main Steam Line Break (MSLB), Fuel Handling Accident (FHA), and Control Rod Drop Accident (CRDA)).

Implementation consisted of the following steps:

- Identification of the AST based on plant-specific analysis of core fission product inventory,
- Calculation of the release fractions for the four DBAs that could potentially result in control room and offsite doses (i.e., LOCA, MSLB, FHA, and CRDA),
- Analysis of the atmospheric dispersion for the radiological propagation pathways,
- Calculation of fission product deposition rates and removal mechanisms,
- Calculation of offsite and control room personnel Total Effective Dose Equivalent (TEDE) doses.

15.7.4.5.1 Regulatory Approach

The analyses are prepared in accordance with the guidance provided by Regulatory Guide 1.183 (Ref. 15.7-5).

15.7.4.5.2 Dose Acceptance Criteria

The AST acceptance criteria for Control Room dose for postulated major credible accident scenarios such as those resulting in substantial meltdown of the core with release of appreciable quantities of fission products is provided by 10CFR50.67, which requires:

> "Adequate radiation protection is provided to permit access to and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 0.05 Sv (5 rem) total effective dose equivalent (TEDE) for the duration of the accident."

This limit is applied by Regulatory Guide 1.183 to all of the accidents considered with AST.

The AST acceptance criteria for an individual located at any point on the boundary of the exclusion area (the Exclusion Area Boundary or EAB) are provided by 10 CFR 50.67 as 25 rem TEDE for any 2-hour period following the onset of the postulated fission product release.

The AST acceptance criteria for an individual located at any point on the outer boundary of the low population zone (LPZ) are provided by 10CFR50.67 as 25 rem TEDE during the entire period of passage of the radioactive cloud resulting from the postulated fission product release.

These limits are applied by Regulatory Guide 1.183 to events with a higher probability of occurrence (including CRDA, MSLB, and FHA considered herein) to provide the following acceptance criteria:

- For the BWR MSLB for the case of an accident assuming fuel damage or a pre-incident Iodine spike, doses at the EAB and LPZ should not exceed 25 rem TEDE for the accident duration (2-hour dose for EAB and 30-day dose for LPZ). For MSLB accidents assuming normal equilibrium Iodine activity, doses should not exceed 2.5 rem TEDE for the accident duration.
- For the BWR CRDA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2-hour dose for EAB and 24-hour dose for LPZ).
- For the FHA, doses at the EAB and LPZ should not exceed 6.3 rem TEDE for the accident duration (2-hour dose for EAB and 30-day dose for LPZ).

15.7.4.5.3 Computer Codes

New AST calculations were prepared for the FHA to simulate the radionuclide release, transport, removal, and dose estimates associated with the postulated accident.

The RADTRAD computer code (Ref. 15.7-9) endorsed by the NRC for AST analyses was used in the calculations for analyzing the FHA. The RADTRAD program is a radiological consequence analysis code used to estimate post-accident doses at plant offsite locations and in the control room. The FHA assessment takes no credit for SGTS operation, control room isolation, emergency ventilation or filtration of intake air for the duration of the accident event.

Offsite X/Qs were calculated with the PAVAN computer code (Ref. 15.7-10), using the guidance of Regulatory Guide 1.145 (Ref. 15.7-11). Control room X/Qs were calculated with the ARCON96 computer code (Ref. 15.7-12). The PAVAN and ARCON96 codes calculate relative concentrations in plumes from nuclear power plants at offsite locations and control room air intakes, respectively.

All of these computer codes have been used by the NRC staff in its safety reviews.

15.7.4.5.4 Source Terms

Core Inventory

As with the LOCA analysis, the inventory of reactor core fission products used as input to RADTRAD for the AST FHA analysis is based on maximum full power operation at a power level of 3527 MWth, which includes a 2% instrument error per Reg. Guide 1.49 (Ref. 15.7-13). The fission products used for the accidents are the 60 isotopes of the standard RADTRAD input library, determined by the code developer as significant in dose consequences. These were extracted from Attachment A of the LGS Design Analysis LM-0645 (Ref. 15.7-14), and

correspond to 24 month cycle burnup parameters, conservatively calculated using the ORIGEN-ARP code.

Release Fraction

Current design basis accident evaluations as modified by Regulatory Guide 1.183 (Ref. 15.7-5) were used to determine the specific releases of radioactive isotopes at the given stages of fuel pin failure and provide these releases as a percentage of the total release for each accident, as summarized below.

15.7.4.5.5 Methodology

Dose Calculations

As per Regulatory Guide 1.183 (Ref. 15.7-5), Total Effective Dose Equivalent (TEDE) doses are determined as the sum of the CEDE and the Effective Dose Equivalent (EDE) using dose conversion factors for inhalation CEDE from Federal Guidance Report No. 11 (Ref. 15.7-15) and for external exposure EDE from Federal Guidance Report No. 12 (Ref. 15.7-16).

Fuel Handling Accident (FHA)

Table 15.7-16 lists the key assumptions and inputs used in the analysis. The AST FHA dose assessments use historical fuel damage assumptions of a total of 212 failed rods based on an 8x8 fuel design containing 62 fuel rods, but with a conservatively higher radial peaking factor (PF) of 1.69 instead of 1.5, as suggested by Reg. Guide 1.183. As per Section 15.7.4, the analytical methodology and licensing bases for determination of fuel damage in an FHA are provided in GESTAR II, and compliance with these bases is verified for each new fuel design. The new radiological analysis applies additional conservative assumptions so as to continue to provide margin.

The assumed accident is an assembly and mast drop from the maximum height allowed by the refueling platform (a height of 32 feet for the fuel assembly, and 47 feet for the mast) over the reactor well onto fuel in the reactor. Based on fuel damage assessments in Ref. 15.7-17, this bounds the damage assessments for various 8x8 and 7x7 array fuel types with 60 and 49 fuel pins per bundle, respectively, and 111 failed pins and a 1.5 PF, as well as GE11 or GE13 9x9 array fuel types with 74 fuel pins per bundle, 140 failed pins and a 1.5 PF, GE14 or GNF2 10x10 array fuel types with 172 failed pins per bundle and a 2.0 PF, and GNF3 10x10 array fuel types with 169 failed pins per bundle and a 2.0 PF.

The analysis assumes that the activity from the damaged fuel is released from the reactor building through the South Vent Stack with no further credit for reactor building holdup or dilution. No credit is taken for the control room emergency ventilation system or standby gas treatment system operation.

The analysis assumptions for the transport, reduction, and release of the radioactive material from the fuel and the reactor coolant are consistent with the guidance provided in Appendix B of Regulatory Guide 1.183, and are provided in the design analysis of Ref. 15.7-14 and Ref 15.7-17.

15.7.4.5.6 Atmospheric Dispersion Factors (X/Qs)

Table 15.7-17 lists X/Q values used for the control room dose assessments, as derived in UFSAR Chapter 2 and applied for the release point (south vent stack) applicable to the FHA, for a zero velocity vent release.

Table 15.7-15 lists X/Q values for the EAB and LPZ boundaries, as also derived in UFSAR Chapter 2 and applied for the release point (south vent stack) applicable to the FHA, for a zero velocity vent release.

15.7.4.5.7 Summary and Conclusions

The radiological consequences of the postulated FHA are given in Table 15.7-18. As indicated, the control room, EAB, and LPZ calculated doses are within regulatory limits after AST implementation.

15.7.5 SPENT FUEL CASK-DROP ACCIDENT

The spent fuel, ISFSI cask, and/or HI-TRAC VW cask will be equipped with lifting lugs and yoke(s) which are single failure proof in accordance with NUREG-0612 compatible with the single failure proof reactor enclosure crane and main hook, thus precluding a cask-drop due to a single failure. Therefore, an analysis of the cask-drop is not required. Refer to Section 9.1.5 for a description of the reactor enclosure crane and the interlocks that prevent moving the cask over the fuel pool.

15.7.6 MOVEMENT OF LOADS WITHOUT SECONDARY CONTAINMENT

The methodology provided in the reference 15.7-3 calculation allows the movement of various loads over irradiated fuel, without refueling area secondary containment integrity in place. The calculation provides the methodology to determine the consequences of dropping a load onto irradiated fuel, without secondary containment integrity, to remain bounded by the Fuel Handling Accident Analysis. Using the methodology provided in reference 15.7-3 ensures that the offsite dose values for the UFSAR Fuel Handling Accident Analysis will not be exceeded if the load being carried over irradiated fuel is dropped.

15.8 ANTICIPATED TRANSIENTS WITHOUT SCRAM

15.8.1 REQUIREMENTS

The LGS plant incorporates many features and systems designed to mitigate ATWS events. These features were originally incorporated into LGS in response to NRC concerns. They were based on extensive assessments of ATWS mitigation and are consistent with Alternate 3A (Reference 15.8-1). These features and systems, which meet the current ATWS requirements of 10CFR50.62, are described briefly below.

15.8.2 PLANT CAPABILITIES

The LGS design uses diverse, redundant, and reliable scram systems. This includes the normal scram systems plus the electrically diverse alternate rod insertion system. Each of these systems is frequently tested and would insert the control rods even if multiple component failures should occur, thus making the probability of an ATWS event extremely remote.

The ATWS-RPT feature prevents reactor vessel overpressure and possible short-term fuel damage for the most limiting postulated ATWS event by reducing reactor power. Subsequent to an ATWS event for which the ARI system does not insert the control rods, the long-term shutdown of the reactor can be accomplished by either manual insertion of the control rods or injection of sodium pentaborate solution into the vessel by the SLCS.

15.8.3 EQUIPMENT DESCRIPTION

This section describes the equipment and control logic added or modified exclusively for ATWS prevention or mitigation. The description covers design and functional requirements and references that contain more detailed information. The dynamic and environmental qualifications are described in Sections 3.9, 3.10, and 3.11.

15.8.3.1 Redundant Reactivity Control System

The RRCS determines that a transient is under way that exceeds expected operating parameters. After deciding that ATWS mitigation is the appropriate action, the RRCS activates ATWS prevention equipment and then ATWS mitigation equipment. The RRCS uses transient detection sensors for high vessel dome pressure and low vessel water level and the actuation logic to initiate ARI, RPT, SLCS injection, and feedwater runback.

The RRCS consists of two completely redundant divisions. Each division is initiated automatically by the ATWS detection sensors, which are independent of the RPS sensors, or manually by switches that require the same type of operator actions as manual scram.

Additional information on the RRCS is contained in Sections 7.1 and 7.6.

15.8.3.2 Alternate Rod Insertion

The ARI is designed to provide a parallel path for actuation of the scram valves, which results in control rod insertion. ARI consists of the redundant valves on the scram valve pilot air headers that are actuated by the RRCS logic. The RRCS logic is designed so that successful ARI performance will avoid subsequent ATWS mitigation action (feedwater runback and SLCS initiation).

Additional information on the ARI system is contained in Sections 7.1 and 7.6.

15.8.3.3 Recirculation Pump Trip

The recirculation pump motors are tripped by the RRCS logic. The purpose of the RPT is to reduce core flow and create core voids to decrease power generation, thus limiting any power or pressure disturbance. The RPT function is single failure proof and is provided with in service test capability (except for the action of the final breakers).

Additional information on the RPT function of the RRCS is contained in Sections 7.1 and 7.6.

15.8.3.4 Feedwater Runback

Upon the receipt of a high pressure signal from the RRCS and after a specified time-delay, if core power is not reduced as evidenced by the APRMs reading downscale (not low water level), feedwater flow would be automatically limited by the RRCS, thereby reducing power and steam discharge to the suppression pool. The system provides for manual operation to be returned to the operator after a time-delay to allow an increase in feedwater flow if needed.

Additional information on the feedwater runback function of the RRCS is contained in Sections 7.1 and 7.6.

15.8.3.5 Standby Liquid Control System

The SLCS is automatically actuated by the RRCS or manually initiated by an operator in the main control room upon indication of a failure to scram and in accordance with plant operating procedures. The system is designed to inject sodium pentaborate solution through a core spray sparger. Simultaneous operation of at least two of the three pumps at full capacity allows adequate margin to control the power production. The system can be periodically tested without affecting its ability to respond to an actuation signal.

Additional information on the SLCS is provided in Sections 3.9, 7.1, 7.4, and 9.3.5.

15.8.3.6 Scram Discharge Volume

The SDV of the CRD system minimizes the potential for a common mode failure of the scram function. Redundant instrument volume water level sensors for the CRDs and instrument line piping ensure the availability of sufficient capacity to receive water from a full reactor scram. The design employs redundant Class 1E sensors and redundant vent and drain valves. Performance of the safety functions is assured in the event of a single active failure or the bypass of the sensors during plant operation.

Additional information on the SDV is contained in Section 4.6. Instrumentation is described in Chapter 7.

15.8.3.7 HPCI Flow Split Modification

LGS, although a BWR/4, shares some design characteristics in common with BWR/5 reactors. The HPCI system has been split into two components. About one-half of the flow goes into the core spray sparger, similar to the high pressure core spray system of a BWR/5. The remaining portion is routed to the feedwater sparger as is typical of BWR/4s. Also, as mentioned in Section

15.8.3.5, the SLCS flow is injected via the core spray sparger, which is also typical of BWR/5s. The flow split modification maintains proper HPCI flow mixing with the reactor coolant and avoids encountering localized fuel channel hydrodynamic effects that might cause local power peaking, if an adjacent control rod should fail to fully insert. Drawing E41-1020-G-002 shows flow rates at the ATWS condition.

The additional HPCI flow split equipment consist of cross-tie piping between the HPCI and feedwater injection lines, an MOV with associated control logic and equipment, and two flow balancing orifices as shown on drawings M-55 and M-56.

15.8.3.8 Steam Flow Induced Process Measurement Error

An additional steam flow induced process measurement error (SFIE) in the Level 3 (L3) scram was evaluated by GE in Reference 15.8-2 for the ATWS event and it was concluded that it is not affected by a change in the L3 analytical limit (AL) as there is no L3 function directly credited by the ATWS events. However since there is no scram there is bypass steam flow in the annular region outside the dryer, which causes an SFIE induced error in the L2 trip.

For the limiting A TWS events, the scenario involves pressurization due to the MSIV closure. The reactor isolation leads to a recirculation pump trip (ATWS APT) very early in the transient and the trip is usually reached at about the same time the MSIVs are full closed. The ATWS APT rapidly reduces power and steaming rate and is the key feature that reduces the steaming rate to be within the capacity of the Safety / Relief Valves. The post APT power level is on the order of 50 to 55% power and by the time the level is near the Level 2 AL, the power and steaming rate is below 50%.

With the reactor steaming rate reduced to 50%, the error will be significantly reduced, and the SFIE effect with be approximately 1/4 of the effect at rated conditions. This would reduce the SFIE of 6 inches, for example, at rated power to about 1.5 inches at these conditions. Since the RCIC / HPCI initiation at this water level for ATWS is not critical to the event mitigation, this error and delay to L2 is considered insignificant.
A small delay for the RCIC / HPCI initiation would be slightly beneficial as the water level would be lower during a portion of the transient and would result in a reduced reactor power and reduced steaming rate to the suppression pool.

The long-term mitigation of these events involves controlling water level to low levels in the vessel. Again the small error at these conditions (< 2 inches) is insignificant for water level control and power generation compared to the analysis.

Non-limiting ATWS events that may initiate the Level 2 ATWS-RPT or other L2 functions for ATWS would also be affected by L3 analytical limit error. An example would be the LOFW event. This event would result in recirculation runback associated with the loss of flow and low level (e.g., level 4). This would reduce the power and steaming rate. The power would also reduce due to the reduced subcooling associated with the loss of feedwater flow. The combined effect would reduce the error to approximately half of the condition at rated power (based on an estimated power and steaming rate reduced to 70% prior to level 2). As events that trip ATWS-RPT on low level are power and pressure reduction events, they do not challenge the ATWS acceptance criteria and therefore a low level ATWS APT delay due

to L3 scram error is not significant for compliance to the ATWS acceptance criteria. Therefore, the expected SFIE (approximately half of the error at rated conditions) will have no significant effect on the power and pressure events, and these events will remain far from limiting.

15.9 PLANT NUCLEAR SAFETY OPERATIONAL ANALYSIS (A SYSTEM LEVEL/QUALITATIVE-TYPE PLANT FMEA)

15.9.1 OBJECTIVES

The objectives of the nuclear safety operational analysis are listed below:

a. Essential Protective Sequences: Identify and demonstrate that the essential protection sequences needed to accommodate normal plant operations, anticipated and abnormal operational transients, and DBAs are available and adequate. Each event considered in Chapter 15 is further examined and analyzed. Specific essential protective sequences are identified. The appropriate sequence is discussed for all BWR operating modes.

b. Design Basis Adequacy: Identify and demonstrate that the safety design basis of the various structures, systems, or components needed to satisfy the plant essential protection sequences are appropriate, available, and adequate. Each protective sequence identifies the specific structures, systems, or components performing safety or power generation functions. Interrelationships between primary systems and secondary (or auxiliary equipment) in providing these functions are shown. The individual design bases (identified throughout the UFSAR for each structure, system, or component) are brought together by the analysis in this section. In addition to the individual equipment design bases, the plant-wide design bases are examined and presented here.

c. System Level/Qualitative-Type FMEA: Identify a system level/qualitative-type FMEA of essential protective sequences to show compliance with the single active component failure or single operator error criteria. Each protective sequence entry is evaluated relative to single active component failure or single operator error criteria. Safety classification aspects and interrelationships between systems are also considered.

d. NSOA Criteria Relative to Plant Safety Analysis: Identify the systems, equipment, or components' operational conditions and requirements which are essential to satisfy the nuclear safety operational criteria utilized in the Chapter 15 plant events.

e. Technical Specification Operational Basis: Establish limiting operating conditions, testing, and surveillance bases relative to plant Technical Specification operational requirements.

15.9.2 APPROACH TO OPERATIONAL NUCLEAR SAFETY

15.9.2.1 Classification of Plant Events

The specified measures of safety used in this analysis are referred to as "unacceptable consequences." They are analytically determinable limits on the consequences of different classifications of plant events. The NSOA is thus an evaluation oriented to "event consequence." Refer to Figure 15.9-1 for a description of the systematic process by which these unacceptable results are converted so as to conform to safety requirements.

15.9.2.2 NSOA Development

The following guidelines are used to develop the NSOA:

15.9.2.2.1 Scope and Classification Of Plant Events

The scope and classification of the situations analyzed include the following:

a. Normal Operations

Normal operations are those under planned conditions without significant abnormalities. Operations subsequent to an incident (transient, accident, or special event) are not considered planned operations until the procedures being followed or equipment being used are identical to those used during any one of the defined planned operations. Specific events are listed in Table 15.9-1.

b. Anticipated Operational Transients

Anticipated operational transients are deviations from normal conditions that are expected to occur with moderate frequency and, as such, the design should include capability to withstand the conditions without operational impairment. Included are incidents that result from a single operator error, a control malfunction. These and other incidents are listed in Table 15.9-2.

c. Abnormal Operational Transients

Abnormal operational transients are deviations from normal conditions that occur infrequently. The design should include a capability to withstand these conditions without operational impairment. Refer to Table 15.9-3 which lists events included within this classification.

d. Design Basis Accident

A DBA is an hypothesized accident, whose characteristics and consequences are utilized in the design of those systems and components pertinent to the preservation of radioactive material barriers and the restriction of radioactive material release from the barriers. The potential radiation exposures resulting from a DBA are greater than for any similar accident postulated from the same general accident assumptions. DBAs are listed in Table 15.9-4.

e. Special Events

Special events are postulated to demonstrate some special capability of the plant in accordance with NRC requirements. For analyzed events within this classification, see Table 15.9-5.

15.9.2.2.2 Safety and Power Generation

Safety functions include:

a. Accommodation of abnormal operational transients and postulated DBAs

b. Maintenance of containment integrity

c. Assurance of ECCS

d. Continuance of RCPB

Safety classified aspects are related to Regulatory Guide 1.183 and 10CFR50.67 dose limits, infrequent and low probability occurrences, single active component failure criteria, worst case operating conditions and initial assumptions, automatic (less than 10 minutes) corrective action, significant unacceptable dose and environmental effects, and the involvement of other coincident (mechanistic or nonmechanistic) plant and environmental situations.

Power generation classified considerations are related to continued plant power generation operation, equipment operational matters, component availability aspects, and long-term offsite public effects.

Power generation functions include:

a. Accommodation of planned operations and anticipated operational transients.

b. Minimization of radiological releases to appropriate levels.

c. Assurance of safe and orderly reactor shutdown and/or return to power generation operation.

d. Continuance of plant equipment design conditions to ensure long-term reliable operation.

Power generation is related to 10CFR20, 10CFR50, Appendix I, moderate and high probability occurrences, nominal operating conditions and initial assumptions, allowable immediate operator manual actions, and environmental effects.

15.9.2.2.3 Frequency of Events

Consideration of the frequency of the initial (or initiating) event is reasonably straightforward. Added considerations (e.g., further failures or operator errors) influence the classification grouping. The events in this Section are grouped according to initiating frequency occurrence. The imposition of additional failures necessitates further classification to a lower frequency category.

The introduction of single active component failure or single operator error into the examination of planned operation, anticipated operational transients, or abnormal operational transient evaluations has not been previously considered a design basis or evaluation prerequisite. It is included and provided here to demonstrate the plant's capability to accommodate this requirement.

15.9.2.2.4 Conservative Analysis Margins

The unacceptable consequences established in this section relative to public health and safety are in strict and conservative conformance to regulatory requirements.

15.9.2.2.5 Safety Function Definition

The essential protective sequences shown for an event in this section list the minimum structures and systems that are required to satisfy the single active component failure or single operator error evaluation of the event. Protective success paths other than those shown exist in some cases. Not all the events involve the same natural, environmental, or plant conditional assumptions. In Event 40, control rod-drop accident is not assumed to be associated with any SSE or OBE occurrence. Therefore, seismic safety function requirements are not considered for Event 40. Some of the safety function equipment associated with the Event 40 protective sequence are also capable of more limiting events, such as Event 42.

The primary containment may perform a safety function for some events (when uncontained radiological release would be unacceptable), but for other events, it may not be applicable (e.g., during refueling). The requirement to maintain the containment in postaccident recovery is needed to limit doses to less than 10CFR50.67 and Regulatory Guide 1.183 limits. After radiological sources are depleted with time, the further use of primary containment is unnecessary. Thus, the "time domain" and "need for" aspects of a function should be, and are, taken into account when evaluating events.

The operation of ESF equipment for normal operational events should not be misunderstood to mean that ESF equipment requirements apply to this event category. Also, the interpretation of the use of ESF single active component failure capable systems for anticipated operational transient protective sequences should not imply that these equipment requirements (seismic, redundancy, diversity, testable, IEEE, etc.) are appropriately required for anticipated operational transients.

15.9.2.2.6 Envelope and Actual Event Analyses

Study of the actual plant occurrences, their frequency, and their actual impact are reflected in their categorization in this section. This places the plant safety evaluations into a better perspective by focusing attention on the envelope analysis.

15.9.2.2.7 Analysis Consistency

Figure 15.9-2 illustrates three inconsistencies. Panel A shows the possible inconsistency resulting from operational requirements being placed on separated levels of protection for one event. If the second and sixth levels of protection are important enough to warrant operational requirements, then so are the third, fourth, and fifth levels. Panel B shows the possible inconsistency resulting from operational requirements being arbitrarily placed on some action thought to be important to safety. In the case shown, scram represents different protection levels for two similar events in one category; if the fourth level of protection for Event B is important enough to warrant an operational requirement, then so is the fourth level for Event A. Thus, to simply place operational requirements on all equipment needed for some action (scram, isolation, etc.) could be inconsistent and unreasonable if different protection levels are represented. Panel C shows the possible inconsistency resulting from operational requirements being placed on some arbitrary level of protection for any and all postulated events. Here, the

inconsistency is not recognizing and accounting for different event categories based upon cause or expected frequency of occurrence.

Inconsistencies of the types illustrated in Figure 15.9-2 are avoided in the NSOA by directing the analysis to event consequences oriented aspects. Analytical inconsistencies are avoided by treating all the events of a category under the same set of functional rules, by applying another set of functional rules to another category, and by having a consistent set of rules between categories. Thus, it is valid to compare the results of the analyses of the events in any one category and invalid to compare events of a different categories (with different rules). An example of this is the different rules (limits, assumptions, etc.) of accidents compared to anticipated transients.

15.9.2.3 Comprehensiveness of the Analysis

The method of analysis must be sufficiently comprehensive so that all plant hardware and the full range of plant operating conditions are considered. The tendency to be preoccupied with "worst cases" (those that appear to give the most severe consequences) is recognized; however, the protection sequences essential to lesser cases may be different (more or less restrictive) from the worst case sequence. To assure that operational and design basis requirements are defined and appropriate for all equipment essential to attaining acceptable consequences, all essential protection sequences must be identified for each of the plant safety events examined. Only in this way is a comprehensive level of safety attained. Thus, the NSOA is also protection sequence oriented.

15.9.2.4 Systematic Approach of the Analysis

In summary, the systematic method utilized in this analysis contributes to both the consistency and comprehensiveness of the analysis mentioned above. The desired characteristics representative of a systematic approach to selecting BWR operational requirements are as follows:

a. Specify measures of safety/unacceptable consequences.

b. Consider all normal operations.

c. Systematic event selection.

d. Common treatment analysis of all events of any one type.

e. Systematic identification of plant actions and systems essential to avoid unacceptable consequences.

f. Emergence of operational requirements and limits from system analysis.

Figure 15.9-1 illustrates the systematic process by which the operational and design basis nuclear safety requirements and technical specifications are derived. The process involves the evaluation of carefully selected plant events relative to the unacceptable consequences (specified measures of safety). Those limits, actions, systems, and components found to be essential to achieving acceptable consequences are the subjects of operational requirements.

15.9.2.5 Relationship of Nuclear Safety Operational Analysis to Safety Analyses of Chapter 15

One of the main objectives of the operational analysis is to identify all essential protection sequences and establish the detailed equipment conditions essential to satisfy the nuclear safety operational criteria. The spectrum of events examined in Chapter 15 represent a complete set of plant safety considerations. The main objective of the earlier analyses of Chapter 15 was to provide detailed worst case (limiting or envelope) analyses of plant events. The worst cases are correspondingly analyzed and treated in this section. However, here the frequency of occurrence, unacceptable consequences, assumption categories, etc are taken into account.

Tables 15.9-1 through 15.9-5 provide cross-correlation between the NSOA event, its protection sequence diagram, and its safety evaluation in Chapter 15.

15.9.2.6 Relationship Between NSOA and Operational Requirements, Technical Specifications, Design Bases, and Single Active Component Failure Aspects

By definition, an "operational requirement" is a requirement or restriction (limit) on either the value of a plant variable or the operability condition associated with a plant system. Such requirements must be observed during all modes of plant operation (not just at full power) to assure that the plant is operated safely to avoid unacceptable results. There are two kinds of operational requirements for plant hardware:

a. Limiting condition for operation: the required condition for a system while the reactor is operating in a specified state.

b. Surveillance requirements: the nature and frequency of tests required to ensure that the system is capable of performing its essential functions.

Operational requirements are systematically selected for one of two basic reasons:

a. To ensure that unacceptable consequences are mitigated following specified plant events by examining and challenging the system design.

b. To ensure the consequences of a transient or accident are acceptable with the existence of a single active component failure or single operator error.

The individual structures and systems that perform a safety function are required to do so under design basis conditions including environmental considerations and under single active component failure assumptions. The NSOA confirms the previous examination of the individual equipment (Section 15.0.3) requirement conformance analyses.

15.9.2.7 Unacceptable Consequences Criteria

Tables 15.9-6 through 15.9-10 identify the unacceptable consequences associated with different event categories. In order to prevent or mitigate them, they are recognized as the major bases for identifying system operational requirements as well as the bases for all other safety analysis criteria throughout the UFSAR.

15.9.2.8 General Nuclear Safety Operational Criteria

The following general nuclear safety operational criteria are used to select operational requirements:

Applicability	Nuclear Safety Operational Criteria
Planned operation anticipated, abnormal operational transients, DBAs, additional special plant capability events	The Plant shall be operated so as to avoid unacceptable consequences.
Anticipated and abnormal operational transients and DBA.	The plant shall be operated such that no single active component failure can prevent the safety actions essential to avoid the unacceptable consequences associated with anticipated or abnormal operational transients or DBAs. However, this requirement is not applicable during structure, system, or component repair if the availability of the safety action is maintained either by restricting the allowable repair time or by more frequent testing of a redundant structure, system, or component.

The unacceptable consequences associated with the different categories of plant operation and events are dictated by:

a. Probability of occurrence.

b. Allowable limits (per the probability) related to radiological, structural, environmental, etc., aspects.

c. Coincidence of other related or unrelated disturbances.

d. Time domain of event and consequences consideration.

15.9.3 METHOD OF ANALYSIS

15.9.3.1 General Approach

The NSOA is performed on the plant as designed. The end products of the analysis are the nuclear safety operational requirements and the restrictions on plant hardware and its operation that must be observed both to satisfy the nuclear safety operational criteria and to show compliance of the plant safety and power generation systems with plant wide requirements. Figure 15.9-1 shows the process used in the analysis. The following inputs are required for the analysis of specific plant events:

a. Unacceptable consequences criteria (Section 15.9.2.7).

b. General nuclear safety operational criteria (Section 15.9.2.8).

c. Definition of BWR operating states (Section 15.9.3.2).

d. Selection of events for analysis (Section 15.9.3.3).

e. Guidelines for event analysis (Section 15.9.3.5).

With the above information, each selected event can be evaluated systematically to determine the actions, systems, and limits essential to avoid unacceptable consequences. The essential plant components and limits so identified are then considered to be in agreement with, and subject to, nuclear operational design basis requirements and Technical Specification restrictions.

15.9.3.2 BWR Operating States

The four BWR operating states in which the reactor can exist are defined in Section 15.9.6.2.4 and summarized in Table 15.9-11.

The main objective in selecting operating states is to divide the BWR operating spectrum into sets of initial conditions to facilitate consideration of various events in each state.

Each operating state includes a wide spectrum of values for important plant parameters. Within each state, these parameters are considered over their entire range to determine the limits on their values necessary to satisfy the nuclear safety operational criteria. Such limitations are presented in the sections of the UFSAR that describe the systems associated with the parameter limit. The plant parameters to be considered in this manner include the following:

a. Reactor coolant temperature

b. Reactor vessel water level

c. Reactor vessel pressure

d. Reactor vessel water quality

e. Reactor coolant forced circulation flow rate

f. Reactor power level (thermal and neutron flux)

g. Core neutron flux distribution

h. Feedwater temperature

i. Primary containment temperature and pressure

j. Suppression pool water temperature and level

k. Control rod worth

15.9.3.3 Selection of Events for Analysis

15.9.3.3.1 Normal Operations

Operations subsequent to an incident (transient, accident, or additional plant capability event) are not considered planned operations until the actions taken or equipment used in the plant are identical to those that would be used had the incident not occurred. As defined, planned operations can be considered in the following chronological sequence: refueling outage, achieving criticality, heatup, power operation, achieving shutdown, cooldown, refueling outage.

For the analyses in Section 15.9, the normal operations events are defined as follows:

a. Refueling Outage: Includes all the planned operations associated with a normal refueling outage except those tests in which the reactor is taken critical and returned to the shutdown condition. The following planned operations are included in a refueling outage:

    1. Planned, physical movement of core components (fuel, control rods, etc.)

    2. Refueling test operations (except criticality and shutdown margin tests)

    3. Planned maintenance

    4. Required inspection

b. Achieving Criticality: Includes all plant actions normally accomplished in bringing the plant from a condition in which all control rods are fully inserted to a condition in which nuclear criticality is achieved and maintained.

c. Heatup: Begins when achieving criticality ends and includes all plant actions normally accomplished in approaching nuclear system rated temperature and pressure by using nuclear power (reactor critical). Heatup extends through warmup and synchronization of the main turbine-generator.

d. Power Operation: Begins when heatup ends and includes continued plant operation at power levels in excess of heatup power.

e. Achieving Shutdown: Begins when the main generator is unloaded and includes all plant actions normally accomplished in achieving nuclear shutdown (more than one rod subcritical) following power operation.

f. Cooldown: Begins when achieving nuclear shutdown ends and includes all plant actions normal to the continued removal of decay heat and the reduction of reactor temperature and pressure.

The exact point at which some of the planned operations end and others begin cannot be precisely determined. It will be shown later that such precision is not required, because the protection requirements are adequately defined in passing from one state to the next. Dependence of several planned operations on the one rod subcritical condition provides an exact point on either side of which protection (especially scram) requirements differ. Thus, where a precise boundary between planned operations is needed, the definitions provide the needed precision.

Together, BWR operating states and planned operations define the full spectrum of conditions from which transients, accidents, and special events are initiated. The BWR operating states define only the physical condition (pressure, temperature, etc.) of the reactor; the planned operations define the condition of the plant. The separation of physical conditions from the operation being performed is deliberate and facilitates careful consideration of all possible initial conditions from which incidents may occur.

15.9.3.3.2 Anticipated Operational Transients

To select anticipated operational transients, eight nuclear system parameter variations are considered as potential initiating causes of threats to the fuel and the RCPB. The parameter variations are as follows:

a. Reactor coolant pressure increase

b. Reactor coolant (moderator) temperature decrease

c. Control rod withdrawal

d. Reactor coolant inventory decrease

e. Reactor coolant flow decrease

f. Reactor coolant flow increase

g. Reactor coolant temperature increase

h. Reactor coolant inventory increase

These parameter variations, if uncontrolled, could result in damage to the reactor fuel or RCPB or both. A nuclear system pressure increase threatens to rupture the RCPB from internal pressure. A pressure increase also collapses voids in the moderator, causing an insertion of positive reactivity that threatens fuel damage as a result of overheating. A reactor coolant temperature decrease results in an insertion of positive reactivity as density increases. This could lead to fuel overheating. Positive reactivity insertions are possible from causes other than nuclear system pressure or moderator temperature changes; such reactivity insertions threaten fuel damage caused by overheating. Both reactor coolant inventory decrease and a reduction in coolant flow through the core threaten the integrity of the fuel. An increase in coolant flow through the core reduces the void content of the moderator and results in an insertion of positive reactivity. Core coolant temperature increase threatens the integrity of the fuel; such a variation could be the result of a heat exchanger malfunction during operation in the shutdown cooling mode. An excess of coolant inventory could be the result of malfunctioning water level control equipment; such a malfunction can result in a turbine trip, which causes an expected increase in nuclear system pressure and power.

Anticipated operational transients are defined as transients resulting from an single active component failure or single operator error that can be reasonably expected (moderate probability of occurrence, once per day to once in 20 years) during any mode of plant operation. Examples of single operational failures or operator errors in this range of probability are:

a. Opening or closing any single valve (a check valve is not assumed to close against normal flow).

b. Starting or stopping any single component.

c. Malfunction or maloperation of any single control device.

d. Any single electrical failure.

e. Any single operator error.

An operator error is defined as an active deviation from nuclear plant standard operating practices. A single operator error is the set of actions that is a direct consequence of a single reasonably expected erroneous decision. The set of actions is limited as follows:

a. Those that could be performed by only one person.

b. Those that would have constituted a correct procedure had the initial decision been correct.

c. Those that are subsequent to the initial operator error and that affect the designed operation of the plant, but are not necessarily directly related to the operator error.

Examples of single operator errors are as follows:

a. An increase in power above the established flow control power limits by control rod withdrawal in the specified sequences while observing all normal core power distribution related fuel thermal limits.

b. The selection and complete withdrawal of a single control rod out-of-sequence.

c. An incorrect calibration of an APRM.

d. Manual isolation of the main steam lines caused by operator misinterpretation of an alarm or indication.

The various types of single active component failure or single operator error are applied to various plant systems, with consideration for a variety of plant conditions, to discover events directly resulting in an undesired parameter variation. Once discovered, each event is evaluated for the threat it poses to the integrity of the radioactive material barriers.

15.9.3.3.3 Abnormal Operational Transients

To select abnormal operational transients, eight nuclear system parameter variations are considered as potential initiating causes of gross corewide fuel failures and threats to the RCPB. The parameter variations are as follows:

a. Reactor coolant pressure increase

b. Reactor coolant (moderator) temperature decrease

c. Control rod withdrawal

d. Reactor coolant inventory decrease

e. Reactor coolant flow decrease

f. Reactor coolant flow increase

g. Reactor coolant temperature increase

h. Reactor coolant inventory increase

The eight parameter variations listed above include all effects within the nuclear system caused by abnormal operational transients that threaten gross corewide reactor fuel integrity, or seriously affect the reactor coolant pressure boundary. Variation of any one parameter may cause a change in another listed parameter; however, for analysis purposes, threats to barrier integrity are evaluated by groups according to the parameter variation originating the threat.

Abnormal operational transients are defined as incidents resulting from single or multiple equipment failures and/or single or multiple operator errors that are not reasonably expected (less than one event in 20 years to one in 100 years) during any mode of plant operation. Examples of single or multiple operational failures and/or single or multiple operator errors are:

a. Failure of major power generation equipment components.

b. Multiple electrical failures.

c. Multiple operator errors.

d. Combinations of equipment failure and an operator error.

Operator error is defined as an active deviation from nuclear plant standard operating practices. A multiple operator error is the set of actions that is a direct consequence of several unexpected erroneous decisions.

An example of multiple operator errors is inadvertent loading of a fuel assembly in an improper position and operating with the fuel assembly in an improper position.

The various types of single errors and/or single malfunctions are applied to various plant systems, with consideration for a variety of plant conditions, to discover events directly resulting in an undesired parameter variation. Once discovered, each event is evaluated for the threat it poses to the integrity of the various radioactive material barriers.

15.9.3.3.4 Design Basis Accidents

Accidents are defined as hypothesized events that affect the radioactive material barriers and are not expected during plant operations. These are plant events, equipment failures, and combinations of initial conditions that are of extremely low probability (once in 100 years to once in 10,000 years). The postulated accident types considered are as follows:

a. Mechanical failure of a single component leading to the release of radioactive material from one or more barriers. The components referred to here are not those that act as radioactive material barriers. An example of mechanical failure is the breakage of the coupling between a CRD and the control rod.

b. Arbitrary rupture of any single pipe up to, and including, complete severance of the largest pipe in the RCPB. This kind of accident is considered only under conditions in which the nuclear system is pressurized.

For purposes of analysis, accidents are categorized as those events that result in releasing radioactive material (Tables 15.9-4 and 15.9-5):

a. From the fuel with the RCPB and reactor enclosure initially intact (Event 40).

b. Directly to the primary containment (Event 42).

c. Directly to the reactor, or turbine enclosures, with the primary containment initially intact (Events 40, 43, 44, 45, 50).

d. Directly to the reactor enclosure with the primary containment not intact (Events 41, 50).

e. Directly to the spent fuel-containing facilities (Events 41, 50).

f. Directly to the turbine enclosure (Events 46, 47).

g. Directly to the environs (Events 48, 49).

The effects of various accident types are investigated, with consideration for the full spectrum of plant conditions, to examine events that result in the release of radioactive material.

15.9.3.3.5 Special Events

A number of additional events are evaluated to demonstrate plant capabilities relative to special arbitrary nuclear safety criteria. These special events involve extremely low probability situations. As an example, the adequacy of the redundant reactivity control system is demonstrated by evaluating the special event: "reactor shutdown without control rods." Another similar example, the capability to perform a safe shutdown from outside the main control room, is demonstrated by evaluating the special event: "reactor shutdown from outside the main control room."

15.9.3.4 Applicability of Events to Operating States

The first step in performing an operational analysis for a given incident (transient, accident, or special event) is to determine in which operating states the incident can occur. An incident is considered applicable within an operating state if the incident can be initiated from the physical conditions that characterize the operating state. Applicability of the "normal operations" to the operating states follows from the definitions of planned operations. A planned operation is considered applicable within an operating state if the planned operation can be conducted when the reactor exists under the physical conditions defining the operating state.

15.9.3.5 Guidelines for Event Analysis

Functional guidelines followed in performing single active component failure, operational, and design basis analyses for the various plant events are listed below:

a. An action, system, or limit shall be considered essential only if it is essential to avoid an unacceptable result or satisfy the nuclear safety operational criteria.

b. The full range of initial conditions (as defined in (c) below) shall be considered for each event analyzed so that all essential protection sequences are identified. Consideration is not limited to worst cases, because lesser cases sometimes may require more restrictive actions or systems different from those of the worst cases.

c. The initial conditions for transients, accidents, and special events shall be limited to conditions that would exist during planned operations in the applicable operating state.

d. For normal operations, consideration shall be made only for actions, limits, and systems essential to avoid the unacceptable consequences during operation in that state (as opposed to transients, accidents, and special events that are followed through to completion). Normal operations are treated differently from other events, because the transfer from one state to another during planned operations is deliberate. For events other than normal operations, the transfer from one state to another may be unavoidable.

e. Limits shall be derived only for those essential parameters that are continuously available for monitoring. Parameter limits associated with the required performance of an essential system are considered to be included in the requirement for the operability of the system. Limits on frequently monitored process parameters are called "envelope limits," and limits on parameters associated with the operability of a safety system are called "operability limits." Systems associated with the control of the envelope parameters are considered nonessential if it is possible to place the plant in a safe condition without using the system in question.

f. For transients, accidents, and special events, consideration shall be made for the entire duration of the event and aftermath until some planned operation is resumed. Normal operation is considered resumed when the procedures being followed or equipment being used are identical to those used during any one of the defined planned operations. Where extended core cooling is an immediate integral part of the event, it will be included in the protection sequence. Where it may be an

eventual part of the event, it will not be directly added but can be implied to be available.

g. Credit for operator action shall be taken on a case-by- case basis depending on the conditions that would exist at the time operator action would be required. Because transients, accidents, and special events are considered through the entire duration of the event until normal operation is resumed, manual operation of certain systems is sometimes required following the more rapid or automatic portions of the event. Credit for operator action is taken only when the operator can reasonably be expected to accomplish the required action under the existing conditions.

h. For transients, accidents, and special events, only those actions, limits, and systems shall be considered essential for which there arises a unique requirement as a result of the event. For instance, if a system that was operating prior to the event (during planned operation) is to be employed in the same manner following the event, and if the event did not affect the operation of the system, then the system would not appear on the protection sequence diagram.

i. The operational analyses shall identify all the support or auxiliary systems essential to the functioning of the front-line safety systems. Safety system auxiliaries whose failure results in safe failure of the front line safety systems shall be considered nonessential.

j. A system or action that plays a unique role in the response to a transient, accident, or special event shall be considered essential unless (1) the effects of the system or action are not included in the detailed analysis of the event or (2) unless failure of the system or action results in an overall event probability less frequent than that within which the initiating event is categorized.

15.9.3.6 Steps in an Operational Analysis

All information needed to perform an operational analysis for each plant event has been presented (Figure 15.9-1). The procedure followed in performing an operational analysis for a given event (selected according to the event selection criteria) is as follows:

a. Determine the BWR operating states in which the event is applicable.

b. Identify all the essential protection sequences (safety actions and front-line safety systems) for the event in each applicable operating state.

c. Identify all the auxiliary systems essential to the functioning of the front-line safety systems.

The preceding three steps are performed in Section 15.9.6. To derive the operational requirements and Technical Specifications for the individual components of a system included in any essential protection sequence, the following steps are taken:

a. Identify all the essential actions within the system (intrasystem actions) necessary for the system to function to the degree necessary to avoid the unacceptable consequences.

b. Identify the minimum hardware conditions necessary for the system to accomplish the minimum intrasystem actions.

c. If the single failure criterion applies, identify the additional hardware conditions necessary to achieve the plant safety actions (scram, pressure relief, isolation, cooling, etc.) in spite of single failures. This step gives the nuclear safety operational requirements for the plant components so identified.

d. Identify surveillance requirements and allowable out-of- service times for the essential plant hardware (Section 15.9.5).

e. Simplify the operational requirements determined in steps (c) and (d), so that Technical Specifications may be obtained that encompass the true operational requirements and are easily used by plant operations and management personnel.

15.9.4 DISPLAY OF OPERATIONAL ANALYSIS RESULTS

15.9.4.1 General

To fully identify and establish the requirements, restrictions, and limitations that must be observed during plant operation, plant systems and components must be related to the needs for their actions in satisfying the nuclear safety operational criteria. This section displays these relationships in a series of block diagrams.

Tables 15.9-1 through 15.9-5 and Table 15.9-11 indicate in which operating states each event is applicable. For each event, a block diagram is presented showing the conditions and systems required to achieve each essential safety action. The block diagrams show only those systems necessary to provide the safety actions so that the nuclear safety operational and design basis criteria are satisfied. The total plant capability to provide a safety action generally is not shown; only the minimum capability essential to satisfy the operational criteria is shown. Only enough protective equipment is cited in the diagram to provide the necessary action. Many events can utilize many more paths to success than are shown. Operational analyses involve the minimum equipment needed to prevent or avert an unacceptable consequence. Thus, the diagrams depict all essential protection sequences for each event with the least amount of protective equipment needed. Once all of the these protection sequences are identified in block diagram form, system requirements are derived by considering all events in which the particular system is employed. The analysis considers the following conceptual aspects:

a. The BWR operating state.

b. Types of operations or events that are possible within the operating state.

c. Relationships of certain safety actions to the unacceptable consequences and to specific types of operations and events.

d. Relationships of certain systems to safety actions, and to specific types of operations and events.

e. Supporting or auxiliary systems essential to the operation of the front-line safety systems.

f. Functional redundancy. (The single failure criterion applied at the safety action level. This is, in effect, a qualitative system level, FMEA-type analysis.)

Each block in the sequence diagrams represents a finding of essentiality for the safety action, system, or limit under consideration. Essentiality in this context means that the safety action, system, or limit is needed to satisfy the nuclear safety operational criteria. Essentiality is determined through an analysis in which the safety action, system, or limit being considered is completely disregarded in the analyses of the applicable operations or events. If the nuclear safety operational criteria are satisfied without the safety action, system, or limit, then the safety action, system, or limit is not essential, and no operational nuclear safety requirement would be indicated. When disregarding a safety action, system, or limit results in violating one or more nuclear safety operational criteria, the safety action, system, or limit is considered essential, and the resulting operational nuclear safety requirements can be related to specific criteria and unacceptable consequences.

15.9.4.2 Protection Sequence and Safety System Auxiliary Diagrams

Block diagrams illustrate essential protection sequences for each event requiring unique safety actions. These protection sequence diagrams show only the required front-line safety systems. The format and conventions used for these diagrams are shown in Figure 15.9-4.

The auxiliary systems essential to the correct functioning of the front-line safety systems are shown on safety system auxiliary diagrams. The format used for these diagrams is shown in Figure 15.9-5. The diagram indicates that auxiliary systems A, B, and C are required for proper operation of front-line safety system X.

With these three types of diagrams, it is possible to determine for each system the detailed functional requirements and conditions to be observed regarding system hardware in each operating state. The detailed conditions to be observed regarding system hardware include such nuclear safety operational requirements as test frequencies and the number of components that must be operable.

15.9.5 BASES FOR TECHNICAL SPECIFICATIONS

15.9.5.1 Surveillance Test Requirements

After the nuclear safety systems and engineered safeguards have been identified by applying the nuclear safety operational criteria, surveillance requirements are established for the safety systems. The purpose of surveillance requirements is to assure, at appropriate intervals, that a failure or failures have not occurred in a safety system while that system is in the standby mode. The appropriate surveillance interval is determined by consideration of the effect of system unavailability on plant safety and the effect of testing on plant safety.

15.9.5.2 Limiting Condition for Operation

Required operating conditions for safety systems, including number of operable channels, minimum or maximum setpoints, and other performance factors are established. If a safety system is found to be in a Limiting Condition for Operation, specified corrective action must be taken.

15.9.5.3 Maximum Allowable Out-of-Service Time

When a safety system does not meet the specified Limiting Condition for Operation, the system should be repaired, retested, and returned to service as quickly as possible consistent with good maintenance practice. A maximum allowable out-of-service time is specified, after which time the specified corrective action must be taken to place the plant in a safer mode of operation. If the nature of the failed condition is such that it is apparent that repair will require longer than the allowable out-of-service time, the specified action should be taken immediately. The maximum allowable out-of-service time is determined by consideration of the effect of the out-of-service condition on plant safety and the effect of the specified corrective action on plant safety. As a general rule, the reactor should not be scrammed for an out-of-service condition, and the maximum allowable out-of-service time should be at least 12 hours if the specified corrective action is plant shutdown. Other considerations include the need for a reasonable time for repair based on experienced or projected mean time to repair and resources involved in taking the specified corrective action.

15.9.6 OPERATIONAL ANALYSES

Results of the operational analyses are discussed in the following paragraphs and displayed in Figures 15.9-7 through 15.9-12 and Tables 15.9-1 through 15.9-5.

15.9.6.1 Safety System Auxiliaries

Figures 15.9-7 and 15.9-8 show the safety system auxiliaries essential to the functioning of each front-line safety system.

15.9.6.2 Normal Operations

15.9.6.2.1 General

Requirements for the normal or planned operations normally involve limits (L) on certain key process variables and restrictions (R) on certain plant equipment. The control block diagrams for each operating state (Figures 15.9-9 through 15.9-12) show only those controls necessary to avoid unacceptable safety consequences 1-1 through 1-4 of Table 15.9-6.

Following is a description of the planned operations (Events 1 through 6) as they pertain to each of the four operating states. The description of each operating state contains a definition of that state, a list of the planned operations that apply to that state, and a list of the safety actions that are required to avoid the unacceptable safety consequences.

15.9.6.2.2 Event Definitions

a. Event 1 - Refueling Outage

Refueling outage includes all the planned operations associated with a normal refueling outage except those tests in which the reactor is made critical and returned to the shutdown condition. The following planned operations are included in refueling outage:

1. Planned, physical movement of core components (fuel, control rods, etc.)

2. Refueling test operations (except criticality and shutdown margin tests)

3. Planned maintenance

4. Required inspection

b. Event 2 - Achieving Criticality

Achieving criticality includes all the plant actions normally accomplished in bringing the plant from a condition in which all control rods are fully inserted to a condition in which nuclear criticality is achieved and maintained.

c. Event 3 - Heatup

Heatup begins where achieving criticality ends and includes all plant actions normally accomplished in approaching nuclear system-rated temperature and pressure by using nuclear power (reactor critical). Heatup extends through warmup and synchronization of the main turbine-generator.

d. Event 4 - Power Operation

Power operation begins where heatup ends and includes plant operation at power levels in excess of heatup power and at steady-state operation. It also includes plant maneuvers such as:

1. Electrical load reduction and recoveries

2. Electrical grid frequency control adjustment

3. Control rod movements

4. Power generation surveillance testing involving:

   (a) Turbine stop valve closing

   (b) Turbine control valve adjustments

   (c) MSIV exercising

e. Event 5 - Achieving Shutdown

Achieving shutdown begins where the main generator is unloaded and includes all plant actions normally accomplished in achieving nuclear shutdown (more than one rod subcritical) following power operation.

f. Event 6 - Reactor Cooldown

Cooldown begins where achieving shutdown ends and includes all plant actions normal to the continued removal of decay heat and the reduction of nuclear system temperature and pressure.

15.9.6.2.3 Required Safety Actions/Related Unacceptable Consequences

The following paragraphs describe the safety actions for planned operations. Each description includes a selection of the operating states that apply to the safety action, the plant system affected by limits or restrictions, and the unacceptable consequence that is avoided. The four operating states are defined in Table 15.9-11. The unacceptable consequences criteria are tabulated in Table 15.9-6.

15.9.6.2.3.1 Radioactive Material Release Control

Radioactive materials may be released to the environs in any operating state; therefore, radioactive material release control is required in all operating states. Because of the significance of preventing excessive release of radioactive materials to the environs, this is the only safety action for which monitoring systems are explicitly shown. Limits are expressed on the gaseous, liquid, and solid radwaste systems, so that the planned releases of radioactive materials comply with the limits given in 10CFR20, 10CFR50, and 10CFR71 (related unacceptable safety result 1-1).

15.9.6.2.3.2 Core Coolant Flow Rate Control

In State D, when above approximately 10% rated power, the core coolant flow rate must be maintained above certain minimums (i.e., limited) to maintain the integrity of the fuel cladding (1-2) and ensure the validity of the plant safety analysis (1-4).

15.9.6.2.3.3 Core Power Level Control

The plant safety analyses of accidental positive reactivity additions have assumed as an initial condition that the neutron source level is above a specified minimum. Because a significant positive reactivity addition can only occur when the reactor is less than one rod subcritical, the assumed minimum source level need be observed only in States B and D. The minimum source level assumed in the analyses has been related to the counts/sec readings on the SRMs; thus, this minimum power level limit on the fuel is expressed as a required SRM count level. Observing the limit ensures the validity of the plant safety analysis (1-4). The count rate limit is conservatively applied to the ALL RODS INSERTED condition prior to initial control rod withdrawal. Any expected ALL RODS INSERTED count rate within the SRM monitoring range will fully satisfy the safety analysis criteria for noncritical initiating conditions. Maximum core power limits are also expressed for operating States B and D to maintain fuel integrity (1-2) and remain below the maximum power levels assumed in the plant safety analysis (1-4).

15.9.6.2.3.4 Core Neutron Flux Distribution Control

Core neutron flux distribution must be limited in State D; otherwise, core power peaking could result in fuel failure (1-2). Additional limits are expressed in this state, because the core neutron flux distribution must be maintained within the envelope of conditions considered by plant safety analysis (1-4).

15.9.6.2.3.5 Reactor Vessel Water Level Control

In any operating state, the reactor vessel water level could, unless controlled, drop to a level that will not provide adequate core cooling; therefore, reactor vessel water level control applies to all operating states. Observation of the RPV water level limits protects against fuel failure (1-2) and ensures the validity of the plant safety analysis (1-4).

15.9.6.2.3.6 Nuclear System Pressure Control

System pressure control is not needed in States A and B, because vessel pressure cannot be increased above atmospheric pressure. In State C, a limit is expressed on the reactor vessel to ensure that it is not hydrostatically tested until the temperature is above the NDTT plus 60°F; this prevents excessive stress (1-3). Also, in States C and D a limit is expressed on the RHR system to ensure that it is not operated in the shutdown cooling mode when the RPV pressure is greater than the RHR shutdown cooling interlock pressure; this prevents excessive stress (1-3). In States C and D, a limit on the RPV pressure is necessitated by the plant safety analysis (1-4).

15.9.6.2.3.7 Nuclear System Temperature Control

In operating States C and D, a limit is expressed on the reactor vessel to prevent the reactor vessel head bolting studs from being in tension when the temperature is less than the minimum bolt-up temperature to avoid excessive stress (1-3) on the reactor vessel flange. This limit does not apply in States A and B, because the head will not be bolted in place during criticality tests or refueling. In all operating states, a limit is expressed on the reactor vessel to prevent an excessive rate of change of the reactor vessel temperature to avoid excessive stress (1-3). In States C and D, where it is planned operation to use the feedwater system, a limit is placed on the reactor fuel, so that the feedwater temperature is maintained within the envelope of conditions considered by the plant safety analysis (1-4). For State D, a limit is placed on the temperature difference between the recirculation system and the reactor vessel to prevent the starting of the recirculation pumps when a large differential temperature exists. This operating restriction and limit prevents excessive stress in the reactor vessel (1-3).

15.9.6.2.3.8 Nuclear System Water Quality Control

In all operating states, water of improper chemical quality could produce excessive stress as a result of chemical corrosion (1-3). Therefore, a limit is placed on reactor coolant chemical quality in all operating states. For all operating states where the nuclear system can be pressurized (States C and D), an additional limit on reactor coolant activity ensures the validity of the analysis of the main steam line break accident (1-4).

15.9.6.2.3.9 Nuclear System Leakage Control

Because excessive nuclear system leakage could occur only while the reactor vessel is pressurized, limits are applied only to the reactor vessel in States C and D. Observing these limits prevents vessel damage due to excessive stress (1-3) and ensures the validity of the plant safety analysis (1-4).

15.9.6.2.3.10 Core Reactivity Control

In State A, during refueling outages, a limit is imposed on core loading (fuel) to ensure that core reactivity is maintained within the envelope of conditions considered by the plant safety analysis (1-4). In all states, limits are imposed on the control rod drive system to ensure adequate control of core reactivity, so that core reactivity remains within the envelope of conditions considered by the plant safety analysis (1-4).

15.9.6.2.3.11 Control Rod Worth Control

Any time the reactor is not shut down and is generating less than the low power setpoint (State D), a limit is imposed on the control rod pattern to ensure that control rod worth is maintained within the envelope of conditions considered by the analysis of the control rod-drop accident (1-4).

15.9.6.2.3.12 Refueling Restriction

By definition, planned operation Event 1 (refueling outage) applies only to State A. Observing the restrictions on the reactor fuel and on the operation of the CRD system within the specified limit maintains plant conditions within the envelope considered by the plant safety analysis (1-4).

15.9.6.2.3.13 Primary Containment Pressure and Temperature Control

In States C and D, limits are imposed on the primary containment pressure and suppression pool temperature to maintain pressure and temperature within the envelope considered by plant safety analysis (1-4). These limits ensure an environment in which instruments and equipment can operate correctly within the drywell. Limits on the pressure-suppression pool apply to the water temperature and water level to ensure that it has the capability of absorbing the energy discharged during an SRV blowdown or a LOCA.

15.9.6.2.3.14 Stored Fuel Shielding, Cooling, and Reactivity Control

Because both new and spent fuel will be stored during all operating states, stored fuel shielding, cooling, and reactivity control apply to all operating states. Limits are imposed on the spent fuel pool storage positions, water level, fuel handling procedures, and water temperature. Observing the limits on fuel storage positions ensures that spent fuel reactivity remains within the envelope of conditions considered by the plant safety analysis (1-4). Observing the limits on water level ensures shielding in order to maintain conditions within the envelope of conditions considered by the plant safety analysis (1-4), and provides the fuel cooling necessary to avoid fuel damage (1-2). Observing the limit on water temperature avoids excessive fuel pool stress (1-3).

15.9.6.2.4 Operational Safety Evaluations

a. State A

In State A, the reactor is in a shutdown condition, the vessel head is off, and the vessel is at atmospheric pressure. The applicable events for planned operations are refueling outage, achieving criticality, and cooldown (Events 1, 2, and 6, respectively).

Figure 15.9-9 shows the necessary safety actions for planned operations, corresponding plant systems, and the event for which these actions are necessary. As indicated in the diagram, the required safety actions are as follows:

1. Radioactive material release control

2. Reactor vessel water level control

3. Nuclear system temperature control

4. Nuclear system water quality control

5. Core reactivity control

6. Refueling restrictions

7. Stored fuel shielding, cooling, and reactivity control

b. State B

In State B, the reactor vessel head is off, the reactor is not shutdown, and the vessel is at atmospheric pressure. Applicable planned operations are achieving criticality and shutdown (Events 2 and 5, respectively).

Figure 15.9-10 relates the necessary safety actions for planned operations, plant systems, and the event for which the safety actions are necessary. The required safety actions for planned operation in State B are as follows:

1. Radioactive material release control

2. Core power level control

3. Reactor vessel water level control

4. Nuclear system temperature control

5. Nuclear system water quality control

6. Core reactivity control

7. Rod worth control

8. Stored fuel shielding, cooling, and reactivity control

c. State C

In State C, the reactor vessel head is on and the reactor is shut down. Applicable planned operations are achieving criticality and cooldown (Events 2 and 6, respectively).

Sequence diagrams relating safety actions for planned operations, plant systems, and applicable events are shown in Figure 15.9-11. The required safety actions for planned operation in State C are as follows:

1. Radioactive material release control

2. Reactor vessel water level control

3. Nuclear system pressure control

4. Nuclear system temperature control

5. Nuclear system water quality control

6. Nuclear system leakage control

7. Core reactivity control

8. Primary containment pressure and temperature control

9. Stored fuel shielding, cooling, and reactivity control

d. State D

In State D, the reactor vessel head is on and the reactor is not shut down. Applicable planned operations are achieving criticality, heatup, power operation, and shutdown (Events 2, 3, 4, and 5, respectively).

Figure 15.9-12 relates safety actions for planned operations, corresponding plant systems, and events for which the safety actions are necessary. The required safety actions for planned operation in State D are as follows:

1. Radioactive material release control

2. Core coolant flow rate control

3. Core power level control

4. Core neutron flux distribution control

5. Reactor vessel water level control

6. Nuclear system pressure control

7. Nuclear system temperature control

8. Nuclear system water quality control

9. Nuclear system leakage control

10. Core reactivity control

11. Rod worth control

12. Primary containment pressure and temperature control

13. Stored fuel shielding, cooling, and reactivity control

15.9.6.3 Anticipated Operational Transients

15.9.6.3.1 General

The safety requirements and protection sequences for anticipated operational transients are described in the following paragraphs for Events 7 through 29. The protection sequence block diagrams show the sequence of front-line safety systems. (Figures 15.9-13 through 15.9-34 and 15.9-36). The auxiliaries for the front-line safety system are indicated in the auxiliary diagrams (Figures 15.9-7 and 15.9-8).

15.9.6.3.2 Required Safety Actions/Related Unacceptable Consequences

Safety actions for anticipated operational transients that mitigate or prevent the unacceptable safety consequences are listed below. Refer to Table 15.9-7 for the unacceptable consequences criteria.

Safety Action	Related Unacceptable Consequence Criteria	Reason Action Required
Scram and/or RPT	2-2 2-3	To prevent fuel damage and limit nuclear system pressure rise
Pressure relief	2-3	To prevent excessive nuclear system pressure rise
Core and primary containment cooling	2-1 2-2 2-4	To prevent fuel and primary containment damage in the event that normal cooling is interrupted
Reactor vessel isolation	2-2	To prevent fuel damage by reducing the outflow of steam and water from the reactor vessel, thereby limiting the decrease in reactor vessel water level
Restore ac power	2-2	To prevent fuel damage by restoring ac power to systems essential to other safety actions
Prohibit rod motion	2-2	To prevent exceeding fuel limits during transients
Primary containment isolation	2-1 2-4	To minimize radiological effects

15.9.6.3.3 Event Definitions and Operational Safety Evaluations

a. Event 7 - Manual and Inadvertent Scram

The deliberate manual or inadvertent automatic scram due to single operator error is an event that can occur under any operating condition. Although assumed to

occur here for examination purposes, multiple operator error or action is necessary to initiate such an event.

While all the safety criteria apply, no unique safety actions are required to control the planned operation-like event after effects of the subject initiation actions. In all operating states, therefore, the safety criteria are met through the basic design of the plant systems. Figure 15.9-13 identifies the protection sequences for this event.

b. Event 8 - Loss of Plant Instrument/Service Air System

Loss of the plant instrument and service air systems causes reactor shutdown and the closure of MSIVs. Although these actions occur, they are not a requirement to prevent unacceptable consequences in themselves. Multiple equipment failures would be necessary to cause the deterioration of the subject system to the point that the components supplied with instrument or service air would cease to operate normally and/or fail-safe. The resulting actions are identical to Event 14 described later.

Isolation of the main steam lines can result in a transient for which some degree of protection is required only in operating States C and D. In operating States A and B, the main steam lines are normally isolated.

The effect of isolation of all main steam lines is most severe in operating State D during power operation.

Figures 15.9-14 and 15.9-21 show how scram is accomplished by main steam line isolation through the actions of the RPS and CRD system. The MSRV system provides pressure relief. Pressure relief, combined with loss of feedwater flow, causes reactor vessel water level to fall. Either HPCI or RCIC supplies water to maintain water level and protect the core until normal steam flow (or other planned operation) is established.

Adequate reserve pneumatic supplies are maintained exclusively for the continual operation of the ADS SRVs until reactor shutdown is accomplished.

c. Event 9 - Inadvertent NSSS Pump Start (Moderator Temperature Decrease)

An inadvertent pump start (temperature decrease) is defined as an unintentional start of any NSSS pump that adds sufficient cold water to the reactor coolant inventory to cause a measurable decrease in moderator temperature. This event is considered in all operating states, because it can potentially occur under any operating condition. Since the HPCI pump operates over nearly the entire range of the operating states and delivers by far the greatest amount of cold water to the vessel, the following analysis will describe its inadvertent operation rather than other NSSS pumps (e.g., RCIC, RHR, core spray).

While all the safety criteria apply, no unique safety actions are required to control the adverse effects of such a pump start (i.e., pressure increase and temperature decrease in States A and C). In these operating states, the safety criteria are met through the basic design of the plant systems, and no safety action is specified. In States B and D, where the reactor is not shut down, the operator or the plant's

normal control system can control any power changes in the normal manner of power control.

Figure 15.9-15 illustrates the protection sequence for the subject event. Single failures to the plant's normal control system pressure regulator or the feedwater controller systems will result in further protection sequences. These are shown in Events 22 and 23. The single failure aspects of their protection sequences will, of course, not be required.

d. Event 10 - Startup of Idle Recirculation Pump

The cold loop startup of an idle recirculation pump can occur in any state. The attendant reactivity insertion effects are most severe and rapid for those operating states in which the reactor may be critical (States B and D). If the reactivity insertion is sufficient to require safety action, a high neutron flux signal (IRM or APRM) that exceeds the specified trip setpoint will occur.

As shown in Figure 15.9-16, the required safety action is accomplished through the combined actions of the NMS, RPS, and CRD system.

e. Event 11 - Recirculation Flow Control Failure (Increasing Flow)

A recirculation flow control failure causing increased flow is applicable in States C and D. In State D, the resulting increase in power level is limited by a reactor scram. As shown in Figure 15.9-17, the required safety action is accomplished through the combined actions of the NMS, RPS, and CRD system.

f. Event 12 - Recirculation Flow Control Failure (Decreasing Flow)

This recirculation flow control malfunction causes a decrease in core coolant flow. This event is not applicable to States A and B, because the reactor vessel head is off and the recirculation pumps normally would not be in use.

The number and type of flow controller failure modes determine the protection sequence for the event. ASD controller failures (for one or both ASD trains will result in a transient bounded by the previous transient associated with the original configuration for the MG set controller failures (a transient bounded by one or two RPT transients (Figure 15.9-18)).

g. Event 13 - Trip of One or Both Recirculation Pumps

The trip of one recirculation pump produces a milder transient than does the simultaneous trip of two recirculation pumps.

The transient resulting from this two-loop trip is not severe enough to require any unique safety action. The transient is compensated for by the inherent nuclear stability of the reactor. This event is not applicable in States A and B, because the reactor vessel head is off and the recirculation pumps normally would not be in use. Figure 15.9-19 provides the protection sequence for the event for one or both pump trip actuations for States C and D.

This event constitutes an acceptable operational technique to reduce or minimize the effects of other event conditions. To this end, an engineered recirculation pump trip capability is included in the plant design to reduce pressure and thermal-hydraulic transient effects.

A two-pump trip can result in a high water level trip of the main turbine, which further causes a stop valve closure and its subsequent scram actuation. Containment isolation occurs and RCIC/HPCI systems initiate on low water level. Relief valve actuation will follow.

h. Event 14 - Isolation of One or All Main Steam Lines

Isolation of the main steam lines can result in a transient for which some degree of protection is required only in operating States C and D. In operating States A and B, the main steam lines are normally isolated.

Isolation of all main steam lines is most severe and rapid in operating State D during power operation.

Figure 15.9-20 shows how a scram is initiated by main steam line isolation triggering the actions of the RPS and CRD systems. The MSRV system provides pressure relief. Pressure relief, combined with loss of feedwater flow, causes reactor vessel water level to fall and either HPCI or RCIC supply water to maintain water level and protect the core until adequate long-term cooling is established.

Isolation of one main steam line causes a significant transient only in State D during operation above approximately 90% power. If the feedwater system and main condenser remain in operation following the event, no unique requirement arises for core cooling.

As shown in Figure 15.9-21, the required safety action is accomplished.

i. Event 15 - Inadvertent Opening of an MSRV

The inadvertent opening of an MSRV is only possible in operating States C and D. In State C the water level cannot be lowered far enough to threaten fuel damage; therefore, no safety actions are required. The protection sequences in State D are shown in Figure 15.9-22.

In State D, there is a slight decrease in reactor pressure following the event. The pressure regulator closes the main turbine control valves enough to stabilize pressure at a level slightly below the initial value. There are no unique safety system requirements for this event.

j. Event 16 - Control Rod Withdrawal Error For Refueling and Startup Operations

Because a control rod withdrawal error resulting in an increase of positive reactivity can occur under any operating condition, it must be considered in all operating states. For this specific event situation, only States A and B apply.

1. Refueling

No unique safety action is required in operating State A for the withdrawal of one control rod, because the core is more than one control rod subcritical. Withdrawal of more than one control rod is precluded by the protection sequence shown in Figure 15.9-23. During core alterations, the mode switch is normally in the REFUEL position, which allows the refueling equipment to be positioned over the core and also inhibits control rod withdrawal. Therefore, this transient applies only to operating State A.

No safety action is required, because the total worth (positive reactivity) of one fuel assembly or control rod is not adequate to cause criticality. Moreover, mechanical design of the control rod assembly prevents physical removal without removing the adjacent fuel assemblies.

2. Startup

During low power operation, the NMS via the RPS will initiate scram if necessary (Figure 15.9-23).

k. Event 17 - Control Rod Withdrawal Error (During Power Operation)

Because a control rod withdrawal error resulting in an increase of positive reactivity can occur under any operating condition, it must be considered in all operating states. For this specific event situation, only States C and D apply.

During power operation (State D), a number of plant protective devices of various designs prohibit the control rod motion before critical levels are reached (Figure 15.9-24).

Below the low power setpoint, the selection of an out- of-sequence rod movement is prevented by the RWM which uses banked position withdrawal sequences. In addition, the movement of the rod is monitored and limited within acceptable intervals either by neutronic effects or actual rod motion. The RBM provides movement surveillance. Beyond these rod motion control limits are the fuel/core scram protection systems.

While in State C, no protection action is needed.

l. Event 18 - Loss of Shutdown Cooling

The loss of RHR system shutdown cooling can occur only during the low pressure portion of a normal reactor shutdown and cooldown.

As shown in Figure 15.9-25, for most single failures that could result in primary loss of shutdown cooling capabilities, no unique safety actions are required; in these cases, shutdown cooling is simply re-established using redundant shutdown cooling equipment. In the cases where the RHR shutdown cooling suction line becomes inoperative, a unique arrangement for cooling arises. In States A and B, in which the reactor vessel head is off, the LPCI and CS can be used to maintain RPV water level. In State C, in which the reactor vessel head is on and the system can be

pressurized, the ADS or manual operation of relief valves in conjunction with any of the ECCS and the RHR suppression pool cooling mode (both manually operated) can be used to maintain water level and remove decay heat. Suppression pool cooling is actuated to remove heat energy from the suppression pool system.

m. Event 19 - RHR Shutdown Cooling - Increased Cooling

An RHR shutdown cooling malfunction causing a moderator temperature decrease must be considered in all operating states. However, this event is not considered in States C and D if nuclear system pressure is too high to permit operation of the RHR shutdown cooling (Figure 15.9-26). No unique safety actions are required to avoid the unacceptable safety consequences for transients as a result of a reactor coolant temperature decrease induced by misoperation of the shutdown cooling heat exchangers.

In States B and D, where the reactor is at or near critical, the slow power increase resulting from the cooler moderator temperature would be controlled by the operator in the same manner normally used to control power in the source or intermediate power ranges.

n. Event 20 - Loss of All Feedwater Flow

A loss of feedwater flow results in a net decrease in the coolant inventory available for core cooling. A loss of feedwater flow can occur in States C and D. Appropriate responses to this transient include a reactor scram on low water level and restoration of reactor vessel water level by HPCI and RCIC.

As shown in Figure 15.9-27, the RPS and CRD systems effect a scram on low water level. The PCRVICS acts to isolate the containment. Either the RCIC or HPCI system can maintain adequate water level for initial core cooling and to restore and maintain water level.

The requirements for operating State C are the same as for State D, except that the scram initiation is not required in State C.

o. Event 21 - Loss of a Feedwater Heater

Loss of a feedwater heater must be considered with regard to the nuclear safety operational criteria only in operating State D, because significant feedwater heating does not occur in any other operating state.

A loss of feedwater heating transient causes a neutron flux increase that might reach the scram setpoint depending upon the degree of feedwater heating loss. As shown in Figure 15.9-28 required safety action is accomplished through actions of the NMS, RPS, and CRD system.

p. Event 22 - Feedwater Controller Failure (Maximum Demand)

A feedwater controller failure, causing an excess of coolant inventory in the reactor vessel, is possible in all operating states. Feedwater controller failures considered are those that would give failures of automatic or manual level controls. In

operating States A and B, no safety actions are required, since the vessel head is removed and the moderator temperature is low. In operating State D, any positive reactivity effects responses by the reactor caused by cooling of the moderator can be mitigated by a scram. As shown in Figure 15.9-29, scram is accomplished through the combined actions of the neutron monitoring, reactor protection, and CRD systems. Pressure relief is required in States C and D and is achieved through the operation of the MSRV system. Initial restoration of the core water level is by the RCIC and HPCI systems. Planned operations will proceed to achieve long-term cooling.

q. Event 23 - Pressure Regulator Failure (Open Direction)

A pressure regulator failure in the open direction, causing the opening of a turbine control or bypass valve, applies only in operating States C and D, because in other states the pressure regulator is not in operation. A pressure regulator failure is most severe and rapid in operating State D at low power.

The various protection sequences giving the safety actions are shown in Figure 15.9-30. Depending on plant conditions existing prior to the event, scram will be initiated either on main steam line isolation, main turbine trip or reactor vessel low water level. The sequence resulting in reactor vessel isolation also depends on initial conditions. With the mode switch in RUN, isolation is initiated when main steam line pressure drops below the low turbine inlet pressure setpoint. After isolation is completed, decay heat will cause nuclear system pressure to increase until limited by the operation of the relief valves. Core cooling following isolation can be provided by RCIC or HPCI. Shortly after reactor vessel isolation, normal core cooling can be re-established via the main condenser and feedwater systems or, if prolonged isolation is necessary, extended core and containment cooling will be manually actuated.

r. Event 24 - Pressure Regulator Failure (Closed Direction)

A pressure regulator failure in the closed direction, causing the closing of turbine control valves, applies only in operating States C and D, because in other states the pressure regulator is not in operation.

A single pressure regulator failure would result in little or no effect on the plant operation. The second pressure regulator would provide control. Failure of the second unit, which would result in the worst situation, is much less severe than Events 25, 27, 30, and 31. The dual pressure regulator failures are most severe and rapid in operating State D at high power.

The various protection sequences giving the safety actions are shown in Figure 15.9-31. Upon failure of one pressure regulator, normally a backup regulator will maintain the plant in the normal status. An additional failure of the backup regulator will result in a high flux or pressure scram, containment isolation, and subsequent HPCI/RCIC actuations. Closure of the turbine stop valve and bypass valves effectively isolates the reactor vessel.

s. Event 25 - Main Turbine Trips With Bypass System Operation

A main turbine trip can occur only in operating State D (during heatup or power operation). A turbine trip during heatup is not as severe as a trip at full power, because operation of the turbine bypass system minimizes the effects of the transient, enabling return to planned operations. For a turbine trip above the bypass capacity, a scram as well as RPT will occur via turbine stop valve closure. Subsequent relief valve actuation will occur. Eventual containment isolation and RCIC and HPCI system initiation will result from low water level. Figure 15.9-32 depicts the protection sequences required for main turbine trips. Main turbine trip and main generator trip are similar anticipated operational transients, and the required safety actions are the same.

t. Event 26 - Loss of Main Condenser Vacuum (Turbine Trip)

A loss of vacuum in the main turbine condenser can occur any time steam pressure is available and the condenser is in use; it is applicable to operating States C and D. This nuclear system pressure increase transient is the most severe of the pressure increase transients. However, scram protection in State C is not needed, since the reactor is not coupled to the turbine system.

For State D, above the turbine stop valve closure scram bypass setpoint, loss of condenser vacuum will initiate a turbine trip with its attendant stop valve closures (which lead to scram and an RPT). RCIC and HPCI are initiated on low water level. Below the turbine stop valve closure scram bypass setpoint (State D), scram is initiated by a high neutron flux signal. Figure 15.9-33 shows the protection sequences. Decay heat will necessitate extended core and suppression pool cooling. When the RPV depressurizes sufficiently, the low pressure core cooling systems provide core cooling until a planned operation via RHR shutdown cooling is achieved.

u. Event 27 - Main Generator Trip With Bypass System Operation

A main generator trip with bypass system operation can occur only in operating State D (during heatup or power operation). Fast closure of the main turbine control valves is initiated whenever an electrical grid disturbance occurs, which results in significant loss of electrical load on the generator. The turbine control valves are required to close as rapidly as possible to prevent excessive overspeed of the main turbine-generator rotor. Closure of the turbine control valves will cause a sudden reduction in steam flow, which results in an increase in system pressure. Above the turbine control valve closure scram bypass setpoint, scram and RPT will occur as a result of fast control valve closure. Subsequently, containment isolation will result, and pressure relief and initial core cooling by RCIC and HPCI will take place. Planned operation can be resumed to achieve shutdown. A generator trip during heatup is not severe when the turbine bypass system can accommodate decoupling the reactor and the turbine-generator unit. Figure 15.9-34 depicts the protection sequences required for a main generator trip. Main generator trip and main turbine trip are similar anticipated operational transients, and the required safety actions for both are the same sequence.

v. Event 28 - Loss of Auxiliary Power Transformers

There are a variety of possible plant electrical component failures that could affect the reactor system. The total loss of ac auxiliary power is the most severe. The loss of auxiliary power results in a sequence of events similar to that resulting from a loss of all connections to the grid. The most severe situation occurs in State D during power operation. This event requires the same protection sequences as shown for Event 29 in Figure 15.9-36.

w. Event 29 - Loss of Offsite Power - Grid Loss

There are a variety of plant grid electrical component failures that can affect reactor operation. The total loss of ac auxiliary power is the most severe. The loss of all auxiliary power sources results in a sequence of events similar to that resulting from a main generator trip with bypass (Event 27), with respect to response of reactor systems. The most severe case occurs in State D during power operation. Figure 15.9-36 shows the safety actions required for a total loss of offsite power in all States (A, B, C, and D).

Scram and RPT will be initiated by turbine control valve fast closure. Loss of condenser circulating water will reduce condenser vacuum, which will close the turbine bypass valves and MSIVs. After the MSIVs close, system pressure rises to the lowest relief valve setting. Pressure is relieved by the MSRV system. After the reactor is isolated and feedwater flow has been lost, decay heat continues to increase nuclear system pressure, periodically causing relief valves to lift and, therefore, causing reactor water level to decrease. The core and containment cooling sequence shown in Figure 15.9-36 shows the sequence for achieving adequate cooling.

15.9.6.4 Abnormal Operational Transients

15.9.6.4.1 General

The safety requirements and protection sequences for abnormal operational transients are described in the following paragraphs for Events 30 through 37. The protection sequence block diagrams show the sequence of front-line safety systems (Figures 15.9-37 through 15.9-39). The auxiliaries for the front-line safety systems are indicated in the auxiliary diagrams (Figures 15.9-7 and 15.9-8).

15.9.6.4.2 Required Safety Actions/Related Unacceptable Consequences

The following list relates the safety actions for abnormal operational transients to mitigate or prevent the unacceptable safety consequences cited in Table 15.9-8.

Safety Action	Related Unacceptable Consequence	Reason Action Required
Scram and/or RPT	3-2 3-3 3-5	To limit gross core-wide fuel damage and to limit nuclear system pressure rise

Pressure relief	3-3 3-5	To prevent excessive nuclear system pressure rise
Core, suppression pool, and primary containment cooling	3-2 3-4	To limit further fuel and containment damage if normal cooling is interrupted
Reactor vessel isolation	3-2	To limit further fuel damage by reducing the outflow of steam and water from the reactor vessel, thereby limiting the decrease in reactor vessel water level
Restore ac power	3-2	To limit initial fuel damage by restoring ac power to systems essential to other safety actions
Primary containment isolation	3-1	To limit radiological effects

15.9.6.4.3 Event Definition and Operational Safety Evaluation

a. Event 30 - Main Generator Trip Without Bypass System Operation

A main generator trip without bypass system operation can occur only in operating State D (during heatup or power operation). The thermal-hydraulic effects on the core are more severe than with the bypass operating (Event 27).

Figure 15.9-37 depicts the protection sequences required for a main generator trip with bypass failure. If the turbine control valve closure scram bypass setpoint is exceeded, a turbine control valve fast closure signal will initiate RPS and RPT. Containment isolation, relief valve actuation, and RCIC and HPCI operation will follow. Turbine control valve closure with bypass valve failure effectively isolates the reactor. Prolonged shutdown will necessitate extended core and containment/suppression pool cooling.

The load rejection and turbine trip are similar abnormal operational transients, and the required safety actions are the same.

b. Event 31 - Main Turbine Trip Without Bypass System Operation

A main turbine trip without bypass can occur only in operating State D (during heatup or power operation). Figure 15.9-38 depicts the protection sequences required for main turbine trips. Turbine stop valve closure with bypass valve failure effectively isolates the reactor.

Turbine trips without bypass system operations result in severe thermal-hydraulic effects on the reactor core.

c. Event 32 - Inadvertent Loading and Operation with Assembly in Improper Position

Operation with a fuel assembly in the improper position is shown in Figure 15.9-39 and can occur in all operating states. No protection sequences are necessary relative to this event. Calculated results of worst fuel bundle loading error will not cause fuel cladding integrity damage. It requires three independent equipment/operator errors to allow this situation to develop.

d. Events 33 through 37 - (Not Used)

15.9.6.5 Design Basis Accidents

15.9.6.5.1 General

The safety requirements and protection sequences for accidents are described in the follow paragraphs for Events 38 through 49. The protection sequence block diagrams show the safety actions and the sequence of front-line safety systems used for the accidents (refer to Figures 15.9-40 through 15.9-49). The auxiliaries for the front-line safety systems are indicated in the auxiliary diagrams (Figures 15.9-7 and 15.9-8).

15.9.6.5.2 Required Safety Actions/Unacceptable Consequences

The following list relates the safety actions for design basis accident to mitigate or prevent the unacceptable consequences cited in Table 15.9-9.

Safety Action	Related Unacceptable Consequence	Reason Action Required
Scram	4-2 4-3	To prevent fuel cladding failure(1) and prevent excessive nuclear system pressures
Pressure relief	4-3	To prevent excessive nuclear system pressure
Core cooling	4-2	To prevent fuel cladding failure
Reactor vessel isolation	4-1	To limit radiological effect to not exceed the values of 10CFR50.67 and Regulatory Guide 1.183
Establish primary containment	4-1	To limit radiological effects to not exceed the values of 10CFR50.67 and Regulatory Guide 1.183
Primary containment cooling	4-4	To prevent excessive pressure in the containment when containment is required.
Prevent control rod ejection	4-2	To prevent fuel cladding failure
Restrict loss of reactor coolant (passive)	4-2	To prevent fuel cladding failure
Main control room	4-5	To prevent overexposure to radiation of

environmental control		plant personnel in the control room
Limit reactivity insertion rate (passive)	4-2 4-3	To prevent fuel cladding failure and excessive nuclear system pressure

(1) Failure of fuel barrier includes fuel cladding fragmentation (LOCA) and excessive fuel enthalpy (control rod-drop accident).

15.9.6.5.3 Event Definition and Operational Safety Evaluations

a. Event 38 - Recirculation Pump Seizure

A recirculation pump seizure event considers the instantaneous stoppage of the pump motor shaft of one recirculation loop pump. The case involves operation at design power in State D. It assumed that a main turbine trip will occur as reactor vessel water level swell exceeds the turbine trip setpoint. This results in a scram and an RPT when the turbine stop valves close. Relief valve opening will occur to control pressure level and temperatures. RCIC or HPCI system will maintain vessel water level.

The protection sequence for this event is given in Figure 15.9-40. If reactor vessel swell does not exceed the turbine trip setpoint, then no safety actions are required.

b. Event 39 - Recirculation Pump Shaft Break

A recirculation pump shaft break event considers the degraded, delayed stoppage of the pump motor shaft of one recirculation loop pump. The case involves operation at design power in State D. It is assumed that a main turbine trip will occur as reactor vessel water level swell exceeds the turbine trip setpoint. This results in a scram and an RPT when the turbine stop valves close. Relief valve opening will occur to control pressure and temperature. RCIC or HPCI systems will maintain vessel water level.

The production sequence for this event is given in Figure 15.9-41. If reactor vessel swell does not exceed the turbine trip setpoint, then no safety actions arre required.

c. Event 40 - Control Rod-Drop Accident

The control rod-drop accident results from an assumed failure of the control rod-to-drive mechanism coupling after the control rod (very reactive rod) becomes stuck in its fully inserted position. It is assumed that the control rod drive is then fully withdrawn before the stuck rod falls out of the core. The control rod velocity limiter, an engineered safeguard, limits the control rod-drop velocity. The resultant radioactive material release is maintained far below the values of 10CFR50.67 and Regulatory Guide 1.183.

No safety actions are required in States A or C where the plant is in a shutdown state by more than the reactivity worth of one rod prior to the accident. The control rod-drop accident is applicable only in States B and D. In State B the low fission product inventory assures inconsequential radiological releases should a control rod-drop accident occur. Direct radiation dose to personnel on the refueling floor is maintained acceptable by the shielding provided by water above the core and by administrative procedures controlling personnel access. For State B, control rod worth is limited by the RWM system such that damage to the reactor coolant pressure boundary is prevented. Under most instances fuel failures are not expected. Therefore, the only safety response required in State B is scram.

Figure 15.9-42 presents the different protection sequences for the control rod-drop accident. As shown in Figure 15.9-42, the reactor is automatically scrammed and, in some cases, isolated. For all design basis cases, the NMS, RPS, and CRD system will provide a scram from high neutron flux. Because LGS utilizes the banked position withdrawal sequence which mitigates rod-drop consequences, no fuel failures are expected.

After the reactor has been scrammed and isolated, the pressure relief system allows the steam (produced by decay heat) to be directed to the suppression pool. Initial core cooling is accomplished by either the RCIC or HPCI or the normal feedwater system. With prolonged isolation, as indicated in Figure 15.9-42, the reactor operator initiates the RHR/suppression pool cooling mode and depressurizes the vessel with the manual mode of the ADS or via normal manual relief valve operation. The RHR/shutdown cooling mode accomplishes extended core cooling.

d. Event 41 - Fuel Handling Accident

Because a fuel handling accident can potentially occur any time when fuel assemblies are being manipulated, either over the reactor core or in a spent fuel pool, this accident is considered in all operating states. Considerations include mechanical fuel damage caused by drop impact and a subsequent release of fission products. The protection sequences pertinent to this accident are shown in Figure 15.9-43. Refueling area isolation and SGTS operation are automatically initiated by the ventilation radiation monitoring systems.

e. Event 42 - LOCAs Resulting from Postulated Piping Breaks Within RCPB Inside Containment (DBA LOCA)

Pipe breaks inside the containment are considered only when the nuclear system is significantly pressurized (States C and D). The result is a release of steam and water into the containment. Consistent with NSOA criteria, the protection requirements consider all size line breaks, from large liquid recirculation loop piping breaks down to small steam instrument line breaks. The most severe cases are the circumferential break of the largest (liquid) recirculation system pipe and the circumferential break of the largest main steam line.

As shown in Figure 15.9-44, in operating State C (reactor shutdown, but pressurized), a pipe break accident up to the DBA can be accommodated within the nuclear safety operational criteria through the various operations of the main steam

line isolation valves, emergency core cooling systems (HPCI, ADS, LPCI, and CS), PCRVICS, containment, reactor enclosure, SGTS, control room heating, cooling and ventilation system, ESW and RHRSW systems, hydrogen control system, equipment cooling systems, and the incident detection circuitry. For small pipe breaks inside the containment, pressure relief is effected by the MSRV system, which transfers decay heat to the suppression pool. For large breaks, depressurization takes place through the break itself. In State D (reactor not shut down, but pressurized), the same equipment is required as in State C but, in addition, the RPS and the CRD system must operate to scram the reactor. The limiting items, upon which the operation of the above equipment is based, are the allowable fuel cladding temperature and the containment pressure capability. The CRD housing supports are considered necessary whenever the system is pressurized to prevent excessive control rod movement through the RPV following the postulated rupture of one CRD housing (a lesser case of the design basis LOCA and a related preventive of a postulated rod ejection accident).

After completion of the automatic action of the above equipment, manual operation of the RHR system (suppression pool cooling mode) or relief valves and ADS (controlled depressurization) is required to maintain containment pressure and fuel cladding temperature within limits during extended core cooling.

f. Events 43, 44, 45 - Piping Breaks Outside Containment

Pipe break accidents outside the containment are assumed to occur any time the nuclear system is pressurized (States C and D). This accident is most severe during operation at high power (State D). In State C, this accident becomes a subset of the State D sequence.

The protection sequences for the various possible pipe breaks outside the containment are shown in Figure 15.9-45. For small breaks, the reactor operator can use a large number of process indications to identify and isolate the break.

In operating State D (reactor not shut down, but pressurized), scram is accomplished through operation of the RPS and the CRD system. Reactor vessel isolation is accomplished through operation of the MSIVs and the PCRVICS.

For a main steam line break, initial core cooling is accomplished by HPCI, RCIC, ADS, or manual relief valve operation in conjunction with CS and LPCI. These systems provide parallel paths to effect initial core cooling, thereby satisfying the single failure criterion. Extended core cooling is accomplished by the single failure proof, parallel combination of CS and LPCI. The ADS or relief valve system operation and the RHR suppression pool cooling mode (both manually operated) are required to maintain containment pressure and fuel cladding temperature within limits during extended core cooling.

g. Event 46 - Gaseous Radwaste System Leak or Failure

It is assumed that the line leading to the SJAE fails near the main condenser. This results in activity normally processed by the offgas treatment system being discharged directly to the turbine enclosure and subsequently through the ventilation system to the environment. This failure is indicated by a lack of flow in

the offgas discharge line. This event can be considered only under States C and D and is shown in Figure 15.9-46.

The reactor operator initiates shutdown of the SJAEs/offgas system to reduce the gaseous activity being discharged. A loss of main condenser vacuum will result (timing depending on main condenser air inleakage rate) in a main turbine trip and ultimately a reactor shutdown. Refer to Event 26 for reactor protection sequence (Figure 15.9-33).

h. Event 47 - Augmented Offgas Treatment System Failure

An evaluation of those events that could cause a gross failure in the offgas system has resulted in the identification of a postulated seismic event, more severe than the one for which the system is designed, as the only conceivable event that could cause significant damage.

The gross failure of this system requires a manual isolation of the system from the main condenser. The isolation results in a loss of main condenser vacuum (timing dependent on air inleakage rate). Protection sequences for this event are shown in Figure 15.9-47.

i. Event 48 - Liquid Radwaste System Leak or Failure

Releases that could occur inside and outside of the containment, not covered by Events 38 through 47, include small spills and equipment leaks of radioactive materials inside structures housing the subject process equipment. Conservative values for leakage have been assumed and evaluated in the plant under routine releases (Section 11.2). The offsite dose that results from any small spill that could occur outside containment will be negligible in comparison to the dose resulting from the accountable (expected) plant leakages.

The protective sequences for this event are provided in Figure 15.9-48.

j. Event 49 - Liquid Radwaste System - Storage Tank Failure

Refer to Section 2.4 for a discussion of liquid tank failures.

The protective sequences for this event are provided in Figure 15.9-49.

15.9.6.6 Special Events

15.9.6.6.1 General

Additional special events are postulated to demonstrate that the plant is capable of accommodating off-design occurrences. (refer to Events 50 through 53). As such, these events are beyond the safety requirements of the other event categories. The safety actions shown in the sequence diagrams (Figures 15.9-50 through 15.9-53) for the additional special events follow directly from the requirements cited in the demonstration of the plant's capability.

Auxiliary systems are shown in Figures 15.9-7 and 15.9-8.

15.9.6.6.2 Required Safety Action/Unacceptable Consequences

The following list relates the safety actions for special events to prevent the unacceptable consequences cited in Table 15.9-10.

Safety Action	Related Unacceptable Consequence	Reason For Action Available
Main Control Room Considerations		
Manually initiate all shutdown controls from remote shutdown panel or local panels	5-1 5-2	Local panel control has been provided and is available outside main control room
Manually initiate SLCS	-3	SLCS to control reactivity to cold shutdown available

15.9.6.6.3 Event Definitions and Operational Safety Evaluation

a. Event 50 - Shipping Cask-Drop

Due to the redundant nature of the plant crane, the cask-drop accident is not believed to be a credible accident. However, the accident is hypothetically assumed to occur as a consequence of an unspecified failure of the cask-lifting mechanism, thereby allowing the cask to fall.

It is assumed that an ISFSI transfer cask, HI-TRAC VW cask and/or spent fuel shipping cask containing irradiated fuel assemblies is in the process of being moved with the cask suspended from the crane above the rail car. The fuel assemblies have been out of the reactor for at least 90 days.

Through some unspecified failure, the cask is released from the crane and falls onto the rail car. Some of the coolant in the outer cask structure may leak from the cask.

The reactor operator will ascertain the degree of cask damage and, if possible, make the necessary repairs and refill the cask coolant to its normal level if coolant has been lost.

It is assumed that if the coolant is lost from the external cask shield, the operator will establish forced cooling of the cask by introducing water into the outer structure annulus or by spraying water on the cask exterior surface. Maintaining the cask in a cool condition will, therefore, ensure no fuel damage as a result of a temperature increase due to decay heat.

Because the cask is still within the refueling area volume, any activity postulated to be released can be accommodated by the SGTS.

The protective sequences for this event are provided in Figure 15.9-50.

b. Event 51 - Reactor Shutdown, Anticipated Transient Without Scram

Reactor shutdown from a plant transient occurrence without the use of control rods is applicable in State D only. The protection sequences for this extremely improbable class of events in shown in Figure 15.9-51.

On initiation of the plant transient situation by a turbine trip, for example, a scram is automatically initiated, but no control rods are assumed to move; the operator may attempt to insert control rods manually. The recirculation pumps are tripped as a consequence of the initial turbine trip. If the nuclear system becomes isolated from the main condenser, heat can be transferred from the reactor to the suppression pool via the relief valves; the HPCI and RCIC are initiated on low water level and then maintain reactor vessel water level. The RRCS, on detecting high pressure or low water level in the reactor, will also attempt to insert control rods by actuation of the ARI valves of the CRD system and will also initiate a recirculation pump trip (which has previously occurred for this transient). If the reactor power is still significant after appropriate time delays, the RRCS automatically initiates feedwater runback and SLCS operation. Operation of the SLCS results in a transition from low power neutron heat to decay heat. The RHR suppression pool cooling mode is used to remove the low power neutron and decay heat from the suppression pool as required. After attaining hot shutdown, further depressurization to the suppression pool and use of the RHR shutdown cooling mode results in achieving a cold shutdown condition.

c. Event 52 - Reactor Shutdown From Outside Control Room

Reactor shutdown from outside the control room is an event investigated to evaluate the capability of the plant to be safely shut down and cooled to the cold shutdown state from outside the control room.

Figure 15.9-52 shows the protection sequences for this event in operating States B, C and D. In State A, no sequence is shown, because the reactor is already in the condition finally required for the event. In State C, only cooldown is required, since the reactor is already shut down.

A scram from outside the control room can be achieved by opening the ac supply breakers for the RPS. Reactor pressure will be controlled and decay heat transferred to the suppression pool via the relief valves. Reactor water level will be maintained by the RCIC system, and the suppression pool will be cooled using the RHR suppression pool cooling mode. When system pressure is sufficiently reduced, the RHR shutdown cooling mode will be used for long-term cooling.

d. Event 53 - Reactor Shutdown Without Control Rods

Reactor shutdown without control rods is an event requiring an alternate method of reactivity control: the SLCS. By definition, this event can occur only when the reactor is not already shut down. Therefore, this event is considered only in operating States B and D.

The SLCS must operate to meet capability demonstration requirement 5-3. The design bases for the SLCS result from these operating criteria when applied under the most severe conditions (State D at rated power). As indicated in Figure 15.9-53, the SLCS is manually initiated and controlled in States B and D.

15.9.7 SUMMARY AND CONCLUSIONS

With the information presented in the protection sequence block diagrams and the auxiliary diagrams, it is possible to examine the functional and hardware requirements for each system. This is done by considering the events in which the systems are employed and deriving sets of operational requirements. This limiting set of operational requirements establishes the lowest acceptable level of performance for a system or component, or the minimum number of components or portions of a system that must be operable so that plant operation may continue, as indicated in Section 15.9.5.

Safety actions to maintain core cooling are, in general, automatically controlled by NSSS ESF systems. Required manual actions are limited to RHR system adjustment to control suppression pool temperatures.

For LOCA events, all short-term (t = 0 through 10 minutes) safety functions are automatically initiated and controlled. All safety actions to provide adequate core cooling over the long-term (t = 10 minutes to 30 days) are automatically provided by the necessary NSSS ESF systems. Control of LOCA suppression pool thermal response, however, may require the operator to place one loop of the containment cooling system (RHR) into operation, but no such action is required earlier than 10 minutes into the event. Extended long-term NSSS ESF manual actions would be centered around RHR shutdown cooling aspects.

For anticipated operational transient events, no operator action is required in less than 10 minutes to mitigate the consequences of the event or to achieve a steady reactor condition or a controlled shutdown mode. Most events involve automatic process control systems (e.g., feedwater or pressure controls that are usually in operation). Some events allow operator manual control adjustments (e.g., control rod insertion) prior to an automatic protection action, but in no case will the failure or error of the operator manual action negate any protective function or cause a radiological safety problem. Operator actions may improve the course of a transient, but no credit is taken (ahead of 10 minutes) in the current safety evaluation analyses.

When the initial stages of these events are completed and the operator has taken over manual control, the EOPs govern all actions taken.

The operational requirements derived using the above process may be complicated functions of operating states, parameter ranges, and hardware conditions. The final step is to translate these results into technical specifications that encompass the operational requirements and can be used by plant operations and management personnel.

It is concluded that the nuclear safety operational and plant design basis criteria are satisfied when the plant is operated in accordance with the nuclear safety operational requirements determined by the method presented in this section.

UNACCEPTABLE CONSEQUENCES CONSIDERATIONS
PLANT EVENT CATEGORY - SPECIAL EVENTS

Special Events Considered

A. Reactor shutdown from outside control room.

B. Reactor shutdown without control rods.

C. Reactor shutdown with ATWS.

D. ISFSI Transfer Cask, HI-TRAC VW cask and/or Shipping Cask-Drop.

Capability Demonstration

5-1	Ability to shut down reactor by manipulating controls and equipment outside the main control room.
5-2	Ability to bring the reactor to the cold shutdown condition from outside the main control room.
5-3	Ability to shut down the reactor independent of control rods.
5-4	Ability to contain radiological contamination.
5-5	Ability to limit radiological exposure.

Table 15.9-11

BWR OPERATING STATES[1]

Conditions[2]	States A	B	C	D
Reactor vessel head	X	X		
Reactor vessel head on			X	X
Shut down		X		X
Not shut down		X		X

(1) Further discussion is provided in Section 15.9.6.2.4.

(2) Shutdown: K_{eff} sufficiently less than 1 that the full withdrawal of any one control rod could not produce criticality under the most restrictive potential conditions of temperature, pressure, core age, and fission product concentrations.

15.10 ACCIDENT DOSE MODEL DESCRIPTIONS

15.10.1 OFFSITE DOSE MODEL

This discussion identifies the models used to calculate offsite radiological doses that would result from releases of radioactivity due to various postulated accidents.

The following assumptions are basic to both the model for the whole body dose from immersion in a cloud of radioactivity and the model for the thyroid dose from inhalation of radioactivity:

a. Direct radiation from the source point is negligible compared with whole body radiation due to submersion in the radioactivity leakage cloud.

b. All radioactivity releases are treated as ground level releases regardless of the point of discharge.

c. The dose receptor is a standard man, as defined by the International Commission on Radiological Protection (Reference 15.10-1).

d. Isotopic data, such as decay constants, are taken from the Table of Isotopes (Reference 15.10-2). Table 15.10-1 lists those values.

e. Dose conversion factors are taken from TID-14844 (Reference 15.10-3), Federal Guidance Report 11 (Reference 15.10-16) and from Regulatory Guide 1.109. Gamma and beta dose conversion factors are found by using the method of Meteorology and Atomic Energy (Reference 15.10-4). Table 15.10-1 lists those values.

15.10.1.1 Whole Body Gamma Dose

Calculation of the gamma dose from an extended source, such as a cloud, starts with the consideration that the radiation received by the receptor from a differential area or volume is the same as if it came from a point source. If the dimensions of a homogeneous cloud of gamma-emitting material are large compared with the distance that the gamma rays travel, an equilibrium condition occurs, provided the receptor volume is small. A cloud with these dimensions acts as though the plume were an infinite source of gamma-emitting material. For a receptor at ground level, only half the passing cloud contributes to the gamma dose of the receptor.

The semi-infinite whole body gamma dose as described in Reference 15.10-4 is given by the following equation:

$$D_\gamma = X/Q \sum_{i=1}^{N} (DCF_i)\, Q_i \qquad \text{(EQ. 15.10-1)}$$

where:

D_γ = gamma dose from semi-infinite cloud, rem

DCF_i = gamma dose conversion factor for isotope (i), rem-m^3/Ci-sec

Q_i = source strength for isotope (i), Ci

X/Q = atmospheric dilution factor, sec/m^3

15.10.1.2 Thyroid Inhalation Dose

Assuming the atmospheric dilution factors given in Table 2.3.4-4, the thyroid dose for a given time is obtained from the following equation:

$$D_T = (X/Q)\, B \sum_{i=1}^{N} Q_i\, DCF_i \qquad \text{(EQ. 15.10-2)}$$

where:

D_T = thyroid inhalation dose, rem

X/Q = atmospheric dilution factor, sec/m^3

N = number of isotopes

B = breathing rate, m^3/sec

Q_i = total activity of iodine isotope (i) released, Ci

DCF_i = dose conversion factor for iodine isotope (i), rem/Ci

The isotopic data and breathing rates are given in Tables 15.10-1 and 15.10-3, respectively.

15.10.1.3 Beta Skin Dose

Assuming the atmospheric dilution factor given in Table 2.3.4-4, the dose in air for a semi-infinite cloud of beta radiation is given by:

$$D_\beta = (X/Q) \sum_{i=1}^{N} Q_i\, DCF_i \qquad \text{(EQ. 15.10-3)}$$

where:

D_β = beta dose from a semi-infinite cloud, rem
X/Q = atmospheric dilution factor, sec/m^3
N = number of isotopes
Q_ι = source strength for isotope (ι), Ci
DCF_1 = dose conversion factor, rem-m^3/Ci-sec

15.10.2 CONTROL ROOM DOSES

15.10.2.1 Calculation of Control Room X/Q

This section describes the governing atmospheric dispersion modeling equations and assumptions in accordance with Draft Regulatory Guide 1111 (Reference 15.10-6). Estimates of atmospheric diffusion (X/Q) are made at the control room intake for releases from the North and South Stacks for periods of 2, 8, and 16 hours and for 3 and 26 days. The NRC recommended model, ARCON96, in Reference 15.10-5 is utilized. Since the North and South Stacks are not 2.5 times the height of the adjacent structures, they do not qualify as an elevated release per DG-1111, therefore, ARCON96 is executed in vent release mode. With an assumed zero (0) vertical exit velocity, vent releases are treated as ground-level releases by ARCON96.

15.10.2.1.1 Diffusion Model (excerpted from NUREG/CR-6331 Rev. 1)

The ARCON96 code implements a straight-line Gaussian diffusion model. The basic model for a ground-level release is

$$\frac{X}{Q'} = \frac{1}{\pi\sigma_y\sigma_z U} \exp\left[-0.5\left(\frac{y}{\sigma_y}\right)^2\right] \qquad (15.10\text{-}4a)$$

X/Q' = relative concentration (concentration divided by release rate) [(ci/m^3)/(ci/s)]
σ_y, σ_z = diffusion coefficients (m)
U = wind speed *(m/s)*
Y = distance from the center of the plume (m)

This equation assumes that the release is continuous, constant, and of sufficient duration to establish a representative mean concentration. It also assumes that the material being released is reflected by the ground. Diffusion coefficients are typically determined from atmospheric stability and distance from the release point using empirical relationships. A diffusion coefficient parameterization from the NRC PAYAN (Reference 15.10-6) and XOQDOQ (Reference 15.10-7) codes is used for σ_y and σ_z.

The diffusion coefficients have the general form

$$\sigma = ax^b + c$$

were x is the distance from the release point, in meters, and a , b, and c are parameters that are functions of stability. The parameters are defined for 3 distance ranges – 0 to 100 m, 100 to 1000 m, and greater than 1000 m. The parameter values may be found in the listing of Subroutine NSIGMA1 in Appendix A of NUREG/CR-6331 Rev. 1.

Diffusion coefficient adjustments for wakes and low wind speeds are incorporated as follows:

To estimate diffusion in building wakes, composite wake diffusion coefficients, $\sum_y$ and $\sum_z$, replace σ_y and σ_z. The composite wake diffusion coefficients are defined by

$$\sum_y = \left[\sigma_y^2 + \Delta\sigma_{y1}^2 + \Delta\sigma_{y2}^2 \right]^{1/2} \qquad (15.10\text{-}4b)$$

$$\sum_z = \left[\sigma_z^2 + \Delta\sigma_{z1}^2 + \Delta\sigma_{z2}^2 \right]^{1/2} \qquad (15.10\text{-}4c)$$

Where σ_y and σ_z are the normal diffusion coefficients, $\Delta\sigma_{y1}$ and $\Delta\sigma_{z1}$ are the low wind speed corrections, and $\Delta\sigma_{y2}$ and $\Delta\sigma_{z2}$ are the building wake corrections. These corrections are described and evaluated in Ramsdall and Fosmire (Reference 15.10-8). The form of the low wind speed corrections is

$$\Delta\sigma_{y1}^2 = 9.13 \times 10^5 \left[1 - \left[1 + \frac{x}{1000U} \right] \exp\left[\frac{-x}{1000U} \right] \right] \qquad (15.10\text{-}4d)$$

$$\Delta\sigma_{z1}^2 = 6.67 \times 10^2 \left[1 - \left[1 + \frac{x}{100U} \right] \exp\left[\frac{-x}{100U} \right] \right] \qquad (15.10\text{-}4e)$$

Where x is the distance from the release point to the receptor, in meters, and U is the wind speed in meters per second. It is appropriate to use the slant range distance for x because these corrections are made only when the release is assumed to be at the ground level and the receptor is assumed to be on the axis of the plume. The diffusion coefficients corrections that account for enhanced diffusion in the wake have a similar form. These corrections are

$$\Delta\sigma_{y2}^2 = 5.24 \times 10^{-2} U^2 A \left[1 - \left[1 + \frac{x}{10\sqrt{A}} \right] \exp\left[\frac{-x}{10\sqrt{A}} \right] \right] \qquad (15.10\text{-}4f)$$

$$\Delta\sigma_{z2}^2 = 1.17 \times 10^{-2} U^2 A \left[1 - \left[1 + \frac{x}{10\sqrt{A}} \right] \exp\left[\frac{-x}{10\sqrt{A}} \right] \right] \qquad (15.10\text{-}4g)$$

Where A is the cross-sectional area of the building.

An upper limit is placed on $\sum_y$ as a conservative measure. This limit is the standard deviation associated with a concentration uniformly distributed across a sector with width equal to the circumference of a circle with radius to the distance between the source and receptor. This value is

$$\sum_{ymax} = \frac{2\pi x}{\sqrt{12}}$$

$\cong$ 1.81x (15.1-4h)

15.10.2.1.2 Meteorological Input

The 1996-2000 meteorological database utilized in ARCON96 consists of Tower 1 hourly meteorological data observations of 30 and 175 foot wind speed and direction, and 171-26 foot Delta Temperature Stability Class from Tower 2 data were used only for substitution of any missing Tower 1 data as follows:

Instrument Elevations (above tower grade)

	Tower 1 (primary) (Grade: 250 ft msl)	Tower 2 (backup) Grade: 121 ft msl)
Wind Speed:		
Elevation 1	30 ft	159 ft
Elevation 2	175 ft	304ft
Wind Direction:		
Elevation 1:	30 ft	159 ft
Elevation 2:	175ft	304 ft

Meteorological Evaluation Services Co., Inc. (MES) illustrated that the Tower 2 delta temperature data are sufficiently representative to be substituted for the Tower 1 delta temperature data; however, since the Tower 1 and Tower 2 delta temperature height intervals differ from each other somewhat, and also since for all years shown, the primary Tower 1 has data recovery rates well above the NRC's 90 percent requirements, it was deemed unnecessary to make such substitutions.

The designation of 'calm' is made to all wind speed observations 0.5 mph or less. The higher of the starting speeds of the Climatronics® wind vane and anemometer equipment on each of the towers (i.e., 0.5 mph) was used as the threshold for calm winds, per Regulatory Guide 1.145, Section 1.1 Reference 15.10-9.

15.10.2.1.3 Model Input Parameters

The parameters that were input into the ARCON96 model for use in calculating the Control Room X/Q are summarized below:

	North Stack	South Stack
Release Height (m)	61	61
Intake Height (m)	37.8	37.8
Horizontal Distance from Intake to Stack (m)	16.5	64.8
Elevation Difference between Stack Grade and Intake Grade (m)	0	0
Building Area (m^2)	5851	5851
Direction from Intake to Stack (°)	180	180

Vertical Velocity (m/s)	0	0
Stack Flow (m^3/s)	0	0
Stack Radius (m)	0	0

15.10.2.1.4 Control Room X/Q Results

A summary of the atmospheric diffusion estimates at the Control Room Intake for releases from the North and South Stacks is shown in Table 15.10-2.

15.10.2.2 Control Room Dose Model

The design basis for control room ventilation and shielding design is to limit exposures received by control room operating personnel to 5 rem total effective dose equivalent (TEDE) per 10CFR50.67. This basis is consistent with GDC 19.

The control room shielding is designed to reduce gamma radiation shine from normal and postaccident radiation sources to levels consistent with the requirements of 10CFR20 and GDC 19.

The postaccident ventilation system is designed to preclude entrance of unfiltered air to the control room, and to maintain outleakage of air from this zone with respect to other plant ventilation zones and the air outside the plant.

Details of control room postaccident ventilation system design and instrumentation are discussed in Sections 9.4.1 and 6.4.

During postaccident ventilation system operation, approximately 525 cfm of filtered outside air is supplied to the control room if airborne radioactivity is present outside the control room. If a high radiation accident occurs with the control room in the chlorine isolation mode for testing purposes or as required by the Action statement of an associated Technical Specifications Limiting Condition of Operation, automatic isolation of the control room for high radiation would not occur. Analysis of the event where the MCR HVAC is in a Chlorine Isolation has determined that the MCR HVAC can be in a chlorine isolation for the first seven hours, before it must be transferred into a Radiation Isolation Mode. This analysis assumes 0 scfm filtered air is supplied to the control room for the first seven hours.

In addition to the intake of air through the filter system, some air may enter the control room from inleakage through duct-work and other sources. An infiltration rate of 225 scfm (215 scfm unfiltered inleakage plus 10 scfm due to control room ingress/egress) has been assumed for these unfiltered sources. An assumed inleakage of 10 scfm through the control room doors has been justified by the use of a MCR door seal. The door seal is designed to be erected when thyroid dose in the Turbine Enclosure reaches 10 Rem/Hr. The design of the MCR door seal ensures a minimum cross sectional area through the door way during egress and ingress to ensure air velocity out of the MCR is sufficient to maintain a clean room environment.

Under accident conditions, radiation doses to control room personnel may come from several sources. While in the control room, personnel are exposed to beta and gamma radiation from gaseous fission products that enter after an accident through the ventilation system, or from unfiltered air entering the control room. In addition, personnel are subject to gamma shine dose

from fission products in the containment, and from fission products in the atmosphere outside the control room.

To evaluate the capability of the control room ventilation system and shielding to keep personnel doses within the specified criteria, an estimate of the average cloud activity concentration by time period prior to intake into the control room ventilation system was made. Since the plume is released as leakage from the containment, the released fission products were assumed to mix in the structure wake. The atmospheric dilution factors were determined using the assumptions and methods described in Reference 15.10-12.

The time-dependent concentration of activity outside the control structure is found by the following equation:

$$C_o = A\,(X/Q) \qquad \text{(EQ. 15.10-5)}$$

where:

A = activity release rate as a function of time, Ci/sec

X/Q = atmospheric dilution factor, sec/m^3

The activity in the control room is equal to the amount that enters during a given time, plus the amount present at the beginning of the period. The rate at which activity enters the control structure is given by:

$$Q = 1.7\,(F\,(1.0\text{-}E) + F_{01})C_o \qquad \text{(EQ. 15.10-6)}$$

where:

Q = activity intake rate, Ci/hr

F = ventilation flow rate of air into the control room (525 cfm) (0 cfm when control room HVAC system is in chlorine isolation mode)

E = efficiency of the intake filter (95% for iodine, 0% for the noble gases)

F_{01} = unfiltered air inleakage rate into the control room (225 scfm) (215 scfm unfiltered leakage plus 10 scfm for control room ingress/egress)

1.7 = conversion factor (cfm - 1.7 m^3/hr)

Activity buildup in the control room is given by:

$$\frac{dA}{dt} = Q - \left(\frac{60F}{V} + \frac{60F_{01}}{V} + \lambda_R + \lambda_O\right)A \qquad \text{(EQ. 15.10-7)}$$

where:

Q = activity intake rate, Ci/hr

A = activity present in control room, Ci

V = control room free volume, ft^3

λ_R = $\frac{\text{Recirculation rate}}{V} \cdot$ filter efficiency

= $\frac{(F_R)(E_R)}{V} \cdot 60$

λ_O = isotopic decay constant, hrs^{-1}

F_R = recirculation rate = 2475 cfm (3000 cfm when control room HVAC is in chlorine isolation mode)

E_R = recirculation filter efficiency (95% for iodine, 0% for noble gases)

Equation 15.10-7 can be solved analytically to obtain the activity as a function of time in the control room, A(t), and this integrated over a time period to obtain the time integrated activity inventory in the control room, (I). The time integrated concentration (c) for a given time period is calculated by dividing the inventory (I) by the control room volume. Dose rates in the control room can then be computed by time period.

The whole body dose model for operators inside the control room assumes that the operator is at the center of a finite hemispherical cloud of uniform concentration, whose volume is the same as that of the control room. For a point gamma source, the whole body dose is given by:

$$D_f = D_\infty / GF \qquad \text{(EQ. 15.10-8)}$$

where:

D_f = whole body gamma dose, rem/hr

D_∞ = gamma dose from semi-infinite cloud given by Equation 15.10-10

GF = geometry factor of control room

GF = $\frac{\text{Dose from an infinite cloud}}{\text{Dose from a cloud of volume (V)}}$ (EQ. 15.10-9)

= $\frac{1173}{V^{0.338}}$

(Reference 15.10-12)

V = volume of control room, ft^3

Whole body doses are given by the equation:

$$D_\infty = 3600 \sum_{}^{N} DCF_i \, C_i \qquad \text{(EQ. 15.10-10)}$$

$$\sum_{i=1}$$

where:

DCF_i = whole body gamma dose conversion factor, rem-m^3/Ci-sec

C_i = activity for isotope (i), Ci-hr/m^3

Skin doses from beta radiation are given by the equation:

$$D_s = 3600 \sum_{i=1}^{N} C_i DCF_i \qquad \text{(EQ. 15.10-11)}$$

where:

D_s = beta skin dose, rem

C_i = activity concentration, Ci-hr/m^3

DCF_i = beta dose conversion factor, rem-m^3/Ci-sec

3600 = conversion from hrs to seconds

The beta dose conversion factors are based on the work done by Berger (Reference 15.10-13), and include the effect of attenuation by the layer of dead skin. Values for these dose conversion factors are given in Table 15.10-1.

The thyroid dose for a given time period is given by the equation:

$$D_t = 3600\, B \sum_{i=1}^{N} C_i DCF_i \qquad \text{(EQ. 15.10-12)}$$

where:

D_t = thyroid inhalation dose, rem

B = breathing rate = 3.47×10^{-4} m^3/sec

DCF_i = thyroid dose conversion factors, rem/Ci

C_i = average iodine concentration, Ci-hr/m^3

3600 = conversion from hrs to seconds

15.11 PROBABILISTIC RISK ASSESSMENT

The LGS Probabilistic Risk Assessment was performed as requested by the NRC in its May 6, 1980 letter from D.G. Eisenhut (NRC) to E.G. Bauer, Jr. (PECo). The licensee submitted the PRA to the NRC in its March 17, 1981 letter from E.J. Bradley (PECo) to H.R. Denton (NRC).

15.12 STATION BLACKOUT

15.12.1 REQUIREMENTS AND LIMERICK RESPONSE

10 CFR 50.63 “Loss of All Alternating Current Power” defines the requirements for the Station Blackout and requires each light-water-cooled nuclear power plant licensed to operate to be able to withstand and recover from a station blackout as defined in 10 CFR 50.2. In 1988, the NRC issued Regulatory Guide 1.155, “Station Blackout” which describes a means acceptable to the NRC for meeting the requirements of 10 CFR 50.63. This regulatory guide endorses the document issued by the Nuclear Utility Management and Resources Council, NUMARC 87-00, “Guidelines and Technical Bases for NUMARC Initiatives Addressing Station Blackout at Light Water Reactors.”

LGS Units 1 and 2 were evaluated in accordance with the requirements of the Station Blackout Rule using guidance from NUMARC 87-00, except where RG 1.155 takes precedence. The results of the Limerick analyses and assessments are documented in letters to the NRC (References 15.12-2, 15.12-3, 15.12-4, and 15.12-5). The NRC acceptance of the Limerick responses to the Station Blackout Rule is documented in Safety Evaluation Reports - (References 15.12-6, and 15.12-7).

15.12.2 DETERMINATION OF REQUIRED COPING DURATION

10CFR50.63 requires that the plant be capable of maintaining core cooling and appropriate containment integrity for the station blackout duration. Section 50.63 further requires the following Information:

- A proposed station blackout duration including a justification for the selection based on the redundancy and reliability of the onsite emergency AC power sources, the expected frequency of the loss of offsite power (LOOP), and the probable time needed to restore offsite power;

- A description of the procedures that will be implemented for station blackout events for the duration (as determined in the paragraph above) and for recovery there from; and a list and proposed schedule for any needed modifications to equipment and associated procedures necessary for the specified SBO duration.

The required coping duration category is based upon the following factors:

1. Offsite Power Design - NUMARC 87-00 distinguishes between sites having particular susceptibilities to losing off-site power to plant-centered, grid-related, and weather-related events. Three off-site power design groups are provided and are designed to be mutually exclusive. Of the three groups P2 includes those sites whose off-site power sources are less redundant or independent, or that are more susceptible to extended offsite power losses due to weather-initiated events or more frequent losses due to plant-centered events. Based upon NUMARC 87-00 guidance, Limerick Generating Station is determined to be in AC Power Design Characteristic Group, P2. This determination is based upon the following criteria of NUMARC 87-00.

    a) The expected frequency of grid-related loss of offsite power (LOOP) does not exceed once per twenty years. As discussed in Limerick Generating Station UFSAR Section 15.2.6, the loss of all grid connections is categorized as an incident of moderate frequency.

b) Sites are categorized in groups based upon the estimated frequency of LOOPs due to Extremely Severe Weather. The estimated frequency of loss of off-site power due to ESW is determined by the annual expectation of storms at the site with wind velocities greater than or equal to 125 mph. It has been determined that Limerick Generating Station falls within Extremely Severe Weather Group 3. This was determined utilizing Table 3-1, Extremely Severe Weather Groups Table and Table Extremely Severe Weather Data provided in NUMARC 87-00.

c) The estimated frequency of LOOPs due to severe weather places Limerick Generating Station in Severe Weather Group 2 based on site specific factors. This was determined utilizing Table 3-3, Severe Weather Data and Table 3-4, Severe Weather Group Table provided in NUMARC 87-00.

d) The potential for long duration loss of off-site power events can have a significant impact on station blackout risk and required coping duration. Long duration LOOP events are associated with grid failures due to severe weather conditions or unique transmission system features. Shorter duration LOOP events tend to be associated with specific switchyards features, in particular:

   1) The independence of the off-site power source constituting the preferred power supply to the shutdown buses on-site, and

   2) The power transfer schemes when the normal source of AC power is lost. Limerick Generating Station has two off-site power systems that provide the preferred AC electrical power to all Class 1E loads as discussed in UFSAR Chapter 8 (NUMARC 87-00 Group A).

   Limerick Generating Station also has two electrically-connected switchyards, and all safe shutdown busses are automatically transferred to the alternate power source on loss of the preferred source (NUMARC-87-00 Group 1 ½*).*

2. Onsite Emergency AC (EAC) Power Configuration - After the likelihood of losing off-site power, the redundancy of the emergency AC power system is the next most important contributor to station blackout risk. With greater EAC system redundancy, the potential for station blackout diminishes, as does the likelihood of core damage. Each Limerick unit is equipped with four emergency diesel generators (EDG). Anyone of the EDGs is necessary to operate safe-shutdown equipment at either unit following a loss of offsite power for an extended period.

It is noted that the total shutdown-load requirements for both units combined is greater than the continuous rating of one EDG in each unit and that a minimum of three EDGs are required to support simultaneous shutdown of the two units. Limerick credits excess capacity from the non-blacked out (NBO) unit as the alternate AC (AAC) power source for the blacked out (BO) unit. Limerick does not rely on a single EDG from the NBO unit as the AAC source for the BO unit. Also, a limited amount of operator actions are credited to initiate cross-ties between electrical power sources in order to justify the excess capacity from the NBO unit's EDGs. Shutdown-load requirements are such that the capacity of three EDGs is needed to shutdown the two units following a LOOP. For any Individual unit, the shutdown loads will require the capacity of more than one EDG. Thus, two are the minimum required number of EDGs per unit. Since two of the

four EDGs per unit are needed for shutdown, making the EAC classification of EAC Group B per NUMARC 87-00, Table 3-7.

a) Calculated EDG Reliability - The target emergency diesel generator reliability for Limerick Station is selected to be 0.95. The selection of this value is consistent with NUMARC 87-00 and is based upon having a nuclear unit average reliability for the last 100 demands greater than 0.95.

b) Allowed EDG Reliability - An EDG reliability program has been established to monitor and maintain the EDG target reliability of 0.95 utilizing guidance in RG 1.155, Regulatory Position C.1.2. If the EDG performance falls below the target reliability level of 0.95, action will be taken as required by the EDG reliability program to restore the affected EDG to the target reliability level.

In summary, using the above factors, LGS is a four hour coping duration plant per Table 3-8 in NUMARC 87-00 (Table 2 in RG 1.155).

15.12.3 USE OF ALTERNATE AC SOURCE

The LGS offsite power supplies, the station auxiliary power system, and the onsite 4 kV Safeguard Power System are shown in Drawings E-1, E-15 and E-16. At Limerick, Station Blackout is supported by the use of the diesel generators (excess capacity on non-blacked out unit) as an alternate ac (AAC) power source required to be available within one hour from the initiation of a station blackout event to support safe shutdown and decay heat removal from the blacked out unit for the required four hour coping duration. The potential for excess EAC power sources to be used as AAC is directly related to the existing level of EAC redundancy.

Each Limerick unit is equipped with four emergency diesel generators (EDGs). Any one of the EDGs is necessary to operate safe-shutdown equipment at either unit following a loss of offsite power for an extended period. It is noted that the total shutdown-load requirements for both units combined is greater than the continuous rating of one EDG in each unit and that minimum of three EDGs are required to support simultaneous shutdown of the two units. The AAC design at Limerick Generating Station uses a limited amount of operator actions to initiate electrical cross-ties between power sources in order for the blacked-out (BO) unit to utilize the excess capacity from the NBO EDGs.

There are a number of mechanical systems at LGS whose functions are normally shared between units (e.g., Residual Heat Removal Service Water (RHRSW), and Emergency Service Water (ESW)). Accordingly, the loads for certain of these systems were assumed to be powered by the adjacent unit's power source. Due to the assumed loss of one of the NBO diesels, there is some likelihood that the failed EDG will power an ESW pump and that only one ESW loop will be available in the initial few minutes of the SBO event. The ESW loop will be restored during the cross-tie of the NBO 4kV busses. After the busses are cross-tied, ESW will be restored and the third diesel on the NBO can be restarted to support the BO unit shutdown loads. This is intended to be performed during the first 60 minutes of the SBO event.

For LGS Units 1 and 2, the AAC power source satisfies the requirements for station blackout in conformance with Regulatory Guide 1.155.

15.12.4 ASSESSMENT OF ABILITY TO COPE WITH A STATION BLACKOUT

Coping with station blackout using the AAC approach entails a short period of time in an ac-independent state (up to one hour) while the operators initiate power from the AAC source. Once AAC power is available, the plant transitions to the AAC source which provides decay heat removal until offsite or EAC power becomes available. Therefore, the LGS coping assessments must address the four hour coping duration but certain safe shutdown equipment such as RHR pumps, air compressors, and battery chargers can be repowered after the first hour and used for the remainder of the coping duration. Coping assessments were performed in the following areas: condensate inventory, Class 1E battery capacity, compressed air, loss of ventilation, and containment isolation. In each case, capability to successfully cope with blackout for the four hour period was demonstrated.

15.12.4.1 Condensate Inventory for Decay Heat Removal

A supply of 92,100 gallons of water is required for decay-heat removal during a SBO 4-hour coping period. A calculation was performed to show that the Condensate Storage Tank (CST) provides 138,800 gallons of water, which exceeds the required quantity for coping with a four-hour station blackout. A leakage rate of 25 gpm per recirculation pump was assumed in the calculated analysis. Since the AAC power source will be available within one hour, the residual heat removal (RHR) system would be powered to provide suppression pool cooling. Therefore, the CST inventory will not be required at any time during the four-hour duration of the SBO event. The calculation demonstrates the acceptability of using only the suppression pool inventory for reactor pressure vessel (RPV) makeup and reactor heat removal. No credit for the water volume has been taken in the SBO analysis and the CST inventory is available as an additional heat removal source.

15.12.4.2 Class 1E Battery Capacity

The Class 1E battery bank has sufficient capacity to independently supply the required loads for a design basis accident for 4 hours. The SBO loads are a subset of the design basis accident loads, the station battery capacity is sufficient to meet SBO shutdown requirements for 4 hours. At 1 hour into the SBO event, with the AAC power source available, the ability to power selected battery chargers is available.

15.12.4.3 Compressed Gas

The AAC power source is capable of energizing an instrument air compressor and an instrument gas compressor within one hour of a station blackout. The only air-operated valves relied upon during a station blackout are the Automatic Depressurization System (ADS) valves. These valves have sufficient backup gas supplies to cope with a station blackout for the entire event and sufficient local gas supply is available such that reliance of the air compressor after an hour is not needed. Valves requiring manual operation or that need backup sources will be identified in station procedures.

15.12.4.4 Effects of Loss Of Ventilation

Reasonable assurance of operability is established if the following criteria are met:

1) The temperature in the Dominant Area of Concern (DAC) are calculated to be equal to or less than 120, or

2) The system in the DAC is assumed to operate no longer than 10 minutes after the onset of the blackout, or

3) The methodology outlined in Appendix F of NUMARC 87-00 indicates that no components in the DAC have operability limits below the calculated bulk room temperature.

At Limerick Generating Station, the AAC power supply does not power cooling loads to some plant areas that contain station blackout response equipment during the hour after the onset of the station blackout event. Evaluation of the following specific areas was performed Units 1 and 2 APRM Inverters (Aux Equip Rm), Unit 2 RPS computer and Inverter rooms, RCIC Pump Room, Drywell and Main Control Room. These areas have been evaluated to establish reasonable assurance of operability for station blackout event.

15.12.4.5 Containment Isolation

The station list of containment isolation valves has been reviewed to verify that the valves which must be capable of being closed or that must be operated (cycled) under station blackout conditions can be positioned (with indication) independent *at* the preferred and black-out unit's Class 1E power supplies.

No plant modifications were determined to be required to ensure that appropriate containment integrity can be provided under SSO conditions. Limerick Generating Station procedures include all actions necessary to assure containment integrity.

15.12.4.6 Reactor Coolant Inventory

Adequate reactor coolant system (RCS) inventory is maintained to ensure core cooling for 4-hour duration. HPCI and RCIC system are capable *at* supplying sufficient inventory to keep the core covered. RCS makeup is necessary to remove decay heat, to compensate for RCS cool down, and to replenish an assumed RCS inventory loss of 50 gpm due to the reactor coolant pump seal leakage (25 gpm per pump) and to provide for Technical Specification maximum allowable leakage (30 gpm). The RCIC pump, which is steam-driven, injects at a rate of 600 gpm, which exceeds the average water injection rate necessary for decay heat removal and the 80 gpm leak rate.

The AAC source powers the necessary make-up systems within 1 hour to maintain adequate RCS inventory to ensure that the core is cooled for the required coping duration. The expected rates of reactor coolant inventory loss under SBO conditions do not result in uncovering the core in an SBO of four hours.

15.12.5 PROCEDURES FOR SBO

Limerick Generating Station procedures comply with the guidelines of NUMARC 87-00, Section 4. SBO response guidelines provide for operator actions to be taken in a SBO event; guidance is provided to operations and load dispatcher personnel for actions to restore AC power in a station blackout; and guidance is given for operators to determine the proper actions due to the onset severe weather. During the SBO event, for the NBO unit, excess capacity is not attained by load shedding. This ensures that there is no degradation of the normally available shutdown capability for the LOOP condition. Additionally, there is no load switching or disablement of information readouts or alarms in the main control room that would degrade the normal

shutdown capability for a LOOP in the NBO unit. Limerick Generating Station procedures incorporate these guidelines and are described as follows:

Procedure E-1 – Loss of All AC Power (Station Blackout)

Procedure E-10/20 – Loss of Offsite Power
Verifies Containment Isolation Valves

Procedure SE-9 – Preparation for Severe Weather

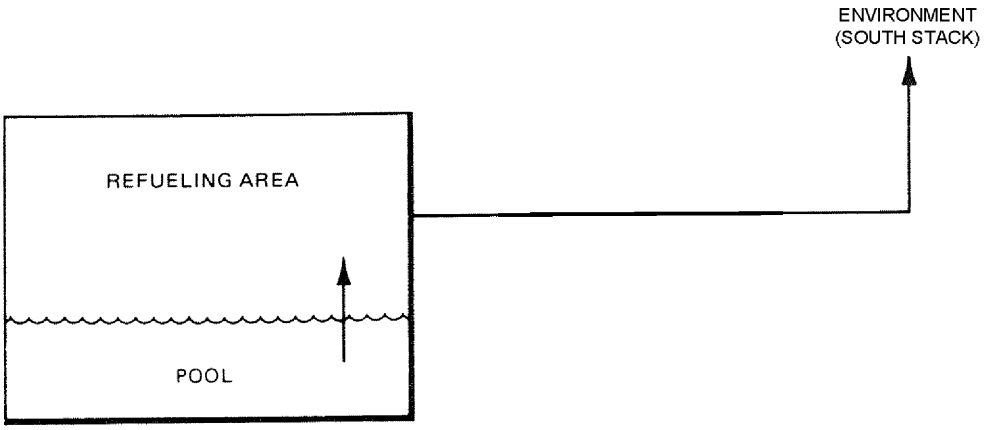
Leakage Rates and Secondary Containment Mixing Parameters		
Path	**Description**	**Parameters & Values**
L_1	Primary Containment Leakage to Secondary Containment	Leak Rate: L_a = 0.50 %/day, 0 - 15.5 min after start of gap release. Release is unfiltered through the North Stack during drawdown period.
P_1	Release from Secondary Containment to Environment through SGTS Filter	L_a = 0.50 %/day, 15.5 min - 24hr Release is SGTS filtered through North Stack. 0.5 x L_a = 0.25 %/day, 1 - 30days Release is SGTS filtered through North Stack.
L_2	MSIV Leakage to Condenser Environment	Leak Rate: Based on LLRT acceptance criterion of 200 scfh for all main steam (MS) lines, 100 scfh maximum for any one MS line when measured at greater than or equal to 22 psig. Two steam lines are each treated as two-node well-mixed volumes each with 100 scfh flow, after various adjustments discussed below. Leak rate reduced to 55.1% after 24 hours. Release is from Turbine Building, unfiltered through North Stack. Analytically, flow is direct from the condenser to the North Stack.
P_2	Leakage Well Mixed in HP Turbine/Condenser Shell. No credit for transport to other shells through available opening. No credit for substantial plateout potential on Condenser Tubing.	
P_3	Leak from Turbine Shaft Seals to Turbine Building Atmosphere	
P_4	Flow from Turbine Building to North Stack. No credit for mixing or holdup or deposition in Turbine Building. No filtration is provided for this flow.	
L_3	**ECCS Leakage (Supp. Pool Water Source) to Secondary Containment**	Leak Rate: 5 gpm, 0 - 15.5 min {2x administrative limit} Release is unfiltered through North Stack during drawdown period.
P_1	Release from Secondary Containment to Environment through SGTS Filter	5 gpm, 15.5 min - 30days {2x administrative limit} Release is SGTS filtered through North Stack.

Figure 15.6-3 (Cont'd)

Layout of Intakes and Release Points
(Sheet 3 of 3)



P_1	**Release of Secondary Containment Atmosphere to the Environment**	Secondary Containment mixing credit in 50% of the Reactor Enclosure Volume. RERS provides the mixing mechanism. Volume (for analysis) = 900,000 cubic feet Outflow (for analysis) = 3000 cfm during drawdown period and 2500 cfm thereafter. For the first 15.5 minutes, flow is directed through the North Stack without RERS or SGTS filter credit.
R_1	Control Room Intake from the Release to the Environment	525 cfm Maximum filtered intake, plus 225 cfm of unfiltered inleakage. Total CREFAS flow is 2700 cfm, with recirculation being the balance after intake is subtracted. CREFAS filters credited at 99% for aerosols (based on HEPA) and 95% for charcoal absorbers (for elemental and organic iodine.)
	Control Room Exhaust to Environment	750 cfm, to balance with intake and inleakage
R_2	Release to Environment for Offsite Dose Assessment Purposes	R_1 and R_2 include Primary Containment to Secondary Containment, ECCS Leakage, and MSIV Leakage related releases

APPENDIX 15A - CONTINUOUS CONTROL ROD WITHDRAWAL TRANSIENT ANALYSIS

15A.1 INTRODUCTION

The continuous control rod withdrawal transient analysis in the startup range (Section 15.4.1.2) was performed to demonstrate that the licensing basis criteria for fuel failure will not be exceeded when an out-of-sequence control rod is withdrawn at the maximum allowable normal drive speed. The sequence and timing assumed in this special analysis are shown in Table 15A-1.

The RWM constraints on rod sequences will prevent the continuous withdrawal of an out-of-sequence rod. This analysis was performed to demonstrate that, even for the unlikely event where the RWM fails to block the continuous withdrawal of an out-of-sequence rod, the licensing basis criterion for fuel failure is still satisfied.

The methods and design basis used for performing the detailed analysis for this event are similar to those previously approved for the control rod-drop accident (References 15A.1 through 15A.3). Additional simplified point model kinetics calculations were performed to evaluate the dependence of peak fuel enthalpy on the control blade worth. For the detailed calculation, the 50% control rod density pattern was selected as the initial starting condition, which is consistent with the approved design basis for the control rod-drop accident (References 15A.1 through 15A-3).

The licensing basis criterion for fuel failure is the contained energy of a fuel pellet located in the peak power region of the core which shall not exceed 170 cal/gm-UO_2.

15A.2 METHODS OF ANALYSIS

Because the rod worth calculations using the approved design basis methods (References 15A.1 through 15A-3) use three-dimensional geometry, it is not practical to do a detailed analysis of this event parameterizing control rod worths. Therefore, the methods of analysis employed were to perform a detailed evaluation of this event for a typical BWR and control rod worth (1.6% Δk) and to use a point model calculation to evaluate the results over the expected ranges of out-of-sequence control rod worths. The detailed calculations are performed to demonstrate (1) the consequences of this event over the expected power operating range and (2) the validity of the approximate point model calculation. The point model calculation will demonstrate that the licensing criterion for fuel failure is satisfied over the range of expected out-of-sequence control rod worths. These methods are described in detail below.

The methods used to perform the detailed calculation are identical to those used to perform the design basis control rod-drop accident with the following exceptions:

a. The rod withdrawal rate is 3.6 in/sec (0.3 fps) rather than the blade drop velocity of 3.11 fps.

b. Scram is initiated either by the IRM or 15% APRM scram in the startup range. The IRM system is assumed to be in the worst bypass condition allowed by Technical Specifications.

c. The blade being withdrawn inserts along with remaining drives at Technical Specification insertion rates upon initiation of scram signal.

Examination of a number of rod withdrawal transients in the low power startup range, using a two-dimensional R-Z model, has shown that higher fuel enthalpy addition would result from transients starting at the 1% power level rather than from lower power levels. The analysis further shows that for continuous rod withdrawal from these initial power levels (1% range) the APRM 15%

power level scram is likely to be reached as soon as the degraded (worst bypass condition) IRM scram. Consequently, credit is taken for either the IRM or APRM 15% scram in meeting the consequences of this event. The transients for this response were initiated at 1% of power and were performed using the 15% APRM scram.

An initial point kinetics calculation was run to determine the time to scram based on an APRM scram setpoint of 15% power and an initial power level of 1%. From this time and the maximum allowable rod withdrawal speed, it is possible to show the degree of rod withdrawal before reinsertion due to the scram. From this information, Figure 15A-1, showing the modified effective reactivity shape, was constructed.

The point model kinetics calculations use the same equations employed in the adiabatic approximation described on page 4-1 of Reference 15A.1. The rod reactivity characteristics and scram reactivity functions are input identically to the adiabatic calculations, and the Doppler reactivity is input as a function of core average fuel enthalpy. The Doppler reactivity feedback function input to the point model calculations was derived from the detailed analysis of the 1.6% rod worth case described above. This is a conservative assumption for higher rod worths because the power peaking and therefore spatial Doppler feedback will be larger for higher rod worths. As will be seen in Section 15A.3, maximum enthalpies resulted from cases initiated at 1% of rated power. In this power range, the APRM will initiate a scram at 15% of power; therefore, the APRM 15% power scram was used for these calculations, thereby eliminating the need to perform the spatial analysis required for the IRM scram. All other inputs are consistent with the detailed transient calculation.

The point model kinetics calculations result in core average enthalpies. The peak enthalpies were calculated using the following equation:

$$h = h_o + (P/A)_T (\bar{h}_f - h_o) \qquad \text{(EQ. 15A-1)}$$

where:

- h = Final peak fuel enthalpy
- h_o = Initial fuel enthalpy
- $\bar{h}_f$ = Final core average fuel enthalpy
- $(P/A)_T$ = Total peaking factor (radial peaking · axial peaking · local fuel pin peaking).

For these calculations, the (radial · axial) peaking factors as a function of rod worth were obtained from the calculations performed in section 3.6 of Reference 15A-2 and are shown in Figure 15A-2. It was conservatively assumed that no power flattening due to Doppler feedback occurred during the course of the transient.

15A.3 RESULTS

The reactivity insertion resulting from moving the control rod is shown in Figure 15A-1 for the point kinetics calculations. The core average power versus time and the global peaking factors from section 3.6 of Reference 15A-2 are shown in Figures 15A-3 and 15A-2, respectively. The results of the point kinetics calculation are summarized in Table 15A-2 along with the results of the detailed analysis.

From Figure 15A-3 and Table 15A-2, it is shown that the core average energy deposition is insensitive to control rod worth; therefore, the only change in peak enthalpy as a function of rod worth will result from differences in the global peaking which increases with rod worth. Comparison of the global peaking factors shown in Figure 15A-2 with the values used in the detailed calculations demonstrates that the Reference 15A-2 values are reasonable for their application in this study. For all cases, the peak fuel enthalpy is well below the licensing design criteria of 170 cal/gm.

Cases 4 and 5 of Table 15A-2 show that the point kinetics calculations give conservative results relative to the detailed evaluations. The primary difference is that the global peaking will flatten during the transient due to Doppler feedback. This is accounted for in the detailed calculation, but the point kinetics calculations conservatively assumed that the peaking remains constant at its initial value.

The differences in core average and peak enthalpy between cases 1 and 5 are due to the fact that for case 1 the scram was initiated by the 15% APRM scram setpoint, whereas in case 5 the scram was initiated by the IRMs. As seen by Figure 15A-4, this occurred at a core average power of 21%. Because the APRM trip point will be reached first, it is reasonable to take credit for the APRM scram.

15A.4 CONCLUSIONS

From this study, the following conclusions can be stated:

a. The resultant peak fuel enthalpies due to the continuous withdrawal of an out-of-sequence rod in the startup range results in peak fuel enthalpies that are significantly less than the licensing basis criteria of 170 cal/gm.

b. The point model calculations used to assess the sensitivity of peak enthalpy as a function of control rod worth are in good agreement with, and slightly conservative relative to the more detailed design basis model which is employed to evaluate the continuous rod withdrawal transient in the startup range.

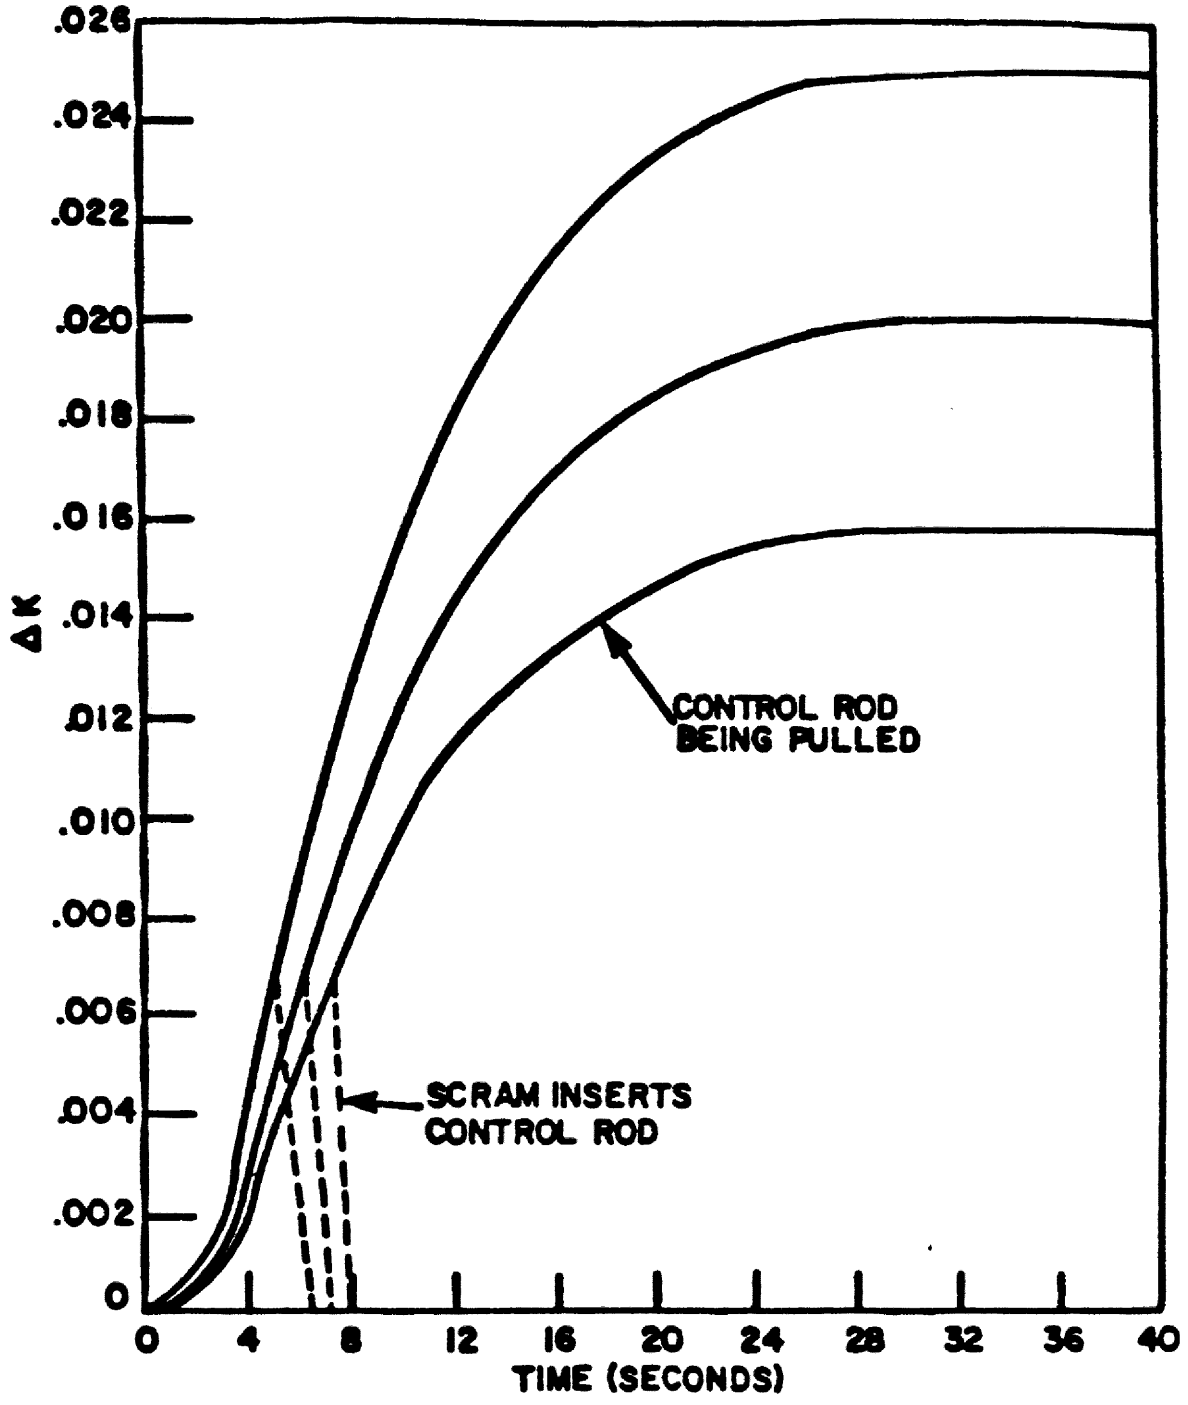
Table 15A-1

SEQUENCE OF EVENTS FOR CONTINUOUS ROD WITHDRAWAL DURING REACTOR STARTUP

TIME (sec)	EVENT
0	The reactor is critical and operating in the startup range.
>0	The operator selects and withdraws an out-of-sequence control rod at the maximum normal drive speed of 3.6 in/sec.
4 sec (Approx)	The RWM fails to block the selection (selection error) and continuous withdrawal (withdraw error) of the out-of-sequence rod.
4-8 sec	The reactor scram is initiated by the IRM system or the APRM system.
5-9 sec	The prompt power burst is terminated by a combination of Doppler and/or scram feedback.
10 sec	The transient is finally terminated by the scram of all rods, including the control rod being withdrawn. Scram insertion times are assumed to be technical specification insertion rates.

Table 15A-2

SUMMARY OF RESULTS FOR DETAILED AND POINT KINETICS EVALUATIONS OF CONTINUOUS ROD WITHDRAWAL IN THE STARTUP RANGE

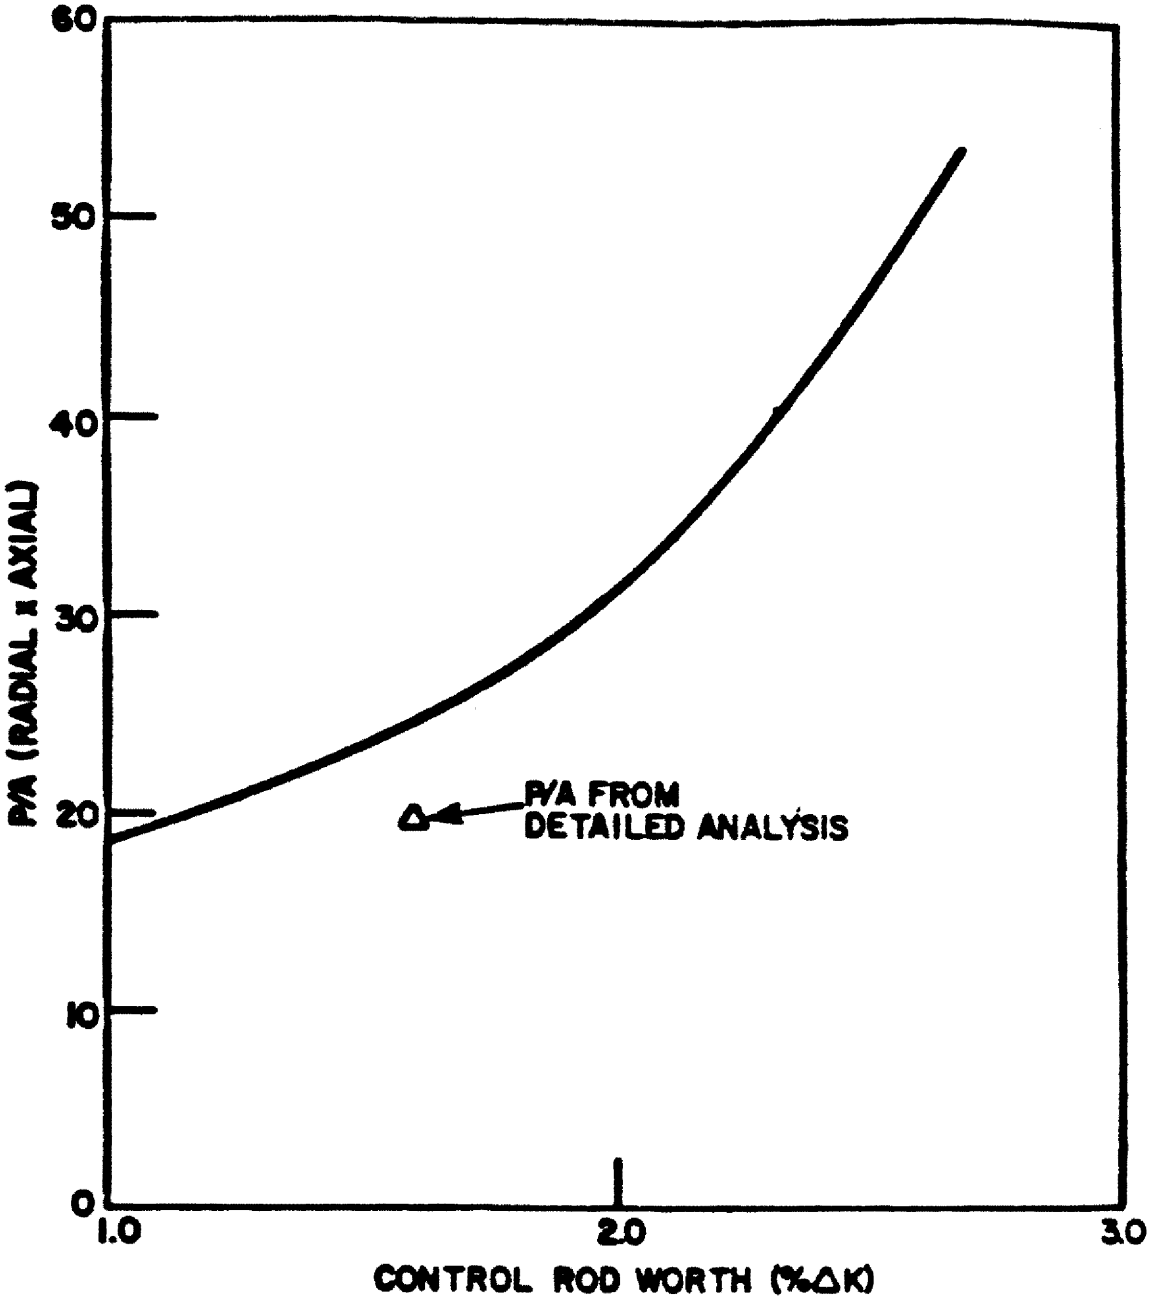


Case	Control Rod Worth (%Δk)	h_f(cal/gm)	P/A[1]	h(cal/gm)
1	1.6	17.3	24.2	42.7
2	2.0	17.3	30.9	50.0
3	2.5	17.2	46.0	58.5
4	1.6[2]	18.3	19.7[3]	56.2
5	1.6[4]	18.3	19.7	59.6

(1) P/A = global peaking factor (Radial · Axial).

(2) Detailed transient calculation. All other data reported are for point kinetics calculations.

(3) The P/A = 19.7 is the initial value. For the detailed analysis, this value will decrease during the course of the transient because the power shape will flatten due to Doppler feedback.



(4) Point kinetics calculation with IRM initiated scram and three-dimensional simulator global peaking.

APPENDIX 15B

Limerick Generating Station, (LGS) Units 1 and 2

15B.0 INTRODUCTION

This appendix summarizes the analyses performed in support of the LGS Units 1 and 2 operating power/flow map expansion and the contingency mode of operation with selected individual equipment out-of-service. The maximum extended operating domain consists of the maximum extended load line region and the increased core flow region. The equipment out-of-service analyses include turbine bypass system, feedwater heaters, end-of-cycle recirculation pump trip and single recirculation loop operation. The power/flow map expansion and equipment out-of-service analyses assume the rerate thermal power of 3458 MWt (References 1 through 6). TRACG implementation analyses results (References 7 and 8) are based on a thermal power of 3,515 MWt.

15B.1 MAXIMUM EXTENDED OPERATING DOMAIN AND PARTIAL FEEDWATER HEATING ANALYSIS

This analysis justifies the operation of LGS Units 1 and 2 in the maximum extended operating domain described in Figure 15.0-1. The safety impact evaluation of this extended region was performed with partial feedwater heating.

15B.1.1 MAXIMUM EXTENDED LOAD LINE LIMIT REGION

The maximum extended load line limit (MELLL) region is defined as a power/flow operating domain bounded by:

a. 100% rated power.

b. the load line which intercepts 100% power, and

c. 100% rated rod line.

MELLL improves operational flexibility during power ascension by providing additional operating room above the original rated load line. It also provides a lower core flow condition at a rated power to allow for flow control reactivity compensation due to fuel burnup during an operating cycle and for improved fuel cycle economics.

The extended power/flow region has been created to provide relief from the operating restrictions inherently imposed during ascension to power by the previous power/flow region. The MELLL boundary (% core flow at the 100% rerated core power) was determined generically, based on safety and evaluations performed to meet required thermal and reactivity margins for BWR plants. When compared to the initial power/flow operating domain, operating in the MELLL region results in plant operation at a higher load line, which allows for higher core power at a given core flow. This condition increases the fluid subcooling in the downcomer region of the reactor vessel which affects the power distribution in the core and potentially affects steady-state operating thermal limits and transient accident/performances. The impact of this operating mode was evaluated to ensure safe plant operation.

The evaluations to support this operational domain at the rerated condition of 3458 Mwt are documented in Reference 1 and 6. The MELLL analyses also considered the equipment out-of-service assumptions.

15B.1.2 INCREASED CORE FLOW/FINAL FEEDWATER TEMPERATURE REDUCTION REGION

The increased core flow (ICF) region (Figure 15.0-1) is defined as a power/flow operating domain bounded by:

a. 100% rated power.

b. 110% rated core flow, and

c. 100% rated core flow.

The ICF region is a feature that improves operational flexibility during power ascension by providing additional flow range at rated power to compensate for xenon variations during power changes. The ICF capability provides reactivity compensation due to fuel burnup during an operation cycle and additional reactivity to extend an operating cycle to improve fuel cycle economics.

The safety evaluation addresses ICF operation throughout the cycle, and ICF with Final Feedwater Temperature Reduction (FFWTR) during end-of-cycle extension and power coastdown. The amount of FFWTR considered in the analysis corresponds to a reduction of 105°F from the nominal feedwater temperature conditions.

Limiting transients events were performed at the bounding condition of 110% of rated core flow, and the results are documented in Reference 3. These ICF/FFWTR evaluations also included various equipment out-of-service such as the turbine bypass system, and the end-of-cycle recirculation pump trip.

15B.1.3 FEEDWATER HEATING OUT-OF-SERVICE

Feedwater heating out-of-service (FWHOOS) is defined as operation with feedwater heaters out-of-service, corresponding to operation with a reduction in feedwater temperature of up to 60°F from nominal.

The FWHOOS feature provides potential improved plant availability by allowing continued unrestricted plant operation with feedwater heaters out-of-service.

The FWHOOS analysis was performed for a core thermal power of 3458 MWt, using the LGS expanded operating domain. The results are described in References 4 and 5.

15B.2 ARTS PROGRAM

The ARTS program is a performance improvement feature which updates fuel thermal limits administration at partial power/flow conditions, improves instrumentation response and increases plant operating flexibility and efficiency.

ARTS provides limits for MCPR and MAPLHGR as a function of power and flow to better ensure fuel cladding integrity. It also modifies the basis of rod block monitor trips to terminate excessive reactivity insertions during rod withdrawal error events. The original flow-biased rod block monitor trips are replaced by local power biased trips.

The ARTS analyses (References 2 and 6) were performed at the rerated power level of 3458 MWt and a maximum core flow of 110% of rated. The analysis also assumes equipment out-of-service such as turbine bypass and end-of-cycle recirculation pump trip and single loop operation. The results are summarized in Reference 2 for all equipment in-service and in Reference 6 for the equipment out-of-service conditions.

15B.3 SINGLE LOOP OPERATION

Single Loop Operation (SLO) at a reduced power is a valuable feature from a plant availability/outage standpoint. The capability to operate with a single recirculation loop is highly desirable in the event that a recirculation pump or other component renders one loop inoperable. The analyses necessary to justify SLO operation are evaluated in Reference 2.

15B.4 OTHER EQUIPMENT OUT-OF-SERVICE

In addition to the FWHOOS feature, LGS also has the turbine bypass system out-of-service (TBSOOS) and the end-of-cycle recirculation pump trip out-of-service (EOC-RPTOOS) features. Subsequent to the analysis supporting power/flow map expansion, an additional equipment out-of-service feature, power load unbalance out-of-service (PLUOOS), was implemented.

15B.4.1 TURBINE BYPASS SYSTEM OUT-OF-SERVICE

Turbine bypass operation has a significant impact on the severity of fast pressurization events. Of these AOOs, the turbine trip no bypass (TTNBP) and load rejection no bypass (LRNBP) events already exclude the turbine bypass operation from their licensing event basis assumptions. The feedwater controller failure (FWCF) normally evaluated with an operable bypass system is therefore re-analyzed without the turbine bypass function.

The TBSOOS option was integrated in the power/flow map expansion and performance improvement programs (including power rerate) previously described. The results of the Anticipated Operating Occurrences (AOO) analysis with TBSOOS are described in Reference 1.

Turbine Bypass System OOS may be referred to as Turbine Bypass Valve (TBVOOS) in some documentation. Starting with Limerick 2 Cycle 14, references to "TBVOOS" that do not meet the definition in Section 15B.4.6 were changed to be referred to as "TBSOOS" to reflect that the bypass valves are assumed to be unable to provide pressure control, and so transients that rely on the bypass system for pressure control (e.g., rod withdrawal error), are analyzed accordingly for the TBSOOS condition.

15B.4.2 END-OF-CYCLE RECIRCULATION PUMP TRIP OUT-OF-SERVICE

The purpose of the end-of-cycle recirculation pump trip (EOC-RPT) is to protect the integrity of the fuel cladding during fast pressurization transients, especially turbine generator trips. It supplements the reactor scram function during these events. The trip of the reactor recirculation pumps early in these transient events decreases the magnitude of the power excursion by adding negative reactivity to the core, consequently resulting in lower thermal operating limits.

For the power/flow map expansion and equipment-out-of-service features previously described, both the limiting TTNBP and FWCF events are analyzed with the EOC-RPTOOS option. The results of these analyses are described in Reference 1.

15B.4.3 POWER LOAD UNBALANCE OUT-OF-SERVICE

The purpose of the power load unbalance (PLU) is to prevent turbine over-speed in the event of a load rejection. The PLU prompts the fast closure of the turbine control valves when an unbalance is detected while operating above 55% power. With the PLUOOS, a load rejection event will not cause fast closure of the TCVs. A backup trip from the generator protection system logic is credited and results in a turbine trip signal.

15B.4.4 PRESSURE REGULATOR OUT-OF-SERVICE

The purpose of the Pressure Regulator Out-of-Service (PROOS) is to support operation when one pressure regulator is out-of-service and the system is no longer single failure proof. Failure of a pressure regulator downscale, when there is no second pressure regulator operable will cause slow closure of the turbine control valves. This event can require more limiting thermal limits.

The results of these analyses are described in References 7 and 8 and/or included as part of the cycle-specific reload analysis.

15B.4.5 SAFETY RELIEF VALVE OUT-OF-SERVICE

The Safety/Relief Valves (S/RVs), as described in UFSAR Chapter 5, ensure that peak reactor pressure is maintained below ASME upset limits. This option provides support to operate the plant with two safety and/or relief valves declared out-of-service (OOS) and is included with the SRV setpoint tolerance increase (Reference 9). The transient analyses are confirmed on a reload-specific basis; other analyses (LOCA, structural, etc.) are performed generically or with fuel-type specific basis.

15B.4.6 TURBINE BYPASS VALVE OUT-OF-SERVICE

This option differs from TBSOOS discussed in 15B.4.1 in that a limited number of Turbine Bypass Valves (TBV) are out-of-service instead of the entire Turbine Bypass System. As permitted by station Technical Specifications, a certain number of TBVs are permitted to be OOS as specified in the Core Operating Limits Report (COLR). If this number is exceeded, the entire Turbine Bypass System is considered to be OOS.

15B.4.7 MAIN STEAM ISOLATION VALVE OUT-OF-SERVICE

This option provides justification for continuous operation with a main steam isolation valve (MSIV) OOS when there is not compliance with the requirements of the technical specifications for the main steam isolation valves closure characteristics (Reference 10). Limitations on the maximum permissible power level when operating with an MSIVOOS are provided in the cycle specific Supplemental Reload Licensing Report (SRLR).

15B.5 SUMMARY AND CONCLUSION

Specific analyses have been performed to determine the impact of LGS plant operation with the above specified reactor performance improvements. The results demonstrate that all licensing basis criteria for the required safety analyses are acceptable. These include the following analysis evaluations.

a. Anticipated Operational Occurrences (AOOs) Analysis

b. Loss-Of-Coolant Analysis

c. Containment Response

d. Reactor Vessel and Internals Mechanical Integrity

e. Miscellaneous Impact Verifications (e.g. Anticipated Transients Without Scram).

The AOOs analyses are cycle-specific and are reanalyzed during subsequent fuel cycles as part of the reload licensing scope of work. The LOCA analysis is fuel type specific and is evaluated or reanalyzed as required. The containment dynamic loads, reactor internal components structural integrity and the miscellaneous analyses are cycle-independent. These tasks are performed during the initial application of the performance improvement programs and remain valid for subsequent fuel reloads, unless the analyses boundaries and/or analytical assumptions are subsequently changed.

CHAPTER 16 - TECHNICAL SPECIFICATIONS

TABLE OF CONTENTS

16.1 PRELIMINARY TECHNICAL SPECIFICATIONS

16.2 PROPOSED FINAL TECHNICAL SPECIFICATIONS

CHAPTER 16 - TECHNICAL SPECIFICATIONS

16.1 PRELIMINARY TECHNICAL SPECIFICATIONS

This section is not applicable to the LGS UFSAR.

16.2 PROPOSED FINAL TECHNICAL SPECIFICATIONS

The final Technical Specifications for Limerick Unit 1 are based on the NRC's Standard Technical Specifications for BWRs (NUREG-0123) and were issued as Appendix A to Facility Operating License NPF-39. The proposed final Technical Specifications for Unit 2 were based on Unit 1 Technical Specifications as a guide. The Unit 2 Technical Specifications were issued as Appendix A to Facility Operating License NPF-85.

CHAPTER 17 - QUALITY ASSURANCE

17.1 QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION

This section is not applicable to the LGS UFSAR.

17.2 QUALITY ASSURANCE DURING THE OPERATIONS PHASE

The licensee is responsible for the operation and maintenance of Limerick Generating Station (LGS). These activities are presently conducted in accordance with the NRC approved Quality Assurance Topical Report (QATR) which describes the formal and comprehensive control methods established to assure compliance with 10CFR50, Appendix B.

The QATR describes how the Quality Assurance Program is to be functionally implemented with due regard to the safety and health of the public and the personnel on site. The LGS Quality Assurance Program as described by the QATR is incorporated herein by reference.

A.5 License Renewal Commitment List 58

A.1 Introduction

The application for a renewed operating license is required by 10 CFR 54.21(d) to include a UFSAR Supplement. This appendix, which includes the following sections, comprises the UFSAR supplement:

- Section A.1.1 contains a listing of the aging management programs that correspond to NUREG-1801 Chapter XI programs.
- Section A.1.2 contains a listing of the plant-specific aging management programs.
- Section A.1.3 contains a listing of aging management programs that correspond to NUREG-1801 Chapter X programs associated with Time-Limited Aging Analyses.
- Section A.1.4 contains a listing of the Time-Limited Aging Analyses summaries (TLAAs).
- Section A.1.5 contains a discussion of the Quality Assurance Program and Administrative Controls.
- Section A.2.1 contains a summarized description of the NUREG-1801 Chapter XI programs for managing the effects of aging.
- Section A.2.2 contains a summarized description of the plant-specific programs for managing the effects of aging.
- Section A.3 contains a summarized description of the NUREG-1801 Chapter X programs that support the TLAAs.
- Section A.4 contains a summarized description of the TLAAs applicable to the period of extended operation.
- Section A.5 contains the License Renewal Commitment List.

The integrated plant assessment for license renewal identified new and existing aging management programs necessary to provide reasonable assurance that systems, structures, and components within the scope of license renewal will continue to perform their intended functions consistent with the Current Licensing Basis (CLB) for the period of extended operation. The period of extended operation is defined as 20 years from the unit's operating license expiration date that existed prior to License Renewal.

A.1.1 NUREG-1801 Chapter XI Aging Management Programs

The NUREG-1801 Chapter XI Aging Management Programs (AMPs) are described in the following sections. The AMPs are either consistent with generally accepted industry methods as discussed in NUREG-1801 or require enhancements.

The following list reflects the status of these programs at the time of the renewed licenses issuance. Commitments for program additions and enhancements are identified in the Appendix A.5 License Renewal Commitment List.

1. ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD (Section A.2.1.1) [Existing]
2. Water Chemistry (Section A.2.1.2) [Existing]
3. Reactor Head Closure Stud Bolting (Section A.2.1.3) [Existing]
4. BWR Vessel ID Attachment Welds (Section A.2.1.4) [Existing]
5. BWR Feedwater Nozzle (Section A.2.1.5) [Existing]
6. BWR Control Rod Drive Return Line Nozzle (Section A.2.1.6) [Existing – Requires Enhancement]
7. BWR Stress Corrosion Cracking (Section A.2.1.7) [Existing]
8. BWR Penetrations (Section A.2.1.8) [Existing]
9. BWR Vessel Internals (Section A.2.1.9) [Existing – Requires Enhancement]
10. Flow-Accelerated Corrosion (Section A.2.1.10) [Existing]
11. Bolting Integrity (Section A.2.1.11) [Existing - Requires Enhancement]
12. Open-Cycle Cooling Water System (Section A.2.1.12) [Existing – Requires Enhancement]
13. Closed Treated Water Systems (Section A.2.1.13) [Existing – Requires Enhancement]
14. Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems (Section A.2.1.14) [Existing – Requires Enhancement]
15. Compressed Air Monitoring (Section A.2.1.15) [Existing]
16. BWR Reactor Water Cleanup System (Section A.2.1.16) [Existing]
17. Fire Protection (Section A.2.1.17) [Existing – Requires Enhancement]
18. Fire Water System (Section A.2.1.18) [Existing – Requires Enhancement]
19. Aboveground Metallic Tanks (Section A.2.1.19) [Existing – Requires Enhancement]
20. Fuel Oil Chemistry (Section A.2.1.20) [Existing – Requires Enhancement]
21. Reactor Vessel Surveillance (A.2.1.21) [Existing]

22. One-Time Inspection (Section A.2.1.22) [New]

23. Selective Leaching (A.2.1.23) [New]

24. One-Time Inspection of ASME Code Class 1 Small-Bore Piping (Section A.2.1.24) [New]

25. External Surfaces Monitoring of Mechanical Components (Section A.2.1.25) [New]

26. Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components (Section A.2.1.26) [New]

27. Lubricating Oil Analysis (Section A.2.1.27) [Existing]

28. Monitoring of Neutron-Absorbing Materials Other than Boraflex (Section A.2.1.28) [Existing – Requires Enhancement]

29. Buried and Underground Piping and Tanks (Section A.2.1.29) [Existing – Requires Enhancement]

30. ASME Section XI, Subsection IWE (Section A.2.1.30) [Existing – Requires Enhancement]

31. ASME Section XI, Subsection IWL (Section A.2.1.31) [Existing – Requires Enhancement]

32. ASME Section XI, Subsection IWF (Section A.2.1.32) [Existing – Requires Enhancement]

33. 10 CFR Part 50, Appendix J (Section A.2.1.33) [Existing]

34. Masonry Walls (Section A.2.1.34) [Existing – Requires Enhancement]

35. Structures Monitoring (Section A.2.1.35) [Existing – Requires Enhancement]

36. RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants (Section A.2.1.36) [Existing – Requires Enhancement]

37. Protective Coating Monitoring and Maintenance Program (Section A.2.1.37) [Existing – Requires Enhancement]

38. Insulation Material for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements (Section A.2.1.38) [New]

39. Insulation Material for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits (Section A.2.1.39) [New]

40. Inaccessible Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements (Section A.2.1.40) [New]

41. Metal Enclosed Bus (Section A.2.1.41) [New]

42. Fuse Holders (Section A.2.1.42) [New]

43. Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements (Section A.2.1.43) [New]

A.1.2 Plant-Specific Aging Management Programs

None. Limerick Generating Station, Units 1 and 2 do not have plant-specific aging management programs as a result of License Renewal.

A.1.3 NUREG-1801 Chapter X Aging Management Programs

The NUREG-1801 Chapter X Aging Management Programs (AMP) associated with Time-Limited Aging Analyses are described in the following sections. The AMPs are either consistent with generally accepted industry methods as discussed in NUREG-1801 Chapter X or require enhancements. The following list reflects the status of these programs at the time of the renewed licenses issuance. Commitments for program additions and enhancements are identified in Appendix A.5 License Renewal Commitment List.

1. Fatigue Monitoring (Section A.3.1.1) [Existing – Requires Enhancement]

2. Environmental Qualification (EQ) of Electric Components (Section A.3.1.2) [Existing]

A.1.4 Time-Limited Aging Analyses

Summaries of the Time-Limited Aging Analyses applicable to the period of extended operation are included in the following sections:

1. Reactor Pressure Vessel Neutron Embrittlement Analysis (Section A.4.2)

2. Metal Fatigue (Section A.4.3)

3. Environmental Qualification (EQ) of Electric Components (Section A.4.4)

4. Containment Liner and Penetrations Fatigue Analysis (Section A.4.5)

5. Other Plant-Specific Time-Limited Aging Analyses (Section A.4.6)

A.1.5 Quality Assurance Program and Administrative Controls

The Quality Assurance Program implements the requirements of 10 CFR 50, Appendix B, and is consistent with the summary in Appendix A.2, “Quality

Assurance For Aging Management Programs (Branch Technical Position IQMB-1)" of NUREG-1800. The Quality Assurance Program includes the elements of corrective action, confirmation process, and administrative controls, and is applicable to the safety-related and nonsafety-related systems, structures, and components (SSCs) that are subject to Aging Management Review (AMR). In many cases, existing activities were found adequate for managing aging effects during the period of extended operation. As permitted by the License Amendment to implement 10 CFR 50.69, "Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors," Alternative Treatments may be applied in lieu of 10 CFR 50 Appendix B for components that have a Risk-Informed Safety Classification (RISC) RISC-3 or RISC-4.

A.1.6 OPERATING EXPERIENCE

The Operating Experience program is an existing program that has been enhanced to ensure, through the ongoing review of both internal and external operating experience, that the license renewal aging management programs are effective to manage the aging effects for which they are credited throughout the period of extended operation. The programs are either enhanced or new programs developed when the review of operating experience indicates that the effects of aging may not be adequately managed.

The Operating Experience program has been enhanced to:

1. Explicitly require the review of operating experience for aging-related degradation.

2. Establish criteria to define aging-related degradation.

3. Establish identification coding for use in identification, trending and communications of aging-related degradation.

4. Require communication of significant internal aging-related degradation, associated with SSCs in the scope of license renewal, to other Exelon plants and to the industry. Criteria will be established for determining when aging-related degradation is significant.

5. Require review of external operating experience for information related to aging management and evaluation of such information for potential improvements to LGS aging management activities.

6. Provide training to those responsible for screening, evaluating and communicating operating experience items related to aging management.

These enhancements were implemented prior to the date that the renewed operating licenses were issued and will be conducted on an ongoing basis throughout the terms of the renewed licenses.

A.2 Aging Management Programs

A.2.1 NUREG-1801 Chapter XI Aging Management Programs

This section provides summaries of the NUREG-1801 programs credited for managing the effects of aging.

A.2.1.1 ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD

The ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD aging management program is an existing program that consists of periodic volumetric and visual examinations of components for assessment, identification of signs of degradation, and establishment of corrective actions. The program includes inspections performed to identify and manage cracking and loss of fracture toughness in Class 1, 2, and 3 piping and components exposed to reactor coolant and treated water environments. The inspections will be implemented in accordance with 10 CFR 50.55(a) and ASME Code, Section XI Subsections IWB, IWC, and IWD. These activities include inspections, and monitoring and trending of results to confirm that aging effects are managed. As permitted by the License Amendment to implement 10 CFR 50.69, "Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors," Alternative Treatments may be applied in lieu of 10 CFR 50.55(a) ASME Section XI Inservice Inspection requirements for ASME Class 2 and Class 3 components that have a Risk-Informed Safety Classification (RISC) RISC-3 or RISC-4.

A.2.1.2 Water Chemistry

The Water Chemistry aging management program is an existing program whose activities consist of monitoring and control of water chemistry to manage the aging of reactor vessel, reactor internals, piping, piping elements and piping components, heat exchangers and tanks that are exposed to treated water. The Water Chemistry aging management program keeps peak levels of various contaminants below system-specific limits based on the industry recognized guidelines of the Boiling Water Reactor Vessel and Internals Project (BWRVIP-190, Revision 1, Electric Power Research Institute - 3002002623) for the prevention or mitigation of loss of material, reduction of heat transfer and cracking aging effects. In addition, the water chemistry program is also credited for mitigating loss of material and cracking for components exposed to sodium pentaborate, steam and reactor coolant environments. To mitigate aging effects on component surfaces the chemistry program is used to control water chemistry for impurities that accelerate corrosion.

A.2.1.3 Reactor Head Closure Stud Bolting

The Reactor Head Closure Stud Bolting program is an existing program that provides for condition monitoring and preventive activities to manage reactor head closure studs and associated nuts, washers and flange threads for cracking and loss of material. The program is implemented through station

procedures based on the examination and inspection requirements specified in ASME Section XI, Table IWB-2500-1 and preventive measures described in NRC Regulatory Guide 1.65, “Materials and Inspection for Reactor Vessel Closure Studs”, with the exception that stud bolting material having a measured yield stress greater than 150 ksi is used.

A.2.1.4 BWR Vessel ID Attachment Welds

The BWR Vessel ID Attachment Welds aging management program is an existing aging management program that incorporates the inspection and evaluation recommendations of BWRVIP-48-A, and the recommendations described in the Water Chemistry (A.2.1.2) program. The program is implemented through station procedures that provide for mitigation of cracking through management of reactor water chemistry and monitoring for cracking through in-vessel examinations of the reactor vessel internal attachment welds. Examinations performed under this program are implemented via augmented inservice inspection requirements.

A.2.1.5 BWR Feedwater Nozzle

The BWR Feedwater Nozzle aging management program is an existing program that manages the effects of cracking in the feedwater nozzles by augmented in-service inspection (ISI) in accordance with the requirements of the ASME Code, Section XI, Subsection IWB, Table IWB-2500-1 and the recommendations provided within BWROG Licensing Topical Report, GE-NE-523-A71-0594-A, Revision 1. Inspections of the feedwater nozzles are performed in accordance with the ISI Program Plan.

A.2.1.6 BWR Control Rod Drive Return Line Nozzle

The BWR Control Rod Drive Return Line (CRDRL) Nozzle aging management program is an existing program that provides for condition monitoring of the CRDRL reactor pressure vessel nozzle for cracking. The CRDRL nozzle has been capped to mitigate thermal fatigue cracking on both units. The program performs In-service Inspection (ISI) examinations to monitor the effects of cracking on the intended function of the CRDRL nozzle. Volumetric ultrasonic inspection is performed on the CRDRL nozzle including the nozzle-to-vessel weld, nozzle blend radius and nozzle-to-cap welds. The CRDRL nozzle and nozzle-to-vessel weld examinations are performed at the frequency specified in ASME Code, Section XI, Table IWB-2500-1. The CRDRL nozzle-to-cap weld examinations are performed at a frequency specified by the BWR Stress Corrosion Cracking (A.2.1.7) program that implements commitments from NRC Generic Letter 88-01 and BWRVIP-75-A. The nozzle, cap and associated welds are included in the visual inspection (VT-2) during the reactor pressure test performed each refueling outage.

A.2.1.7 BWR Stress Corrosion Cracking

The BWR Stress Corrosion Cracking aging management program is an existing augmented Inservice Inspection program that manages intergranular stress corrosion cracking (IGSCC) in relevant piping and piping welds made of stainless steel and nickel based alloy, regardless of code classification, as delineated in NUREG-0313, Revision 2, and NRC Generic Letter 88-01 and its Supplement 1. The program includes preventive measures to mitigate IGSCC, and inspection and flaw evaluation to monitor IGSCC and its effects. The schedule and extent of the inspections are performed in accordance with the NRC staff-approved BWRVIP-75-A report.

A.2.1.8 BWR Penetrations

The BWR Penetrations aging management program is an existing program that manages the effects of cracking of reactor vessel instrumentation penetrations, and CRD housing and incore-monitoring housing penetrations exposed to reactor coolant through water chemistry and in-service inspections. The scope of the program includes beltline instrumentation nozzles and other instrumentation nozzles; except for the core plate differential pressure (dP) instrumentation nozzle and the jet pumps instrumentation nozzles, which are in the scope of the ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD (A.2.1.1) program. The BWR Penetrations aging management program incorporates the inspection and evaluation recommendations of BWRVIP-49-A, "Instrument Penetration Inspection and Flaw Evaluation Guidelines," BWRVIP-47-A, "BWR Lower Plenum Inspection and Flaw Evaluation Guidelines," and the water chemistry recommendations described in the Water Chemistry (A.2.1.2) program.

BWRVIP-27-A does not apply to LGS because Standby Liquid Control (SLC) injects through the Core Spray piping. Inspections of the instrument penetrations and CRD housing and incore-monitoring housing penetrations are implemented through station ISI procedures, which incorporate the requirements of ASME Section XI. The requirements of ASME Section XI are implemented in accordance with 10 CFR 50.55(a).

A.2.1.9 BWR Vessel Internals

The BWR Vessel Internals program is an existing program that manages the effects of cracking, loss of material and loss of fracture toughness of reactor pressure vessel internal components through condition monitoring activities that consist of examinations that are implemented through station procedures consistent with the recommendations of the BWRVIP guidelines and ASME Code, Section XI, Table IWB-2500-1. The program also mitigates these aging effects by managing water chemistry per the Water Chemistry (A.2.1.2) program.

The program will include aging management of reactor internal components fabricated from Cast Austenitic Stainless Steel (CASS) for loss of fracture toughness due to thermal aging and neutron embrittlement.

The BWR Vessel Internals aging management program will be enhanced to:

1. Perform an assessment of the susceptibility of reactor vessel internal components fabricated from Cast Austenitic Stainless Steel (CASS) to loss of fracture toughness due to thermal aging embrittlement. If material properties cannot be determined to perform the screening, they will be assumed susceptible to thermal aging for the purposes of determining program examination requirements.

2. Perform an assessment of the susceptibility of reactor vessel internal components fabricated from Cast Austenitic Stainless Steel (CASS) to loss of fracture toughness due to neutron irradiation embrittlement.

3. Specify the required periodic inspection of CASS components determined to be susceptible to loss of fracture toughness due to thermal aging and neutron irradiation embrittlement.

These enhancements will be implemented prior to the period of extended operation. The initial inspections will be performed either prior to or within 5 years after entering the period of extended operation.

A.2.1.10 Flow-Accelerated Corrosion

The Flow-Accelerated Corrosion (FAC) aging management program is an existing program based on EPRI guidelines in NSAC-202L, “Recommendations for an Effective Flow Accelerated Corrosion Program”. The program provides guidance for prediction, detection, and monitoring wall thinning in piping and fittings, valve bodies, and heat exchangers due to FAC. Analytical evaluations and periodic examinations of locations that are most susceptible to wall thinning due to FAC are used to predict the amount of wall thinning in pipes, fittings, and feedwater heater shells. Program activities include analyses to determine critical locations, baseline inspections to determine the extent of thinning at these critical locations, and follow-up inspections to confirm the predictions. Repairs and replacements are performed as necessary.

The Flow-Accelerated Corrosion aging management program also manages wall thinning caused by mechanisms other than FAC, such as cavitation, flashing, droplet impingement, and solid particle impingement, in situations where periodic monitoring is used in lieu of eliminating the cause of various erosion mechanism(s).

A.2.1.11 Bolting Integrity

The Bolting Integrity aging management program is an existing program that provides for aging management for loss of material, cracking, and loss of preload of pressure retaining bolted joints within the scope of license renewal. The Bolting Integrity program incorporates NRC and industry recommendations delineated in NUREG-1339, “Resolution of Generic Safety Issue 29: Bolting Degradation or Failure in Nuclear Power Plants,” EPRI TR-104213, “Bolted Joint Maintenance & Applications Guide,” and EPRI NP 5769, “Degradation and Failure of Bolting in Nuclear Power Plants,” as part of the comprehensive component pressure retaining bolting program. The program provides for managing loss of material, cracking, and loss of preload by performing visual inspections of safety-related pressure retaining bolted joints at least once per refueling cycle for leakage, loss of material, cracking, and loss of preload. Bolting for other pressure retaining components is inspected for signs of leakage. Inspection activities for bolting in buried and underground applications is performed in conjunction with inspection activities for the Buried and Underground Piping and Tanks (A.2.1.29) aging management program due to the restricted accessibility to these locations.

The Bolting Integrity aging management program is supplemented by aging management activities included in several other programs including ASME Section XI, Inservice Inspection, Subsections IWB, IWC, and IWD (A.2.1.1), Reactor Head Closure Stud Bolting (A.2.1.3), Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems (A.2.1.14), External Surfaces Monitoring of Mechanical Components (A.2.1.25), Buried and Underground Piping and Tanks (A.2.1.29), ASME Section XI, Subsection IWE (A.2.1.30), ASME Section XI, Subsection IWF (A.2.1.32), Structures Monitoring (A.2.1.35), and Reg. Guide 1.127 Inspection of Water Control Structures Associated With Nuclear Power Plants (A.2.1.36).

The Bolting Integrity aging management program will be enhanced to:

1. Provide guidance to ensure proper specification of bolting material, lubricant and sealants, storage, and installation torque or tension to prevent or mitigate degradation and failure of closure bolting for pressure retaining components.

2. Prohibit the use of lubricants containing molybdenum disulfide for pressure retaining components.

3. Minimize the use of high strength bolting (actual measured yield strength equal to or greater than 150 ksi) for closure bolting for pressure retaining components. High strength bolting, if used, will be monitored for cracking.

4. Perform visual inspection of bolting for the Residual Heat Removal System, Core Spray System, High Pressure Coolant Injection System, and Reactor Core Isolation Cooling System suppression pool suction strainers for loss of material and loss of preload during each ISI inspection interval.

The enhancements will be implemented prior to the period of extended operation.

A.2.1.12 Open-Cycle Cooling Water System

The Open-Cycle Cooling Water System (OCCWS) aging management program is an existing program that manages heat exchangers, piping, piping elements and piping components in safety-related and nonsafety-related raw water systems that are exposed to raw water and air/gas-wetted environments for loss of material, reduction of heat transfer, and hardening and loss of strength of elastomers. This is accomplished through tests and inspections per the guidelines of NRC Generic Letter 89-13. System and component testing, visual inspections, non-destructive examination (i. e. Radiographic Testing, Ultrasonic Testing and Eddy Current Testing), and chemical injection are conducted to ensure that aging effects are managed such that system and component intended functions and integrity are maintained.

The OCCWS includes those systems that transfer heat from safety-related structures, systems and components to the ultimate heat sink as defined in GL-89-13 as well as those raw water systems which are in scope for license renewal for spatial interaction but have no safety-related heat transfer function. Periodic heat transfer testing or inspection and cleaning of heat exchangers with a heat transfer intended function is performed in accordance with LGS commitments to GL 89-13 to verify heat transfer capabilities. Heat exchangers which have no safety-related heat transfer function are periodically inspected and cleaned.

Periodic volumetric inspections will be performed in the non-buried portions of the Safety Related Service Water System to provide a sufficient understanding of the buried service water piping conditions throughout the period of extended operation. The inspection locations are selected to ensure that conditions are similar (e. g. flow, temperature) to those in the buried portions of the Safety Related Service Water System piping.

The OCCWS aging management program also manages the loss of coating integrity in a raw water environment. Internal coatings in the service water side of the Main Control Room Chiller Condensers and Reactor Enclosure Cooling Water Heat Exchangers, and in circulating water system piping are visually inspected to ensure that loss of coating integrity is detected. The inspections of the Main Control Room Chiller Condensers and circulating water system piping will be performed by inspectors qualified to international standards endorsed in RG 1.54, including, ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II. The inspections of the Reactor Enclosure Cooling Water Heat Exchangers will be performed by inspectors with a demonstrated working knowledge of EPRI Report 1019157, “Guideline on Nuclear Safety-Related Coatings”. Inspections are performed for signs of coating failures and precursors to coating failures including peeling, delamination, blistering, cracking, flaking, chipping, rusting, and mechanical damage. When acceptance criteria are not met, visual inspection is supplemented by additional testing such as DFT (Dry Film Thickness), adhesion, continuity, or other inspection technique as determined by the qualified inspector to accurately assess coating condition. Adhesion testing will be performed using international standards endorsed in RG 1.54. A coatings specialist qualified to ASTM D-7108 will evaluate the results of the coating inspections. Evaluations are performed for inspection results that do not satisfy established acceptance criteria and the conditions are entered into the LGS 10 CFR 50 Appendix B

corrective action program. The corrective action program ensures that conditions adverse to quality are promptly corrected. Corrective actions may include coating repair or replacement prior to the component being returned to service.

The Open-Cycle Cooling Water System aging management program will be enhanced to:

1. Perform internal inspection of buried Safety Related Service Water Piping when it is accessible during maintenance and repair activities

2. Perform periodic inspections for loss of material in the Nonsafety-Related Service Water System at a minimum of five locations on each unit once every refueling cycle.

3. Replace the supply and return piping for the Core Spray pump compartment unit coolers.

4. Replace degraded RHRSW piping in the pipe tunnel.

5. Perform periodic inspections for loss of material in the Safety Related Service Water System at a minimum of ten locations every two years.

The enhancements will be implemented prior to the period of extended operation.

A.2.1.13 Closed Treated Water Systems

The Closed Treated Water Systems program is an existing mitigation program that includes (a) nitrite-based water treatment, including pH control and the use of corrosion inhibitors for carbon steel and copper alloys, to modify the chemical composition of the water such that the function of the equipment is maintained and such that the effects of corrosion are minimized; and (b) chemical testing of the water to ensure that the water treatment program maintains the water chemistry within acceptable guidelines. The Closed Treated Water Systems program manages the loss of material and the reduction of heat transfer in piping, piping components, piping elements, tanks, and heat exchangers exposed to a closed treated water environment.

The Closed Treated Water Systems aging management program will be enhanced to:

1. Perform condition monitoring and performance monitoring, including periodic testing and opportunistic and periodic NDE, to verify the effectiveness of water chemistry control to mitigate aging effects. A representative sample of piping and components will be selected based on likelihood of corrosion and inspected at an interval not to exceed once in 10 years during the period of extended operation.

2. Perform condition monitoring for the loss of material due to cavitation erosion in the reactor enclosure cooling water piping to the 2A Reactor Water Cleanup System (RWCU) non-regenerative heat exchanger. An

initial inspection frequency of 4 years has been established. The inspection frequency will be re-evaluated and adjusted as necessary based on trend data.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.14 Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems aging management program is an existing condition monitoring program that manages the effects of loss of material on the bridge, bridge rails, bolting and trolley structural components for those cranes, hoists and rigging beams that are within the scope of license renewal. The program also manages loss of preload of associated bolted connections. Procedures and controls implement the guidance on the control of overhead heavy load cranes specified in NUREG-0612, “Control of Heavy Loads at Nuclear Power Plants”. The program utilizes periodic inspections as described in the ASME B30 series of standards for inspection, monitoring and detection of aging effects.

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems aging management program will be enhanced to:

1. Perform annual periodic inspections as defined in the appropriate ASME B30 series standard for all cranes, hoists, and equipment handling systems within the scope of license renewal. For handling systems that are infrequently in service, such as those only used during refueling outages, annual periodic inspections may be deferred until just prior to use.

2. Perform inspections of structural components and bolting for loss of material due to corrosion, rails for loss of material due to wear and corrosion, and bolted connections for loss of preload.

3. Evaluate loss of material due to wear or corrosion and any loss of bolting preload on cranes, hoists, and equipment handling systems per the appropriate ASME B30 series standard.

4. Perform repairs to cranes, hoists, and equipment handling systems per the appropriate ASME B30 series standard.

Enhancements will be implemented prior to the period of extended operation.

A.2.1.15 Compressed Air Monitoring

The Compressed Air Monitoring aging management program is an existing program that manages piping, piping components, piping elements, and valve bodies for loss of material in the compressed air systems. The Compressed Air Monitoring aging management activities consist of air quality monitoring and trending, preventive maintenance, and condition monitoring measures to manage the aging effects.

The Compressed Air Monitoring program is based on the LGS response to NRC Generic letter 88-14, "Instrument Air Supply Problems" and utilizes guidance and standards provided in INPO SOER 88-01. The Compressed Air Monitoring program activities implement the moisture and contaminant criteria of ANSI MC11.1 (ISA S7.3, incorporated into ANSI/ISA-S7.0.01). Program activities include air quality checks at various locations to ensure that dew point, particulates, lubricant content and contaminants are maintained within the specified limits.

The Compressed Air Monitoring Program will be enhanced to:

1. Perform periodic analysis and trending of air quality monitoring results.

This enhancement will be implemented prior to the period of extended operation.

A.2.1.16 BWR Reactor Water Cleanup System

The BWR Reactor Water Cleanup System program is an existing condition monitoring and mitigation program that describes the requirements for augmented inservice inspection (ISI) for stress corrosion cracking (SCC) or intergranular stress corrosion cracking (IGSCC) on stainless steel Reactor Water Cleanup (RWCU) System piping welds outboard of the second (outboard) primary containment isolation valves. The program includes the measures delineated in NUREG-0313, Rev. 2, and in NRC Generic Letter (GL) 88-01 and its Supplement 1. The program is implemented in conjunction with the Water Chemistry (A.2.1.2) program to minimize the potential of cracking due to SCC or IGSCC in a treated water environment. The BWR Reactor Water Cleanup System program activities, and the control of reactor water chemistry, manage the aging effects in stainless steel RWCU System piping welds outboard of the second primary containment isolation valves thereby maintaining the intended function of this piping.

The BWR Reactor Water Cleanup System program includes acceptable inspection alternatives to staff positions delineated in GL 88-01 as described in GL 88-01, Supplement 1. In accordance with the staff's criteria regarding the acceptable inspection schedules for the portion of the RWCU System piping welds outboard of the second primary containment isolation valves, the NRC has approved the elimination of the requirements to perform examinations of the outboard portion of the RWCU System for both LGS Unit 1 and Unit 2. If one or more of the RWCU System welds inboard of the primary containment isolation valves inspected as part of the on-going GL 88-01 inspections under the BWR Stress Corrosion Cracking (A.2.1.7) program have confirmed IGSCC or SCC indications, then an additional sample of RWCU system welds outboard of the primary containment isolation valves is selected and examined based on the requirements of GL 88-01.

A.2.1.17 Fire Protection

The Fire Protection aging management program is an existing program that includes fire barrier visual inspections, and halon system visual inspections and functional tests. The fire barrier inspection program requires periodic visual inspection of fire barrier penetration seals, fire barrier walls, ceilings, floors and other materials that perform a fire barrier function. Periodic visual inspection and functional testing of the fire rated doors and visual inspection of fire rated dampers is performed to ensure that their functionality is maintained. The program also includes visual inspections and periodic operability tests of halon fire suppression systems using the National Fire Protection Association Codes and Standards for guidance.

The Fire Protection aging management program will be enhanced to:

1. Provide additional inspection guidance to identify degradation of fire barrier walls, ceilings, and floors for aging effects such as cracking, spalling and loss of material.

2. Provide additional inspection guidance for identification of excessive loss of material due to corrosion on the external surfaces of the halon system.

Enhancements will be implemented prior to the period of extended operation.

A.2.1.18 Fire Water System

The Fire Water System aging management program is an existing program that provides for system pressure monitoring, fire system header flushing and flow testing, pump performance testing, hydrant flushing, and visual inspection activities. System flow tests measure hydraulic resistance and compare results with previous testing as a means of evaluating the internal piping conditions. The program manages loss of material due to corrosion, including MIC, fouling, flow blockage because of fouling, and loss of coating integrity. Major component types include piping, piping components and piping elements, tanks, pump casings, and valve bodies. Monitoring system piping flow characteristics ensures that signs of loss of material will be detected in a timely manner. Monitoring system piping flow characteristics and opportunistic internal inspections of the cement lined fire main ensure that signs of loss of coating integrity will be detected in a timely manner. Within 10 years prior to the PEO, five inspections of the cement lined fire main will be performed. Pump performance tests, hydrant flushing and system inspections are based on guidance from the applicable National Fire Protection Association (NFPA) standards. The fire water system is normally maintained at required operating pressure and is monitored such that loss of system pressure is immediately detected and corrective actions initiated. Fire system main header flow tests, sprinkler system inspections, visual yard hydrant inspections, hydrostatic tests, gasket inspections, volumetric inspections, and fire hydrant flow tests and pump capacity tests are performed periodically to assure that aging effects are managed such that the system intended functions are maintained.

The Fire Water System aging management program will be enhanced to:

1. Replace sprinkler heads or perform 50-year sprinkler head testing using the guidance of NFPA 25 “Standard for the Inspection, Testing and Maintenance of Water-Based Fire Protection Systems” (2011 Edition), Section 5.3.1.1.1. This testing will be performed after the 50-year in-service date and every 10 years thereafter.

2. Inspect selected portions of the water based fire protection system piping located aboveground and exposed to the fire water internal environment by non-intrusive volumetric examinations. These inspections shall be performed prior to the period of extended operation and will be performed every 10 years thereafter.

3. Inspect and clean line strainers for deluge systems after each actuation. Strainers for deluge systems subject to periodic full flow testing will be inspected and cleaned on a frequency consistent with the deluge system test frequency.

4. Inspect and clean the foam system water supply strainer after each system actuation and no less than once per refueling interval.

5. Perform external visual inspection of deluge piping and nozzles for the HVAC charcoal filters for signs of leakage, corrosion, physical damage, and correct orientation each time the charcoal is removed for replacement.

6. Perform flow tests for the hydraulically most remote hose stations once every five years, scheduling the testing so that some of the tests are performed in each year of the five year interval.

7. Perform a main drain test annually for the fire water piping in each of the following locations: Unit 1 Reactor Enclosure, Unit 2 Reactor Enclosure, Unit 1 Turbine Enclosure, Unit 2 Turbine Enclosure, Control Enclosure, and Radwaste Enclosure. Flow blockage or abnormal discharge identified during flow testing or any change in pressure during the test greater than ten percent at a specific location is entered into the corrective action program for evaluation.

8. Perform charcoal filter deluge valve exercise testing and air flow testing each time the charcoal is removed for replacement interval and perform air flow testing for the deluge systems for the hydrogen seal oil units and lube oil reservoirs every two years.

9. Perform the following for Fire Water System sprinkler and deluge systems:

   - Perform visual internal inspections, consistent with NFPA 25, for corrosion and obstructions to flow on at least five wet pipe sprinkler systems every five years.

- Collect and evaluate solids discharged from wet pipe sprinkler system flow testing. Flow testing through the inspector's test valve will be performed on an interval no greater than 18 months for each wet pipe system.

- Perform visual internal inspections for corrosion and obstructions to flow for dry pipe preaction sprinkler systems of surfaces made accessible when preaction and water deluge valves are serviced on an interval no greater than a refueling interval.

- Perform visual internal inspections for corrosion and obstructions to flow for deluge systems of surfaces made accessible when deluge valves are serviced on at least ten deluge systems on an interval no greater than three years. To provide reasonable assurance of the presence of sufficient coating, two of the ten inspections will be associated with the galvanized transformer deluge system piping.

- Perform a visual internal inspection for corrosion and obstructions to flow for any wet pipe, dry pipe preaction, or deluge system after any system actuation prior to return to service.

- Perform an obstruction evaluation for conditions that indicate degraded flow.

- Perform follow-up volumetric inspections for pipe wall thickness if internal visual inspections detect surface irregularities that could be indicative of wall loss below nominal wall thickness.

- Sprinkler and deluge systems that are normally dry but may be wetted as the result of testing or actuations will have augmented tests and inspections on piping segments that cannot be drained or piping segments that allow water to collect. These augmented inspections will be performed in each five year interval beginning five years prior to the period of extended operation and consist of either a flow test or flush sufficient to detect potential flow blockage or a visual inspection of 100 percent of the internal surface of piping segments that cannot be drained or piping segments that allow water to collect. In addition, in each five year interval of the period of extended operation, 20 percent of the length of piping segments that cannot be drained or piping segments that allow water to collect is subject to volumetric wall thickness inspections.

10. Perform wall thickness measurements using UT or other suitable techniques at five selected locations every year to identify loss of material in the carbon steel backup fire water piping. When these examinations identify pipe degradation, additional examinations will be performed in accordance with the following criteria:

    - At least four additional locations will be examined if wall loss is greater than 50 percent of nominal wall thickness,

- Two additional locations will be examined if wall loss is 30 percent to 50 percent of nominal wall thickness and the calculated remaining life is less than two years,

- No additional examinations will be performed if wall loss is less than 30 percent of nominal wall thickness.

These inspections will be performed until the piping degradation no longer meets the criteria for recurring internal corrosion.

Enhancements will be implemented prior to the period of extended operation, with the testing and inspections performed in accordance with the schedule described above.

A.2.1.19 Aboveground Metallic Tanks

The Aboveground Metallic Tanks aging management program is an existing program that manages the loss of material aging effect of the Backup Water Storage Tank. Paint is a corrosion preventive measure, and periodic visual inspections will monitor degradation of the paint and any resulting metal degradation of metallic tanks.

The Aboveground Metallic Tanks aging management program will be enhanced to:

1. Include UT measurements of the bottom of the Backup Water Storage Tank. Tank bottom UT inspections will be performed within five years prior to entering the period of extended operation and every five years thereafter. If no tank bottom plate material loss is identified after the first two inspections, the remaining inspections will be performed whenever the tank is drained during the period of extended operation.

2. Provide visual inspections of the Backup Water Storage Tank external surfaces and include, on a sampling basis, removal of insulation to permit inspection of the tank surface. An inspection performed prior to entering the period of extended operation will include a minimum of 25 locations to demonstrate that the tank painted surface is not degraded under the insulation. Subsequent tank external surface visual inspection will be conducted on a two-year frequency and include a minimum of four locations. Annual visual inspections will be performed of the tank insulation surface for degradation. Rips, tears and gaps in the insulation skin will be repaired. Evidence of water intrusion beneath the insulation will be evaluated in accordance with the LGS corrective action program.

3. Perform visual inspections of the Backup Water Storage Tank wetted and nonwetted internal surfaces. Tank internal inspections will be performed within five years prior to entering the period of extended operation and every five years thereafter. The tank bottom will be inspected for evidence of voids beneath the floor in accordance with NFPA 25, Section 9.2.6.5. Where pitting and general corrosion to below the nominal wall thickness occurs or any coating failure occurs in which bare metal is exposed, additional inspections and tests shall be performed in accordance with NFPA 25, Section 9.2.7. These tests include adhesion testing of the coating in the vicinity of the coating failure, dry film thickness measurements, spot wet sponge testing, and nondestructive examination to determine remaining wall thickness where bare metal has been exposed. Tank bottom weld seams in the area of degraded coating will be leak tested in accordance with NFPA 25, Section 9.2.7, by vacuum-box testing or magnetic particle (MT) examination. In addition, adhesion testing shall be performed in the vicinity of blisters even though bare metal may not be exposed.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.20 Fuel Oil Chemistry

The Fuel Oil Chemistry aging management program is an existing mitigation and condition monitoring program that includes activities which provide assurance that contaminants are maintained at acceptable levels in fuel oil for systems and components within the scope of license renewal. The Fuel Oil Chemistry program manages loss of material in piping, piping elements, piping components and tanks in a fuel oil environment. The fuel oil tanks within the scope of license renewal are maintained by monitoring and controlling fuel oil contaminants in accordance with the Technical Specifications, Technical Requirements Manual, and ASTM guidelines. Fuel oil sampling and analysis is performed in accordance with approved procedures for new fuel oil and stored fuel oil. Fuel oil tanks are periodically drained of accumulated water and sediment, cleaned, and internally inspected. These activities effectively manage the effects of aging by maintaining potentially harmful contaminants at low concentrations.

The Fuel Oil Chemistry program also manages the loss of coating integrity in a fuel oil environment. Fuel oil tank internal coatings are visually inspected to ensure that loss of coating integrity is detected. The inspections will be performed by inspectors qualified to international standards endorsed in RG 1.54, including, ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II. Inspections are performed for signs of coating failures and precursors to coating failures including peeling, delamination, blistering, cracking, flaking, chipping, rusting, and mechanical damage. When acceptance criteria are not met, visual inspection is supplemented by additional testing such as DFT (Dry Film Thickness), adhesion, continuity, or other inspection technique as determined by the qualified inspector to accurately assess coating condition. Adhesion testing will be performed using international standards endorsed in RG 1.54. A coatings specialist qualified to ASTM D-7108 will evaluate the

results of the coating inspections. Evaluations are performed for inspection results that do not satisfy established acceptance criteria and the conditions are entered into the LGS 10 CFR 50 Appendix B corrective action program. The corrective action program ensures that conditions adverse to quality are promptly corrected. Corrective actions may include coating repair or replacement prior to the component being returned to service.

The Fuel Oil Chemistry aging management program will be enhanced to:

1. Periodically drain water from the Fire Pump Engine Diesel Oil Day Tank and the Fire Pump Diesel Engine Fuel Tank.

2. Perform internal inspections of the Fire Pump Engine Diesel Oil Day Tank, the Fire Pump Diesel Engine Fuel Tank, and the Diesel Generator Day Tanks at least once during the 10-year period prior to the period of extended operation, and, at least once every 10 years during the period of extended operation. Each diesel fuel tank will be drained, cleaned and the internal surfaces either volumetrically or visually inspected. If evidence of degradation is observed during visual inspections, the diesel fuel tanks will require follow-up volumetric inspection.

3. Perform periodic analysis for total particulate concentration and microbiological organisms for the Fire Pump Engine Diesel Oil Day Tank and the Fire Pump Diesel Engine Fuel Tank.

4. Perform periodic analysis for water and sediment and microbiological organisms for the Diesel Generator Diesel Oil Storage Tanks.

5. Perform periodic analysis for water and sediment content, total particulate concentration, and the levels of microbiological organisms for the Diesel Generator Day Tanks.

6. Perform analysis of new fuel oil for water and sediment content, total particulate concentration and the levels of microbiological organisms for the Fire Pump Engine Diesel Oil Day Tank and the Fire Pump Diesel Engine Fuel Tank.

7. Perform analysis of new fuel oil for total particulate concentration and the levels of microbiological organisms for the Diesel Generator Diesel Oil Storage Tanks.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.21 Reactor Vessel Surveillance

The Reactor Vessel Surveillance aging management program is an existing program that manages the loss of fracture toughness due to neutron irradiation embrittlement of the reactor vessel beltline materials. The program meets the requirements of 10 CFR 50, Appendix H. The program evaluates neutron embrittlement by projecting Upper Shelf Energy (USE) for reactor materials and impact on Adjusted Reference Temperature for the development of pressure-temperature limit curves. Embrittlement evaluations are performed in accordance with Regulatory Guide 1.99, Rev. 2. The Reactor Vessel Surveillance program is part of the BWRVIP Integrated Surveillance Program (ISP) described in BWRVIP-86, Rev.1-A, and approved by the NRC staff. The schedule for removing surveillance capsules is in accordance the timetable specified in BWRVIP-86, Rev.1-A for both the current license term and the period of extended operation.

The program monitors plant operating conditions to ensure appropriate steps are taken if reactor vessel exposure conditions are altered; such as the review and updating of 60-year fluence projections to support upper shelf energy calculations and pressure-temperature limit curves. The program also includes condition monitoring by removal and analysis of surveillance capsules as part of the BWRVIP ISP. These measures are effective in detecting the extent of embrittlement to prevent significant degradation of the reactor pressure vessel during the period of extended operation.

A.2.1.22 One-Time Inspection

The One-Time Inspection program is a new condition monitoring program that will be used to verify the system-wide effectiveness of the Water Chemistry (A.2.1.2) program, Fuel Oil Chemistry (A.2.1.20) program, and Lubricating Oil Analysis (A.2.1.27) program which are designed to prevent or minimize aging to the extent that it will not cause a loss of intended function during the period of extended operation. The program manages loss of material, cracking and reduction of heat transfer in piping, piping components, piping elements, heat exchangers, and other components within the scope of license renewal. The program provides inspections focusing on locations that are isolated from the flow stream, that are stagnant, or that have low flow for extended periods and are susceptible to the gradual accumulation or concentration of agents that promote certain aging effects. The inspections will include a representative sample of the system population and will focus on the bounding or lead components most susceptible to aging due to time in service, and severity of operating conditions. The program either verifies that unacceptable degradation is not occurring or triggers additional actions that will assure the intended function of affected components will be maintained during the period of extended operation.

The One-Time Inspection program will be implemented prior to the period of extended operation. The one-time inspections will be performed within the 10 years prior to the period of extended operation.

A.2.1.23 Selective Leaching

The Selective Leaching aging management program is a new condition monitoring program that will include one-time inspections of a representative sample of susceptible components to manage loss of material due to selective leaching. Components include piping and fittings, valve bodies, pump casings, heat exchanger components, tanks, and fire hydrants. The materials of construction for these components are gray cast iron, and copper alloy with greater than 15 percent zinc. These components are exposed to raw water, treated water, closed cycle cooling water, waste water, and soil. These one-time inspections for selective leaching will include visual examinations, supplemented by hardness tests or other mechanical techniques as required. If selective leaching is found, the condition will be evaluated to determine the need to expand inspection scope.

The Selective Leaching program will be implemented prior to the period of extended operation. One-time inspections will be conducted within the five years prior to entering the period of extended operation.

Status of Selective Leaching Program: One-Time Inspections for Selective Leaching were conducted in the five years prior to the Period of Extended Operation. These efforts found instances of selective leaching in the following populations: Gray Cast Iron/Raw Water, Gray Cast Iron/Soil, and Copper Alloy/Raw Water. Based on these results, selective leaching has been determined to be present at Limerick. To expand inspection scope, periodic inspections of components in the above material/environment groupings will be performed during the period of extended operation in accordance with the Selective Leaching Aging Management Program.

A.2.1.24 One-Time Inspection of ASME Code Class 1 Small-Bore Piping

The One-Time Inspection of ASME Code Class 1 Small-Bore Piping aging management program is a new condition monitoring program that will manage the aging effect of cracking in ASME Code Class 1 small-bore piping that is less than nominal pipe size (NPS) 4-inches, and greater than or equal to NPS 1-inch. The program implements one-time inspection of a sample of piping full penetration (butt) and partial penetration (socket) welds that are susceptible to cracking using volumetric examinations. The inspection sample size will include 3 percent or a maximum of 10 welds of each type (butt welds and socket welds), for each LGS unit. This sample size is based upon an OE review following 30 years of service which identified no instances of Code Class 1 small bore piping caused by IGSCC or fatigue at LGS 1 or 2 for components within the scope of the AMP. Inspection of socket welds will be performed by volumetric examination technique demonstrated to be capable of detecting cracking. If such a volumetric technique is not available by the time of the inspections, the examination method will be by destructive examination. Inspections required by the program will augment ASME Code, Section XI requirements.

Cracking of ASME Code Class 1 small-bore piping due to stress corrosion cracking, cyclical (including thermal, mechanical, and vibration fatigue) loading, thermal stratification or thermal turbulence has not been experienced at LGS Units 1 and 2. Therefore, this one-time inspection program is applicable and

adequate to manage this aging effect during the period of extended operation. A plant specific periodic inspection program will be implemented if evidence of cracking caused by IGSCC or fatigue is revealed in ASME Class 1 small-bore piping.

The One-Time Inspection of ASME Code Class 1 Small-Bore Piping program will be implemented prior to the period of extended operation. One-time inspections will be performed within the six years prior to the period of extended operation.

A.2.1.25 External Surfaces Monitoring of Mechanical Components

The External Surfaces Monitoring of Mechanical Components aging management program is a new condition monitoring program that directs visual inspections of external surfaces of components be performed during system inspections and walkdowns. The program consists of periodic visual inspection of metallic and elastomeric components such as piping, piping components, ducting, and other components within the scope of license renewal. The program manages aging effects of metallic and elastomeric materials through visual inspection of external surfaces for evidence of loss of material and cracking. Visual inspections are augmented by physical manipulation as necessary to detect hardening and loss of strength of elastomers.

Inspections are performed at a frequency not to exceed one refueling cycle. This frequency accommodates inspections of components that may be in locations that are normally only accessible during outages. Surfaces that are not readily visible during plant operations and refueling outages are inspected when they are made accessible and at such intervals that would ensure the components' intended functions are maintained.

A sample of outdoor component surfaces that are insulated and a sample of indoor insulated components exposed to condensation (due to the in-scope component being operated below the dew point), are periodically inspected, under the insulation, every 10 years during the period of extended operation. Inspections subsequent to the initial inspection will consist of examination of the exterior surface of the insulation for indications of damage to the jacketing or protective outer layer of the insulation if the initial inspection verifies no loss of material beyond that which could have been present during initial construction and no evidence of cracking. If the external visual inspections of the insulation reveal damage to the exterior surface of the insulation or if there is evidence of water intrusion through the insulation, then periodic inspections under insulation to detect corrosion under insulation will continue.

The external surfaces of components that are buried are inspected via the Buried and Underground Piping and Tanks (A.2.1.29) program. The external surface of the backup fire water storage tank is inspected via the Aboveground Metallic Tanks (A.2.1.19) program.

This new aging management program will be implemented prior to the period of extended operation.

A.2.1.26 Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components

The Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components aging management program is a new condition monitoring program that directs visual inspections of internal surfaces of components be performed when they are made accessible during maintenance activities. The program consists of visual inspections of metallic and elastomeric components such as piping, piping elements and piping components, ducting components, tanks, heat exchangers, elastomers and other components within the scope of license renewal. This program will manage the aging effects of loss of material, loss of fracture toughness, reduction of heat transfer, and cracking for metallic components, and loss of material and hardening and loss of strength for elastomers. The program includes provisions for visual inspections of the internal surfaces of components not managed under other aging management programs, augmented by physical manipulation of flexible elastomers where appropriate.

This opportunistic approach is supplemented to ensure a representative sample of components within the scope of this program are inspected. At a minimum, in each 10-year period during the period of extended operation, a representative sample of 20 percent of the population (defined as components having the same combination of material, environment, and aging effect) or a maximum of 25 components per population is inspected. Where practical, the inspections focus on the bounding or lead components most susceptible to aging because of time in service, and severity of operating conditions. Opportunistic inspections continue in each 10-year period despite meeting the sampling minimum requirement. For the waste water environment, a maximum of 25 components per population will be inspected. To provide reasonable assurance of the presence of sufficient coating, 10 of the 25 internal inspections will be of the normal waste, oily waste, sanitary waste and storm drain galvanized piping, and 15 of the internal inspections will be of the radioactive floor and equipment drain carbon steel piping.

This new aging management program will be implemented prior to the period of extended operation.

A.2.1.27 Lubricating Oil Analysis

The Lubricating Oil Analysis aging management program is an existing program that provides oil condition monitoring activities to manage the loss of material and the reduction of heat transfer in piping, piping components, piping elements, heat exchangers, and tanks within the scope of license renewal exposed to a lubricating oil environment. Sampling, analysis, and condition monitoring activities identify specific wear products and contamination and determine the physical properties of lubricating oil within operating machinery. These activities are used to verify that the wear product and contamination levels and the physical properties of lubricating oil are maintained within acceptable limits to ensure that intended functions are maintained.

The Lubricating Oil Analysis program also manages the loss of coating integrity in a lube oil environment. The RCIC turbine bearing pedestals and HPCI turbine bearing pedestals and oil reservoir internal coatings are visually inspected to ensure that loss of coating integrity is detected. The inspections will be performed by inspectors qualified to international standards endorsed in RG 1.54, including, ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II. Inspections are performed for signs of coating failures and precursors to coating failures including peeling, delamination, blistering, cracking, flaking, chipping, rusting, and mechanical damage. When acceptance criteria are not met, visual inspection is supplemented by additional testing such as DFT (Dry Film Thickness), adhesion, continuity, or other inspection technique as determined by the qualified inspector to accurately assess coating condition. Adhesion testing will be performed using international standards endorsed in RG 1.54. A coatings specialist qualified to ASTM D-7108 will evaluate the results of the coating inspections. Evaluations are performed for inspection results that do not satisfy established acceptance criteria and the conditions are entered into the LGS 10 CFR 50 Appendix B corrective action program. The corrective action program ensures that conditions adverse to quality are promptly corrected.

A.2.1.28 Monitoring of Neutron-Absorbing Materials Other Than Boraflex

The Monitoring of Neutron-Absorbing Materials Other Than Boraflex program is an existing condition monitoring program that periodically analyzes test coupons of the Boral material in the Unit 1 and Unit 2 spent fuel racks to determine if the neutron-absorbing capability of the material has degraded. This program ensures that a 5 percent sub-criticality margin is maintained in the spent fuel pool.

The Monitoring of Neutron-Absorbing Materials Other Than Boraflex aging management program will be enhanced to:

1. Perform test coupon analysis on a ten-year frequency**,** beginning no earlier than 2020 for Unit 1 and 2021 for Unit 2.

2. Initiate corrective action if coupon test result data indicates that acceptance criteria will be exceeded prior to the next scheduled test coupon analysis.

3. Resume the accelerated exposure configuration for the Boral coupons (surrounded by freshly discharged fuel assemblies) at each of five additional refueling cycles, beginning with the next refueling for each unit (2013 for Unit 2, 2014 for Unit 1).

4. Maintain the coupon exposure such that it is bounding for the Boral material in all spent fuel racks, by relocating the coupon tree to a different spent fuel rack cell location each cycle and by surrounding the coupons with a greater number of freshly discharged fuel assemblies than that of any other cell location.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.29 Buried and Underground Piping and Tanks

The Buried and Underground Piping and Tanks aging management program is an existing program that manages the external surface aging effects of loss of material for piping and components in a buried or underground environment. The LGS program activities consist of preventive, mitigative, (i.e., coatings, backfill quality and cathodic protection) and inspection activities to manage, detect and monitor the loss of material due to external corrosion for piping and components within the scope of license renewal that are in a buried or underground environment.

External inspections of buried components will occur opportunistically when they are excavated for any reason.

The Buried and Underground Piping and Tanks aging management program will be enhanced to:

1. If adverse indications are detected during inspection of in-scope buried piping, inspection sample sizes within the affected piping categories are doubled. If adverse indications are found in the expanded sample, an analysis is conducted to determine the extent of condition and extent of cause. The size of the follow-on inspections will be determined based on the extent of condition and extent of cause.

2. Coat the underground Emergency Diesel Generator System fuel oil piping prior to the period of extended operation. The coating will be in accordance with Table 1 of NACE SP0169-2007 or Section 3.4 of NACE RP0285-2002.

3. Perform direct visual inspections and volumetric inspections of the underground Emergency Diesel Generator System fuel oil piping and components during each 10-year period beginning 10 years prior to the entry into the period of extended operation. Prior to the period of extended operation all in scope Emergency Diesel Generator System fuel oil piping and components located in underground vaults will undergo a 100 percent visual inspection. Volumetric inspections will also be performed. After entering the period of extended operation, 2 percent of the linear length of in scope Emergency Diesel Generator System fuel oil piping and components located in underground vaults will undergo direct visual inspections and volumetric inspections every 10 years. Inspection locations after entering the period of extended operation will be selected based on susceptibility to degradation and consequences of failure. Visual inspections will be performed by a NACE Coating Inspector Program Level 2 or 3 qualified inspector or an individual that has attended the EPRI Comprehensive Coatings Course and completed the EPRI Buried Pipe Condition Assessment and Repair Training Computer Based Training Course.

4. Perform two sets of volumetric inspections of the Safety Related Service Water System underground piping and components during each 10-year

period beginning 10 years prior to the entry into the period of extended operation. Each set of volumetric inspections will assess either the entire length of a run of in scope Safety Related Service Water piping and components in the underground vault or a minimum of 10 feet of the linear length of in scope Safety Related Service Water System piping and components in the underground vault. Inspection locations will be selected based on susceptibility to degradation and consequences of failure.

5. Specify that visual inspections of Safety Related Service Water System underground piping and components will be performed by a NACE Coating Inspector Program Level 2 or 3 qualified inspector or an individual that has attended the EPRI Comprehensive Coatings Course and completed the EPRI Buried Pipe Condition Assessment and Repair Training Computer Based Training Course.

6. Perform trending of the cathodic protection testing results to identify changes in the effectiveness of the system and to ensure that the rectifiers remain operational at least 85% of the time and cathodic protection effectiveness will be maintained greater than 80%. Cathodic protection operational and effectiveness requirements shall be met for the 10 years prior to the period of extended operation (PEO), and throughout the PEO.

7. Modify the yearly cathodic protection survey acceptance criterion to meet NACE SP0169-2007 standards and add a statement that if negative polarized potential exceeds -1100mV relative to copper/copper sulfate electrode an issue report will be entered into the corrective action program. In performing cathodic protection surveys, the polarized potential criterion of -850mV for copper/copper sulfate reference electrodes (CSEs) will be used to determine cathodic protection system effectiveness. Other standard reference electrodes may be substituted for the CSEs; however their voltage measurements must be converted to the CSE equivalents in accordance with NACE RP0285-2002.

8. Whenever pipe is excavated and damage to the coating is significant and the damage was caused by non-conforming backfill, an extent of condition evaluation should be conducted to ensure that the as-left condition of backfill in the vicinity of observed damage will not lead to further degradation. Visual inspection of coatings will be performed by a NACE Coating Inspector Program Level 2 or 3 qualified inspector or an individual that has attended the EPRI Comprehensive Coatings Course and completed the EPRI Buried Pipe Condition Assessment and Repair Training Computer Based Training Course.

These enhancements will be implemented prior to the period of extended operation, with the actions performed in accordance with the schedule described above.

A.2.1.30 ASME Section XI, Subsection IWE

The ASME Section XI, Subsection IWE aging management program is an existing program based on ASME Code and complies with the provisions of 10 CFR 50.55(a). The program consists of periodic inspection of the primary containment liner plate surfaces and components, including its integral attachments, diaphragm slab carbon steel liner, downcomers and bracing, penetration sleeves, pressure retaining bolting, personnel airlock and equipment hatches, drywell head, and other pressure retaining components for loss of material, loss of preload, loss of leak-tightness, and fretting or lockup.

Examination methods include visual and volumetric testing as required by ASME Section XI, Subsection IWE. Observed conditions that have the potential for impacting an intended function are evaluated for acceptability in accordance with ASME requirements or corrected in accordance with corrective action program.

The ASME Section XI, Subsection IWE aging management program will be enhanced to:

1. Manage the suppression pool liner and coating system to:

    a. Remove any accumulated sludge in the suppression pool every refueling outage. *De-sludging in 1R18 was not performed due to the COVID-19 pandemic.

    b. Perform an ASME IWE examination of the submerged portion of the suppression pool each ISI period. *The ASME IWE examination in 1R18 was not performed due to the COVID-19 pandemic. This is a one-time exception to the 4-year LR SER inspection interval.

    c. Use the results of the ASME IWE examination to implement a coating maintenance plan to perform the following prior to the period of extended operation (PEO):

        - Local areas (less than 2.5 inches in diameter) of general corrosion that are greater than 100 mils plate thickness loss will be recoated in the outage they are identified. This plate thickness loss criterion for local areas will also be used to determine when the submerged portions of the liner require augmented inspection in accordance with ASME Section XI, Subsection IWE, Category E-C.

        - Areas of general corrosion greater than 65 mils average plate thickness loss will be recoated based on ranking of affected surface area, high to low. This plate thickness loss criterion for areas of general corrosion will also be used to determine when the submerged portions of the liner require augmented inspection in accordance with ASME Section XI, Subsection IWE, Category E-C.

    d. Use the results of the ASME IWE examination to implement a coating maintenance plan to perform the following during the PEO:

- Local areas (less than 2.5 inches in diameter) of general corrosion that are greater than 100 mils plate thickness loss will be recoated in the outage they are identified. This plate thickness loss criterion for local areas will also be used to determine when the submerged portions of the liner require augmented inspection in accordance with ASME Section XI, Subsection IWE, Category E-C.

- Areas of general corrosion greater than 65 mils average plate thickness loss will be recoated in the outage they are identified. This plate thickness loss criterion for areas of general corrosion will also be used to determine when the submerged portions of the liner require augmented inspection in accordance with ASME Section XI, Subsection IWE, Category E-C.

The coating maintenance plan will be initiated in the 2012 refueling outage for Unit 1 and the 2013 refueling outage for Unit 2. The coating maintenance plan will continue through the period of extended operation to ensure the coating protects the liner to avoid significant material loss.

2. Use the results of the ASME IWE inspection of the submerged portions of the suppression pool downcomers to perform the following:

   - Local areas (less than or equal to 5.5 inches in any direction) that have 40 mils or more metal thickness loss will be recoated. This downcomer metal thickness loss criteria for local areas will also be used to determine when the submerged portions of the downcomers require augmented inspection in accordance with ASME Section XI, Subsection IWE, Category E-C.

   - Areas of general corrosion (greater than 5.5 inches in any direction) that have 30 mils or more metal thickness loss will be recoated. This downcomer metal thickness loss criteria for areas of general corrosion will also be used to determine when the submerged portions of the downcomers require augmented inspection in accordance with ASME Section XI, Subsection IWE, Category E-C.

   The downcomer recoat and augmented inspection criteria will be implemented prior to receipt of the renewed licenses.

3. When IWE examinations are conducted, perform ultrasonic thickness measurements on four areas of submerged suppression pool liner affected by general corrosion. The ultrasonic thickness measurement requirements will be implemented prior to receipt of the renewed licenses.

4. Provide guidance for proper specification of bolting material, lubricant and sealants, and installation torque or tension to prevent or mitigate degradation and failure of structural bolting.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.31 ASME Section XI, Subsection IWL

The ASME Section XI, Subsection IWL aging management program is an existing program based on ASME Code and complies with the provisions of 10 CFR 50.55(a). The program requires periodic inspection of Containment Structure concrete surfaces to identify areas of deterioration and distress such as defined in ACI 201.1 and ACI 349.3R, including cracking, loss of bond, and loss of material.

Inspection methods, inspected parameters, and acceptance criteria are in accordance with ASME Section XI, Subsection IWL as approved by 10 CFR 50.55(a). Observed conditions that have the potential for impacting an intended function are evaluated for acceptability in accordance with ASME Section XI, Subsection IWL requirements or corrected in accordance with the corrective action program.

The ASME Section XI, Subsection IWL aging management program will be enhanced to:

1. Include second tier acceptance criteria of ACI 349.3R.

This enhancement will be implemented prior to the period of extended operation.

A.2.1.32 ASME Section XI, Subsection IWF

The ASME Section XI, Subsection IWF aging management program is an existing program that consists of periodic visual examinations of ASME Class 1, 2, 3, and MC piping and component supports for identification of signs of degradation such as loss of material, loss of mechanical function and loss of pre-load. The program is implemented through corporate and station procedures, which provide inspection and acceptance criteria consistent with the requirements of the ASME Code, Section XI, Subsection IWF as approved in 10 CFR 50.55(a). The monitoring methods are effective in detecting the applicable aging effects, and the frequency of monitoring is adequate to prevent significant degradation.

The ASME Section XI, Subsection IWF aging management program will be enhanced to:

1. Provide guidance for proper specification of bolting material, lubricant and sealants, and installation torque or tension to prevent or mitigate degradation and failure of structural bolting.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.33 10 CFR Part 50, Appendix J

The 10 CFR Part 50, Appendix J aging management program is an existing program that monitors leakage rates through the containment pressure boundary, including penetrations and other access openings, in order to detect

age related degradation of the containment pressure boundary. Corrective actions are taken if leakage rates exceed acceptance criteria. The Primary Containment Leakage Rate Testing Program (LRT) provides for aging management of pressure boundary degradation due to aging effects from the loss of material, loss of sealing, loss of leak tightness, or loss of preload in systems penetrating containment. The Appendix J program also detects degradation of gaskets and seals for the primary containment pressure boundary access points. Consistent with the current licensing basis, the containment leak rate tests are performed in accordance with the regulations and guidance provided in 10 CFR 50 Appendix J Option B, Regulatory Guide 1.163, “Performance-Based Containment Leak-Test Program,” NEI 94-01 “Industry Guideline for Implementing Performance-Based Option of 10 CFR Part 50 Appendix J,” and ANSI/ANS 56.8, “Containment System Leakage Testing Requirements.” As permitted by the License Amendment to implement 10 CFR 50.69, "Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors," Alternative Treatments may be applied in lieu of 10 CFR 50 Appendix J requirements for penetrations and valves classified as RISC-3 and RISC-4, meeting the criteria of 10 CFR 50.69(b)(1)(x).

A.2.1.34 Masonry Walls

The Masonry Walls program is an existing program implemented as part of the Structures Monitoring (A.2.1.35) program. Masonry wall condition monitoring is based on guidance provided in IE Bulletin 80-11, "Masonry Wall Design”, and NRC Information Notice 87-67, "Lessons Learned from Regional Inspections of Licensee Actions in Response to IE Bulletin 80-11," and is implemented through station procedures.

The Masonry Walls aging management program addresses loss of material, and cracking due to age-related degradation of concrete for masonry walls and will inspect for shrinkage or separation, along with gaps between the supports and masonry walls. The program relies on periodic visual inspections to monitor and maintain the condition of masonry walls within the scope of license renewal. Masonry walls that are considered fire barriers are also managed by the Fire Protection (A.2.1.17) program.

The Masonry Walls aging management program will be enhanced to:

1. Add the following structures with masonry walls to the program scope:

    a. Administration Building Warehouse

    b. Fuel Oil Pumphouse

    c. Transformer foundation dike walls.

2. Provide additional guidance for inspection of masonry walls for shrinkage, separation, and for gaps between the supports and walls that could impact the wall’s intended function.

3. Require an inspection frequency of not greater than 5 years.

4. Require that personnel performing inspections and evaluations meet the qualifications specified within ACI 349.3R.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.35 Structures Monitoring

The Structures Monitoring program is an existing program that was developed to implement the requirements of 10 CFR 50.65 and is based on NUMARC 93-01, “Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants,” and Regulatory Guide 1.160, “Monitoring the Effectiveness of Maintenance at Nuclear Power Plants.” The program includes elements of the Masonry Walls (A.2.1.34) program. The program relies on periodic visual inspections to monitor the condition of structures and structural components, structural bolting, component supports, and masonry block walls. The inspections are conducted on a frequency not to exceed 5 years.

The Structures Monitoring aging management program will be enhanced to:

1. Add the following structures:

   a. Admin Building Warehouse

   b. Fuel Oil Pumphouse

   c. Service Water Pipe Tunnel

   d. Yard Structures

      - Aux Fire Water Storage Tank Foundation
      - Backup Fire Pump House and Foundation
      - Well Pump #3 Enclosure and Foundation
      - Railroad Bridge
      - Manholes 001 and 002
      - Fuel Oil Storage Tank Dike
      - Transformer foundations and dikes

2. Add the following components and commodities:

   a. Pipe, electrical, and equipment component support members

   b. Pipe whip restraints and jet impingement shields

   c. Panels, Racks, and other enclosures

   d. Sliding surfaces

   e. Sump and Pool liners

   f. Electrical cable trays and conduits

   g. Electrical duct banks

h. Tube tracks

i. Doors

j. Penetration seals

k. Blowout panels

l. Permanent drywell shielding

m. Roof scuppers

3. Monitor groundwater chemistry on a frequency not to exceed 5 years for pH, chlorides, and sulfates and verify that it remains non-aggressive, or evaluate results exceeding criteria to assess impact, if any, on below-grade concrete.

4. Provide guidance for proper specification of bolting material, lubricant and sealants, and installation torque or tension to prevent or mitigate degradation and failure of structural bolting. Revise storage requirements for high strength bolts to include recommendations of Research Council on Structural Connections (RSCS) Specification for Structural Joints Using High Strength Bolts, Section 2.0.

5. Monitor concrete for areas of abrasion, erosion, and cavitation degradation, drummy areas that can exceed the cover concrete thickness in depth, popouts and voids, scaling, and passive settlements or deflections.

6. Perform inspections on a frequency not to exceed 5 years.

7. Perform inspections of sub-drainage sump pit internal concrete on a 5-year frequency as a leading indicator the condition of below grade concrete exposed to ground water.

8. Require that personnel performing inspections and evaluations meet the qualifications specified within ACI 349.3R.

9. Perform inspection of elastomeric vibration isolation elements and structural seals for cracking, loss of material and hardening. Visual inspections of elastomeric vibration isolation elements are to be supplemented by manipulation to detect hardening when vibration isolation function is suspect.

10. Monitor accessible sliding surfaces to detect significant loss of material due to wear, corrosion, debris, or dirt, that could result in lock-up or reduced movement.

11. Perform opportunistic inspection of below grade portions of in scope structures in the event of excavation which exposes normally inaccessible below grade concrete.

12. Include applicable acceptance criteria from ACI 349.3R.

13. Clarify that loose bolts and nuts and cracked high strength bolts are not acceptable unless accepted by engineering evaluations.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.36 RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants

The RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants program is an existing program which will be enhanced to provide management of aging effects for water-control structures. The program monitors the condition of the Spray Pond and Pumphouse and the Yard Facilities dikes around the Condensate Storage Tanks (CST) storage tanks. The RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants aging management program addresses age-related deterioration, degradation due to extreme environmental conditions, and the effects of natural phenomena that may affect the intended function of the water-control structures. The program is used to manage conditions such as, loss of material, loss of preload, cracking, loss of bond, loss of material (spalling, scaling) and cracking, increase in porosity and permeability, loss of strength, or loss of form. Elements of the program are designed to detect degradation and take corrective actions to prevent the loss of an intended function.

The RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants aging management program will be enhanced to:

1. Require inspection of structural bolting integrity (loss of material and loosening of the bolts).

2. Require monitoring of aging effects for increase of porosity and permeability of concrete structures and loss of material for steel components.

3. Require the proper functioning of dike drainage systems.

4. Require increased inspection frequency if the extent of the degradation is such that the structure or component may not meet its design basis if allowed to continue uncorrected until the next normally scheduled inspection.

5. Require (a) evaluation of the acceptability of inaccessible areas when conditions exist in the accessible areas that could indicate the presence of, or result in, degradation to such inaccessible areas, and (b) examination of the exposed portions of the below-grade concrete when excavated for any reason.

6. Monitor raw water chemistry at least once every 5 years for pH, chlorides, and sulfates and verify that it remains non-aggressive, or evaluate results exceeding criteria to assess impact, if any, on submerged concrete.

7. Require visual examinations of the Spray Pond and Pumphouse submerged wetwell concrete for signs of degradation during maintenance activities. If significant concrete degradation is identified, a plant specific aging management program should be implemented to manage the concrete aging during the period of extended operation.

8. Require that active cracks in structural concrete or extent of corrosion in steel are documented and trended, until the condition is no longer occurring or until a corrective action is implemented.

9. Require acceptance and evaluation of structural concrete using quantitative criteria based on Chapter 5 of ACI 349.3R.

10. Provide guidance to ensure proper specification of bolting material, lubricant and sealants, and installation torque or tension to prevent or mitigate degradation and failure of structural bolting. Revise storage requirements for high strength bolts to include recommendations of Research Council on Structural Connections (RSCS) Specification for Structural Joints Using High Strength Bolts, Section 2.0.

These enhancements will be implemented prior to the period of extended operation.

A.2.1.37 Protective Coating Monitoring and Maintenance Program

The Protective Coating Monitoring and Maintenance Program is an existing condition monitoring program that provides for aging management of Service Level I coatings inside the LGS primary containment in air-indoor and treated water environments. The failure of the Service Level I coatings could adversely affect the operation of the Emergency Core Cooling Systems (ECCS) by clogging the ECCS suction strainers. Proper maintenance of the Service Level I coating ensures that coating degradation will not impact the operability of the ECCS systems. The Protective Coating Monitoring and Maintenance Program provides for coating system visual inspection, assessment, and repair for any condition that adversely affects the ability of Service Level I coatings to function as intended.

Service Level I coatings will prevent or minimize the loss of material due to corrosion but these coatings are not credited for managing the effects of corrosion for the carbon steel containment liners and components at LGS. This program ensures that the Service Level I coatings maintain adhesion so as to not effect the intended function of the ECCS suction strainers.

The program also provides controls over the amount of unqualified coating which is defined as coating inside the primary containment that has not passed the required laboratory testing, including irradiation and simulated Design Basis Accident (DBA) conditions. Unqualified coating may fail in a way to affect the intended function of the Emergency Core Cooling Systems (ECCS) suction strainers. Therefore, the quantity of unqualified coating is controlled to ensure that the amount of unqualified coating in the primary containment is kept within acceptable design limits.

The Protective Coating Monitoring and Maintenance Program will be enhanced to:

1. Create the position of Nuclear Coatings Specialist qualified to ASTM D 7108 standards.

This enhancement will be implemented prior to the period of extended operation.

A.2.1.38 Insulation Material for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Insulation Material for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements aging management program is a new program that will be used to manage aging of the insulation material for non-EQ cables and connections during the period of extended operation. Accessible cables and connections located in adverse localized environments will be visually inspected at least once every 10 years for indications of reduced insulation resistance, such as embrittlement, discoloration, cracking, melting, swelling, or surface contamination. An adverse localized environment is a condition in a limited plant area that is significantly more severe than the specified service environment for the cable or connection.

This new program will be implemented prior to the period of extended operation. In addition, the first inspections will be completed prior to the period of extended operation.

A.2.1.39 Insulation Material for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits

The Insulation Material for Electrical Cables and Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements Used in Instrumentation Circuits aging management program is a new program that will be used to manage aging of non-EQ cable and connection insulation of the in scope portions of the Process Radiation Monitoring and Neutron Monitoring Systems.

The in scope process radiation monitoring and neutron monitoring circuits are sensitive instrumentation circuits with high voltage, low-level current signals and are located in areas where the cables and connections could be exposed to adverse localized environments caused by temperature, radiation, or moisture. These adverse localized environments can result in reduced insulation resistance causing increases in leakage currents.

Calibration testing will be performed for the in scope process radiation monitoring circuits. Direct cable testing will be performed for the in scope neutron monitoring circuits. These calibration and cable tests will be performed and results will be assessed for reduced insulation resistance prior to the period of extended operation and at least once every 10 years during the period of extended operation.

A.2.1.40 Inaccessible Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Inaccessible Power Cables Not Subject to 10 CFR 50.49 Environmental Qualification Requirements aging management program is a new program that will be used to manage the aging effects and mechanisms of non-EQ, in scope, inaccessible power cables. For this program, power is defined as greater than or equal to 400 V. These inaccessible power cables may at times be exposed to significant moisture. Power cable exposure to significant moisture may cause reduced insulation resistance that can potentially lead to failure of the cable's insulation system.

The cables in the scope of this aging management program will be tested using a proven test for detecting reduced insulation resistance of the cable's insulation system due to wetting or submergence, such as Dielectric Loss (Dissipation Factor or Power Factor), AC Voltage Withstand, Partial Discharge, Step Voltage, Time Domain Reflectometry, Insulation Resistance and Polarization Index, Line Resonance Analysis, or other testing that is state-of-the-art at the time the test is performed. The cables will be tested at least once every 6 years. More frequent testing may occur based on test results and operating experience. The first tests will be completed prior to the period of extended operation.

Periodic actions will be taken to prevent inaccessible cables from being exposed to significant moisture. Manholes associated with the cables included in this aging management program will be inspected for water collection with subsequent corrective actions (e.g., water removal), as necessary. Prior to the period of extended operation, the frequency of inspections for accumulated water will be established and adjusted based on plant specific operating experience with cable wetting or submergence, including water accumulation over time and event driven occurrences such as heavy rain or flooding. Operation of dewatering devices will be verified prior to any known or predicted heavy rain or flooding event. The first inspections will be completed prior to the period of extended operation. During the period of extended operation, the inspections will occur at least annually.

A.2.1.41 Metal Enclosed Bus

The Metal Enclosed Bus aging management program is a new program that will be used to manage aging of in scope metal enclosed bus during the period of extended operation. The internal portions of the bus enclosure assemblies will be inspected for cracks, corrosion, foreign debris, excessive dust buildup, and evidence of water intrusion. The bus insulation will be visually inspected for signs of reduced insulation resistance, such as embrittlement, cracking, chipping, melting, discoloration, swelling or surface contamination. The internal bus insulating supports will be visually inspected for structural integrity and signs of cracks. Enclosure assembly elastomers will be visually inspected for surface cracking, crazing, scuffing, dimensional change, shrinkage, discoloration, hardening, and loss of strength. A sample of accessible bolted connections will be inspected for increased resistance of connection using thermography. The sample will be 20 percent of the accessible metal enclosed bus bolted connection population with a maximum sample size of 25.

The inspections and thermography will be performed at least once every 10 years for indications of aging degradation. This new program will be implemented prior to the period of extended operation. In addition, the first tests and inspections will be completed prior to the period of extended operation.

A.2.1.42 Fuse Holders

The Fuse Holders aging management program is a new program that applies to fuse holders located outside of active devices that have been identified as susceptible to aging effects. Fuse holders located inside an active device are not within the scope of this program. This program will be used to manage aging of the metallic portions of fuse holders. Stressors managed by this aging management program include frequent manipulation, vibration, chemical contamination, corrosion, oxidation, ohmic heating, thermal cycling and electrical transients. Fuse holders subject to increased resistance of connection or fatigue, will be tested, by a proven test methodology, at least once every 10 years for indications of aging degradation. Visual inspection is not part of this program.

The new Fuse Holders program will be implemented prior to the period of extended operation. In addition, the first tests will be completed prior to the period of extended operation.

A.2.1.43 Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements

The Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements program is a new program. The program will implement one-time testing of a representative sample of non-EQ electrical cable connections to ensure that either increased resistance of connection is not occurring or that the existing preventive maintenance program is effective such that a periodic inspection program is not required. A representative sample of non-EQ electrical cable connections will be selected for one-time testing considering application (medium and low voltage), circuit loading (high loading) and location (high temperature, high humidity and vibration). The sample tested will be 20 percent of the population with a maximum sample size of 25 connections. The technical basis for the sample selected is to be documented. The specific type of test performed will be a proven test for detecting increased resistance of connections, such as thermography, contact resistance measurement, or another appropriate test.

The new Electrical Cable Connections Not Subject to 10 CFR 50.49 Environmental Qualification Requirements aging management program will be implemented prior to the period of extended operation. The one-time tests will be completed prior to the period of extended operation.

A.2.2 Plant-Specific Aging Management Programs

None. Limerick Generating Station, Units 1 and 2 do not have plant-specific aging management programs as a result of License Renewal.

A.3 NUREG-1801 Chapter X Aging Management Programs

A.3.1 Evaluation of Chapter X Aging Management Programs

Aging Management Programs evaluated in Chapter X of NUREG-1801 are associated with Time-Limited Aging Analysis for metal fatigue of the reactor coolant pressure boundary and environmental qualification (EQ) of electric components. These programs are evaluated in this section.

A.3.1.1 Fatigue Monitoring

The Fatigue Monitoring program is an existing program that manages fatigue damage of reactor coolant pressure boundary (RCPB) and other components subject to the reactor coolant, treated water, steam, and air-indoor uncontrolled environments.

The Fatigue Monitoring program is a preventive program that monitors and tracks the number of critical thermal, pressure, and seismic transients to ensure that the cumulative usage factor (CUF) for each analyzed component does not exceed the design limit of 1.0 through the period of extended operation. The program reviews the temperature and pressure profiles of the actual transients and counts them in the appropriate design transient category. The program compares the cumulative cycles for each design transient to the cycle limits specified in Technical Specification 5.6, UFSAR Table 3.9-2, "Design Events," and Table 5.2-9, “RCPB Operating Thermal Cycles.”

If a limit is approached, corrective actions are triggered to prevent exceeding the limit. The fatigue analyses may be revised to account for increased numbers of cycles or increased transient severity such that the cumulative usage factor (CUF) does not exceed the design limit of 1.0, including environmental effects where applicable.

The effect of the reactor coolant environment on RCPB component fatigue life has been determined by performing environmental fatigue analyses for locations selected using NUREG/CR-6260 guidance. Additional environmental fatigue analyses were performed for limiting locations within the RPV and for each RCPB system. Environmentally-adjusted cumulative usage factors (CUFen) were computed in accordance with the requirements specified in NUREG/CR-6909 for each material.

The Fatigue Monitoring aging management program will be enhanced to:

1. Monitor additional plant transients that are significant contributors to fatigue usage and to impose administrative transient cycle limits corresponding to the limiting numbers of cycles used in the environmental fatigue calculations.

This enhancement will be implemented prior to the period of extended operation.

A.3.1.2 Environmental Qualification (EQ) of Electric Components

The Environmental Qualification (EQ) of Electric Components is an existing program that manages the aging of electrical equipment within the scope of 10 CFR 50.49, “Environmental Qualification of Electrical Equipment Important to Safety for Nuclear Power Plants.” The program establishes, demonstrates, and documents the level of qualification, qualified configurations, maintenance, surveillance and replacements necessary to meet 10 CFR 50.49. A qualified life is determined for equipment within the scope of the program and appropriate actions such as replacement or refurbishment are taken prior to or at the end of the qualified life of the equipment so that the aging limit is not exceeded. The various aging effects addressed by this program are adequately managed so that the intended functions of components within the scope of 10 CFR 50.49 are maintained consistent with the current licensing basis during the period of extended operation. As permitted by the License Amendment to implement 10 CFR 50.69, "Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors," Alternative Treatments may be applied in lieu of 10 CFR 50.49 requirements for components classified as RISC-3 and RISC-4.

A.4 Time-Limited Aging Analyses

A.4.1 Identification of Time-Limited Aging Analyses

As part of the application for a renewed license, 10 CFR 54.21(c) requires that an evaluation of Time-Limited Aging Analyses (TLAAs) for the period of extended operation be provided.

10 CFR 54.21(c)(2) requires that the application for a renewed license include a list of plant-specific exemptions granted pursuant to 10 CFR 50.12 and in effect that are based upon TLAAs as defined in 10 CFR 54.3. It also requires an evaluation that justifies the continuation of these exemptions for the period of extended operation. Only two exemptions were identified that are based upon a TLAA. These were associated with Pressure-Temperature (P-T) limits developed using exemptions to 10 CFR 50 Appendix G to permit use of ASME Code Cases N-588 and N-640. Continuation of these exemptions into the PEO is acceptable because the use of Code Cases N-588 and N-640 as a basis for the 32 EFPY P-T limits was approved by the NRC without a limitation with respect to plant operation beyond the original license term. In addition, this is justified because the provisions of Code Cases N-588 and N-640 utilized in developing the current P-T limit curves remain acceptable since they were incorporated into the ASME Code, Section XI, Appendix G, in the 1998 Edition through 2000 Addenda, as described in Regulatory Issue Summary (RIS) 2004-04, and this Code was approved for use as described in 10 CFR 50.55a (b)(2).

PT curves were developed for 57 EFPY in support of the Period of Extended Operation for License Renewal, the methods of ASME Section XI, Appendix G, 2007 Edition with addenda through 2008, has been used.

A.4.2 Reactor Pressure Vessel Neutron Embrittlement Analysis

10 CFR 50.60 requires that all light-water reactors meet the fracture toughness, P-T limits, and material surveillance program requirements for the reactor coolant pressure boundary as set forth in 10 CFR 50 Appendices G and H. The reactor pressure vessel embrittlement calculations for LGS that evaluated reduction of fracture toughness of the Unit 1 and Unit 2 reactor pressure vessel beltline materials for 40 years are based upon a predicted End of License fluence of 32 Effective Full Power Years (EFPY). These analyses are considered TLAAs as defined in 10 CFR 54.21(c) and they were evaluated for the increased neutron fluence associated with 57 EFPY of operation as described in the subsections below.

A.4.2.1 Neutron Fluence Projections

High energy (>1 MeV) neutron fluence was calculated for the RPV beltline welds and shells using the Radiation Analysis Model Application (RAMA) Fluence Methodology. Use of this model was performed in accordance with NRC Regulatory Guide 1.190. This RAMA methodology was used to develop 60-year, 57 EFPY fluence values for LGS. The 57 EFPY fluence projections are used in the evaluations of the neutron embrittlement TLAAs.

The 57 EFPY fluence projections have been determined for reactor vessel beltline materials, which include the reactor vessel plate materials, welds, and forgings that will be exposed to 1.0 E+17 neutrons/cm^2 (n/cm^2) or more during 60 years of operation. Fluence projections have also been determined for specific reactor vessel internals components, both to evaluate fluence-based TLAAs and to determine when specified fluence threshold values may be exceeded that are used to invoke specific aging management requirements for these components, such as inspections.

A.4.2.2 Upper-Shelf Energy

10 CFR 50 Appendix G, Paragraph IV.A.1.a, requires that the reactor vessel beltline materials must maintain Charpy upper-shelf energy (USE) throughout the life of the vessel of no less than 50 ft-lb, unless it is demonstrated in a manner approved by the Director, Office of Nuclear Regulation, that lower values of Charpy upper-shelf energy will provide margins of safety against fracture equivalent to those required by Appendix G of Section XI of the ASME Code.

Upper Shelf Energy (USE) values were computed for all LGS beltline materials that will be exposed to over 1.0 E+17 n/cm^2 by the end of the period of extended operation (57 EFPY). The 57 EFPY USE values for the beltline materials were determined using methods consistent with Regulatory Guide 1.99, Revision 2.

The USE values for LGS beltline materials remain within the limits of 10 CFR 50 Appendix G requirements at 57 EFPY, either by having USE values of at least 50 ft-lb or through an equivalent margins analysis (EMA). Therefore, the analyses are projected for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

A.4.2.3 Adjusted Reference Temperature

The adjusted reference temperature (ART) of the limiting beltline material is used to adjust the beltline P-T limits to account for irradiation effects. The initial nil-ductility reference temperature, RT_{NDT}, is the temperature at which a non-irradiated metal (ferritic steel) changes in fracture characteristics from ductile to brittle behavior. RT_{NDT} is evaluated according to the procedures in the ASME Code, Section III. Neutron embrittlement increases the RT_{NDT} beyond its initial value.

10 CFR 50 Appendix G defines the fracture toughness requirements for the life of the vessel. The shift in the initial RT_{NDT} (ΔRT_{NDT}) is evaluated as the difference in the 30 ft-lb index temperatures from the average Charpy curves measured before and after irradiation. This increase (ΔRT_{NDT}) means that higher temperatures are required for the material to continue to act in a ductile manner. The ART is defined as Initial RT_{NDT} + ΔRT_{NDT} + Margin. The Margin term is defined in Regulatory Guide 1.99, Revision 2.

ART values were computed for LGS beltline materials in accordance with Regulatory Guide 1.99, Revision 2. The ART values of the limiting beltline materials at 57 EFPY for each unit remain below 200 degrees F, which is the RT_{NDT} limit.

The analysis for the adjusted reference temperature has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

A.4.2.4 Pressure – Temperature Limits

10 CFR 50 Appendix G requires that the reactor pressure vessel be maintained within established (P-T) limits, including heatup and cooldown operations. These limits specify the maximum allowable pressure as a function of reactor coolant temperature. As the reactor pressure vessel is exposed to increased neutron irradiation, its fracture toughness is reduced. The P-T limits must account for the anticipated reactor vessel fluence.

The current P-T limits were updated based upon 57 EFPY fluence projections, consistent with the amount of power to be generated over 60 years of plant operation. The P-T limits satisfy the criteria of 10 CFR 54.3(a).

A.4.2.5 Axial Weld Inspection

The BWRVIP recommendations for inspection of reactor pressure vessel shell welds in BWRVIP-05 include examination of 100 percent of the axial welds and inspection of the circumferential welds only at the intersections of these welds with the axial welds. BWRVIP-05 contains generic analyses supporting a conclusion in the NRC Final Safety Evaluation Report (FSER) that the generic-plant axial weld failure rate is orders of magnitude greater than the 40-year end-of-life circumferential weld failure probability and used this analysis to justify relief from inspection of the circumferential welds. The failure frequency is dependent upon given assumptions of flaw density, distribution, and location. Since the axial weld failure probability assessment is based on 32 EFPY fluence values associated with 40 years of operation, it has been identified as a TLAA requiring evaluation for the period of extended operation.

The LGS axial weld failure probability has been projected for the period of extended operation. In order to evaluate the axial weld failure probability assessment for 60 years, 57 EFPY fluence values were derived for the limiting axial weld. Using the 57 EFPY fluence values, the LGS Mean RTNDT values were computed for each unit and compared to the NRC analytical results for 64 EFPY provided in the FSER to BWRVIP-05. Although a conditional failure probability has not been calculated for the LGS units, the fact that the LGS Mean RTNDT values for the period of extended operation are significantly less than the NRC value leads to the conclusion that the Unit 1 and 2 conditional failure probability is bounded by the NRC analysis, consistent with the requirements defined in GL 98-05. This analysis has been projected through the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

A.4.2.6 Circumferential Weld Inspection

ASME Section XI governs the inspection of the reactor pressure vessel circumferential welds, as implemented by the LGS In-service Inspection Program. LGS has received inspection relief for circumferential welds for the remainder of the 40-year license period. The circumferential weld failure probability assessment is based on 32 EFPY fluence values associated with 40 years of operation and has been identified as a TLAA requiring evaluation for the period of extended operation.

In order to evaluate the LGS circumferential weld failure probability assessment for 60 years, 57 EFPY fluence values were derived for the limiting circumferential weld. Using the 57 EFPY fluence values, the LGS Mean RT_{NDT} values were computed for each unit and compared to the NRC analytical results for 64 EFPY provided in the FSER to BWRVIP-05. Although a conditional failure probability has not been calculated for the LGS units, the fact that the LGS Mean RT_{NDT} values for the period of extended operation are significantly less than the NRC value leads to the conclusion that the LGS conditional failure probability is bounded by the NRC analysis, consistent with the requirements defined in GL 98-05.

The effects of aging on the reactor pressure vessel intended functions will be managed in accordance with 10 CFR 54.21(c)(1)(iii) for the period of extended operation by reapplication for circumferential weld examination relief under 10 CFR 50.55a (a)(3). The plant-specific information described above

demonstrates that at the end of the renewal period, the circumferential welds meet the limiting conditional failure probability for circumferential welds specified in the FSER of BWRVIP-05. Operator training and procedures will continue to be utilized during the license renewal term to limit cold over-pressure events.

A.4.2.7 Reactor Pressure Vessel Reflood Thermal Shock

A generic fracture mechanics evaluation was performed in 1979 to evaluate the effects of a postulated Loss of Coolant Accident (LOCA) on the structural integrity of a BWR-6 reactor pressure vessel. The LOCA event considered was a rupture of a main steam line, which was determined to bound all other LOCA events with respect to this evaluation. Several emergency core cooling systems are activated at different times after the LOCA and the vessel is flooded with cooling water. The vessel blowdown and the subsequent injection of cold water produce low temperature and high thermal stresses in the vessel. This analysis concluded that the reactor pressure vessel has a considerable margin to failure by brittle fracture even in the presence of large postulated initial flaws. This generic analysis envelopes LGS and is based on BWR vessel material properties and cumulative fluence assumed for 40 years of operation. Therefore, this analysis has been identified as a TLAA requiring evaluation for the period of extended operation.

An updated 60-year fracture mechanics evaluation was performed for the reflood thermal shock event using plant-specific reactor pressure vessel data for LGS. The analysis determined that during the period of extended operation for both units, there is sufficient toughness margin to prevent fracture due to reflood thermal shock. An existing flaw in the reactor pressure vessel would not propagate due to brittle fracture during a LOCA.

The reactor pressure vessel reflood thermal shock analysis has been projected for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

A.4.3 Metal Fatigue

Metal fatigue was considered explicitly in the design process for pressure boundary components designed in accordance with ASME Section III, Class A or Class 1 requirements. Metal fatigue was evaluated implicitly for components designed in accordance with ASME Section III, Class 2 or 3 requirements or ANSI B31.1 requirements. These fatigue analyses and fatigue exemptions are considered to be Time-Limited Aging Analyses (TLAAs) requiring evaluation for the period of extended operation in accordance with 10 CFR 54.21(c).

A.4.3.1 ASME Section III, Class 1 Fatigue Analyses

The LGS reactor pressure vessel (RPV) and reactor coolant pressure boundary (RCPB) piping and components were designed in accordance with the ASME Code Section III, Class 1 requirements. Fatigue analyses were prepared for these components to determine the effects of cyclic loadings resulting from changes in system temperature and pressure and for seismic loading cycles. These Class 1 fatigue analyses are included in stress reports that evaluated an explicit number and type of transients to envelope the number of occurrences projected during the 40-year design life of the plant. These stress reports include fatigue analyses and fatigue exemptions, where applicable, that have been identified as TLAAs since they are based upon 40-year design transients. Each analysis was required to demonstrate that the Cumulative Usage Factor (CUF) for the component will not exceed the design limit of 1.0 when the component is exposed to all of the postulated transients. The Class 1 valve analyses were required to demonstrate that the valves can be operated for a minimum of 2,000 cycles and that the fatigue usage factor for step changes in fluid temperature It does not exceed a limit of 1.0.

The calculation of fatigue usage factors is part of the current licensing basis and is used to support safety determinations and since the number of occurrences of each transient type was based upon 40-year assumptions, these Class 1 fatigue analyses and fatigue exemptions have been identified as time-limited aging analyses.

Each of the Class 1 fatigue analyses and fatigue exemptions was evaluated for 60 years by determining that the numbers of cycles assumed in the 40-year analysis will remain bounding of the numbers of cycles projected for the component through the end of the period of extended operation. These 60-year projections were based upon cumulative cycles to-date plus future cycles predicted based upon the average rates of past occurrences. In order to ensure that these fatigue analyses and fatigue exemptions remain valid, the Fatigue Monitoring program will be used to ensure the cycle limits are not exceeded during the period of extended operation. The program includes requirements that trigger corrective action if a transient approaches a cycle limit. Corrective action may include reanalysis of affected Class 1 components to address increased numbers of cycles, repair, or replacement of the component.

The effects of aging on the intended functions of components analyzed in accordance with ASME Section III, Class 1 requirements will be adequately managed for the period of extended operation by the Fatigue Monitoring program in accordance with 10 CFR 54.21(c)(1)(iii).

A.4.3.2 ASME Section III, Class 2 and 3 and ANSI B31.1 Allowable Stress Calculations

Piping designed in accordance with ASME Section III, Class 2 or 3 design rules or ANSI B31.1 Piping Code design rules is not required to have an explicit analysis of cumulative fatigue usage, but cyclic loading is considered in the design process. If the numbers of anticipated thermal cycles exceed specified limits, these codes require the application of a stress range reduction factor to the allowable stress to prevent damage from cyclic loading. This is considered to be an implicit fatigue analysis since it is based upon cycles anticipated for the life of the component.

These codes first require the overall number of thermal and pressure cycles expected during the 40-year lifetime of these components to be determined. A stress range reduction factor is then determined for that number of cycles using the applicable design code. If the total number of cycles is 7,000 or less, the stress range reduction factor of 1.0 is applied which would not reduce the allowable stress values. For higher numbers of cycles, the stress range reduction factor limits the allowable stresses that can be applied to the piping.

For the piping and components that are affected by the reactor vessel operational transients, including the Class 2 and 3 piping extending from Class 1 systems, the 60-year cycle projections demonstrate that the total number of thermal and pressure cycles will not exceed 7,000 cycles during the period of extended operation. The effects of aging on the intended function(s) of components will be adequately managed for the period of extended operation by the Fatigue Monitoring program in accordance with 10 CFR 54.21(c)(1)(iii).

For the remaining systems that are affected by different thermal and pressure cycles, an operational review was performed that also concluded that the total number of cycles, projected for the period of extended operation, will not exceed 7,000 cycles for these systems. This includes portions of the Fire Protection, Emergency Diesel Generator, and Auxiliary Steam systems. Systems with operating temperatures below specified thresholds were determined to have low numbers of equivalent full temperature cycles since the fluid temperature changes are small. For these systems, the maximum allowable stress range values for the existing fatigue analysis remain valid in accordance with 10 CFR 54.21(c)(1)(i) because the allowable limit for the number of full thermal range transient cycles will not be exceeded during the period of extended operation.

A.4.3.3 Environmental Fatigue Analyses for RPV and Class 1 Piping

NUREG-1800, Revision 2 provides a recommendation for evaluating the effects of the reactor water environment on the fatigue life of ASME Section III Class 1 components that contact reactor coolant. One method to satisfy this recommendation is to assess the impact of the reactor coolant environment on a sample of critical components as described in NUREG/CR-6260. Additional

component locations are evaluated if they are considered to be more limiting than those considered in NUREG/CR-6260.

Environmental fatigue calculations were performed for component locations listed in NUREG/CR-6260 for the newer-vintage BWR. In order to ensure that any other locations that may not be bounded by the NUREG/CR-6260 locations were evaluated, environmental fatigue calculations were performed for each RPV component location that has a reported cumulative usage factor (CUF) in the RPV stress report and for each ASME Class 1 RCPB piping system. These environmental fatigue calculations were performed for the limiting wetted location for each material within the component that contacts reactor coolant.

NUREG-1800, Revision 2, specifies options for evaluating environmental effects. The formulae specified in the option listed below for each material were used in evaluating the LGS components for environmental effects:

Carbon and Low Alloy Steels

- Those provided in Appendix A of NUREG/CR-6909, using either the applicable ASME Section III fatigue design curve or the fatigue design curve for carbon and low alloy steel provided in NUREG/CR-6909 (Figure A.1 and A.2, respectively, and Table A.1).

Austenitic Stainless Steels

- The formula provided in NUREG/CR-6909, using the fatigue design curve for austenitic stainless steel provided in NUREG/CR-6909 (Figure A.3 and Table A.2).

Nickel Alloys

- The formula provided in NUREG/CR-6909, using the fatigue design curve for austenitic stainless steel provided in NUREG/CR-6909 (Figure A.3 and Table A.2).

Additional refinements were performed as appropriate and several locations required a reduction in the numbers of postulated cycles. The resulting environmentally-adjusted CUF values (CUF_{en}) were demonstrated not to exceed the design Code limit of 1.0.

These environmental fatigue analyses will be managed by the Fatigue Monitoring program in the same manner as all other Class 1 fatigue analyses. The program ensures that the cumulative number of occurrences of each transient type is maintained below the number of cycles used in the most limiting fatigue analysis.

If a cycle limit is approached, corrective actions are triggered to prevent exceeding the limit. The fatigue analyses may be revised to account for increased numbers of cycles or transient severity such that the CUF value does not exceed the Code design limit of 1.0, including environmental effects where applicable.

Prior to the period of extended operation, the Fatigue Monitoring program will be enhanced to impose administrative transient cycle limits corresponding to the limiting numbers of cycles used in the environmental fatigue calculations.

The effects of aging on the intended functions will be adequately managed for the period of extended operation by the LGS Fatigue Monitoring program in accordance with 10 CFR 54.21(c)(1)(iii).

A.4.3.4 Reactor Vessel Internals Fatigue Analyses

The RPV and RPV internal components were included in the NSSS New Loads Design Adequacy Evaluations performed for each unit to address the effects of plant-specific seismic loadings and suppression pool hydrodynamic structural loadings on NSSS equipment. These evaluations included fatigue analyses of components if the applied loadings exceed certain thresholds. These fatigue analyses and fatigue exemptions have been identified as TLAAs that require evaluation for the period of extended operation.

The fatigue analyses and fatigue exemptions performed for the reactor internals components are based upon the same set of design transients as those used in the fatigue analyses for the reactor pressure vessel. Transient cycle projections were prepared that demonstrate the design transient cycle limits will not be exceeded in 60 years. In order to ensure that these fatigue analyses and fatigue exemptions will remain valid, the Fatigue Monitoring program will be used to manage fatigue of these components through the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

A.4.3.5 High-Energy Line Break (HELB) Analyses Based Upon Fatigue

High Energy Line Break (HELB) analyses for LGS used the CUF values from the ASME Class 1 fatigue analyses as input in determining intermediate break locations. Since the Class 1 fatigue analyses that provided the CUF values are based upon 40-year transient assumptions, these analyses have been identified as TLAAs.

Transient cycle projections were performed that determined the 40-year transient cycle limits will not be exceeded in 60 years. The Class 1 piping fatigue analyses were demonstrated to remain valid for the period of extended operation. Therefore, the HELB break determinations based upon these fatigue analyses will also remain valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.4 Environmental Qualification (EQ) of Electric Components

A.4.4.1 Environmental Qualification (EQ) of Electric Components

Thermal, radiation, and cyclical aging analyses of plant electrical and I&C components, developed to meet 10 CFR 50.49 requirements, have been identified as time-limited aging analyses (TLAAs) for LGS. The NRC has established nuclear station environmental qualification (EQ) requirements in 10 CFR 50.49 and 10 CFR 50, Appendix A, Criterion 4. 10 CFR 50.49 specifically requires that an EQ program be established to demonstrate that

certain electrical components located in harsh plant environments are qualified to perform their safety function in those harsh environments after the effects of inservice aging. Harsh environments are defined as those areas of the plant that could be subject to the harsh environmental effects of a loss-of-coolant accident (LOCA), high energy line break (HELB), or post-LOCA radiation. 10 CFR 50.49 requires that the effects of significant aging mechanisms be addressed as part of environmental qualification.

The Environmental Qualification (EQ) of Electric Components (A.3.1.2) program will manage the effects of aging effects for the components associated with the environmental qualification TLAA. This program implements the requirements of 10 CFR 50.49 (as further defined and clarified by NUREG-0588, and RG 1.89, Rev. 1). Component aging evaluations are reanalyzed on a routine basis to extend the qualifications of components as part of the LGS EQ Program. Important attributes for the reanalysis of an aging evaluation include analytical methods, data collection and reduction methods, underlying assumptions, acceptance criteria, and corrective actions (if acceptance criteria are not met). The Environmental Qualification (EQ) of Electric Components (A.3.1.2) program methodology is further described in Appendix A, Section A.3.1.2. As permitted by the License Amendment to implement 10 CFR 50.69, "Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors," Alternative Treatments may be applied in lieu of 10 CFR 50.49 requirements for components classified as RISC-3 and RISC-4.

Under the LGS EQ Program, the reanalysis of an aging evaluation could extend the qualification of the component. If the qualification cannot be extended by reanalysis, the component must be refurbished, replaced, or requalified prior to exceeding the period for which the current qualification remains valid. A reanalysis is to be performed in a timely manner such that sufficient time is available to refurbish, replace, or requalify the component if the reanalysis is unsuccessful.

A.4.5 Containment Liner and Penetrations Fatigue Analysis

A.4.5.1 Containment Liner and Penetrations Fatigue Analysis

The LGS primary containment liner and penetrations were designed and analyzed for transient cycles predicted to occur in 40 years. The Class 1 flued-head penetrations were also analyzed for fatigue using cycles predicted to occur for 40 years. These analyses have been identified as TLAAs.

Transient cycle projections were performed that determined the 40-year transient cycle limits will not be exceeded in 60 years. This includes startup and shutdown cycles and Design Basis Accident events. An operational review was performed for the MSRV lift cycles that concluded the total number of cycles, projected for 60 years, will not exceed the number analyzed for 40 years. Therefore, the analyses remain valid for the period of extended operation in accordance with 10 CFR 54-21(c)(1)(i).

A.4.6 Other Plant–Specific Time-Limited Aging Analyses

A.4.6.1 Reactor Enclosure Crane Cyclic Loading Analysis

The LGS reactor enclosure crane is designed to meet the fatigue requirements of the Crane Manufacturers Association of America (CMAA) Specification 70 for a Class A, Standby or Infrequent Service Crane, as discussed in UFSAR Section 9.1.5.2, "Reactor Enclosure Crane, Equipment Design." This evaluation of cycles over the 40-year plant life is the basis of a safety determination and has been identified as a TLAA that requires evaluation for the period of extended operation.

The reactor enclosure crane was purchased as a Class A crane and can be considered a crane experiencing “irregular occasional use followed by long idle periods”. For this crane, the CMAA design considerations allow a minimum of 20,000 cycles.

The evaluation of the reactor enclosure crane cyclic load limit TLAA included (1) reviewing the existing 40-year design basis to determine the number of load cycles considered in the design of the crane, (2) developing a 60-year projection for load cycles for the crane, and (3) comparing the 60-year projected number of cycles to the minimum allowable design value of 20,000 cycles. The number of cycles projected for 60 years of operation is 3,468 cycles, which is less than 20 percent of the minimum allowable design value. Therefore, the reactor enclosure crane load cycle fatigue analysis remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.6.2 Emergency Diesel Generator Enclosure Cranes Cyclic Loading Analysis

LGS has eight emergency diesel generator enclosure cranes. These cranes were designed to meet or exceed the design fatigue requirements of the Crane Manufacturers Association of America (CMAA) Specification 70 for Class A, Standby or Infrequent Service Cranes. The evaluation of cycles expected over the 40-year life has been identified as a TLAA that requires evaluation for the period of extended operation.

The emergency diesel generator enclosure cranes were evaluated for the period of extended operation by developing 60-year projections for crane load cycles and comparing these projected cycles to the number of cycles evaluated for the design life of the cranes. The emergency diesel generator enclosure cranes were purchased as Class A cranes. They are considered to be cranes experiencing “irregular occasional use followed by long idle periods." For this category of crane, the CMAA design requirements permit a minimum of 20,000 load cycles.

The 60-year load cycle projection includes all load cycles and is based on an estimated 500 load cycles during original construction and 50 load cycles per year during diesel generator maintenance. The 3,500 load cycles are less than 20 percent of the allowable design value of 20,000 cycles. Therefore, the analysis of the emergency diesel generator enclosure cranes remains valid for the period of extended operation.

The analysis remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.6.3 RPV Core Plate Rim Hold-Down Bolt Loss of Preload

The RPV core plate is attached to the core support structure by stainless steel hold-down bolts that are preloaded during initial installation. These bolts are subject to stress relaxation (loss of preload) due to irradiation effects. An analysis was performed concluding that a reduction in preload as high as 19 percent over the 40-year life of the bolts is acceptable to meet design requirements. A subsequent re-evaluation determined that this maximum relaxation value of 19 percent is applicable to an average fluence level of 8.0 E+19 n/cm^2 over the entire length of the bolt located at the azimuthal location with peak fluence. These analyses were identified as TLAAs.

In order to determine if these analyses will remain valid for 60 years, RAMA fluence projections were prepared for LGS for 57 EFPY for the core plate rim bolt located at the azimuthal location with peak fluence. In order to determine the average fluence value along the length of the bolt, fluence projections were made at 75 discrete points along the length of the bolt on the bolt surface nearest the core. These results were integrated and divided by the length of the bolt, resulting in an average fluence value of 3.37 E+19 n/cm^2 along the length of the bolt. This is well below the average fluence of 8.0 E+19 n/cm^2 value previously evaluated. Therefore, the analysis remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.6.4 Main Steam Line Flow Restrictors Erosion Analysis

A main steam line flow restrictor is welded into each of the four main steam lines between the main steam relief valves and the inboard main steam isolation valve (MSIV). The restrictor assemblies consist of a stainless steel venture-type nozzle welded into the carbon steel main steam line piping. The restrictors are designed to limit steam flow prior to MSIV closure in the event of a main steam line break outside of primary containment.

There is no specific analysis of main steam line flow restrictor erosion other than that discussed in UFSAR Section 5.4.4. The UFSAR indicates that very slow erosion occurs with time and such slight enlargement has no safety significance. Since the erosion evaluation could have assumed 40 years of operation, erosion of the main steam line flow restrictor has been identified as a TLAA that requires evaluation for the period of extended operation.

Calculations indicate that even with erosion rates as high as 0.004 inch per year, the increase in choked flow rate would be no more than 5 percent after 40 years of operation, and no more than 10 percent after 60 years. The LGS Main Steam Line Break dose calculation determined that the mass of coolant leaving the reactor through the main steam line break is 108,785 lb, but uses 140,000 lb to determine the dose impact from this event. Therefore, sufficient margin exists in the dose calculation to accommodate the postulated erosion of the main steam line flow restrictor through the end of the period of extended operation.

The analysis remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.6.5 Jet Pump Auxiliary Spring Wedge Assembly

Auxiliary spring wedge assemblies have been designed and installed in LGS jet pumps to maintain lateral support for the jet pump inlet mixer. The design analysis considered potential aging effects based upon a design life of 40 years, including fatigue usage and loss of preload due to neutron fluence. These analyses have been identified as TLAAs.

The jet pump auxiliary spring wedge assembly is not an ASME Code component, but it was evaluated using stress and fatigue limits of the ASME Code as guidelines. The cumulative fatigue usage was determined to be 0.77 using the original design basis load cycles from the reactor vessel thermal cycle diagram. The 60-year transient projections for LGS demonstrate that these transient cycle limits will not be exceeded in 60 years of operation. Therefore, the fatigue TLAA remains valid for the period of extended operation.

The auxiliary spring wedge assembly design analysis also evaluated loss of preload due to integrated neutron fluence of 1.4 E+20 n/cm^2 for 40 years. In order to evaluate loss of bolt preload during the period of extended operation, the maximum service life was first determined. The first Unit 1 wedge assembly installed will have a service life of 41 years by the end of the period of extended operation, and the first Unit 2 wedge assembly will have a service life of 45 years.

The RAMA fluence projections were used to determine how long the auxiliary spring wedge assemblies could remain in service before the analyzed fluence value of 1.4 E+20 n/cm^2 would be reached. The fluence projections for the jet pump riser brace location were used since they are bounding for the locations of the auxiliary spring wedge assembly. The evaluation determined that the auxiliary spring wedge assemblies will not reach the previously evaluated fluence value of 1.4 E+20 n/cm^2. Therefore, the loss of preload TLAA also remains valid for the period of extended operation in accordance with 10CFR 54.21(c)(1)(i).

A.4.6.6 Jet Pump Restrainer Bracket Pad Repair Clamps

Visual inspections at LGS have found wear at the inlet-mixer wedge/restrainer bracket pad interface on several jet pumps. A repair clamp has been designed and installed that replaces the support function of the restrainer bracket pad. The repair clamp design analysis evaluated end-of-life preload relaxation for 40 years based upon a 5 percent decrease due to thermal and radiation effects. This analysis was identified as a TLAA.

The fluence value used to determine the loss of preload in the design analysis is five percent higher than the fluence value calculated for the repair location for a 40-year service life. Since the first clamps were installed in Unit 2 in 2009 and no clamps have been installed in Unit 1, these clamps will have a maximum service life of 40.25 years. Therefore, since the repair clamp design

analysis includes an allowance for loss of preload that is bounding for 42 years, the analysis remains valid in accordance with 10 CFR 54.21(c)(1)(i).

The repair clamp design analysis also evaluated fatigue for 40 years, which was identified as a TLAA. The clamping loads do not cycle except for the load changes associated with startup/shutdown temperature changes. The maximum calculated stress amplitude is 7,781 psi, which is within the American Society of Mechanical Engineers (ASME) Code stress limit for 304 stainless steel of 13,600 psi for 10^{11}cycles, and the General Electric Hitachi design limit of 10,000 psi for flow-induced vibration stress cycles. Since the calculated cyclic loads of 7,781 psi are less than these limits, fatigue usage will be insignificant for up to 10^{11} startup/shutdown cycles. Therefore the fatigue analysis remains valid through the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.6.7 Refueling Bellows and Supports Cyclic Loading Analysis

The refueling bellows and supports were analyzed for cycles predicted to occur in 40 years. Therefore, these fatigue analyses have been identified as TLAAs that require evaluation for the period of extended operation.

Transient cycle projections were performed that determined the 40-year transient cycle limits will not be exceeded in 60 years based upon the average rate of occurrence to-date. The analyses remain valid for the period of extended operation in accordance with 10 CFR 54-21(c)(1)(i).

A.4.6.8 Downcomers and MSRV Discharge Piping Fatigue Analyses

The downcomers and bracing inside the suppression chamber and the MSRV discharge piping quenchers have been evaluated for transient cycles predicted to occur in 40 years. Therefore, these fatigue analyses have been identified as TLAAs.

The downcomers and bracing were analyzed for a minimum of 7,700 MSRV stress cycles that were considered to account for the pool dynamic loads, based on 1,100 actuations of all MSRVs times seven stress cycles per actuation. For the most frequently actuated MSRVs, the analysis was based on 4,700 actuations times three stress cycles per actuation (14,100 total cycles). They were also analyzed for 3,000 chugging cycles that could occur following a LOCA event, 50 OBE cycles (five events with ten cycles per event), and ten SSE cycles (one event with ten cycles). The quenchers were analyzed for 7,000 MSRV actuations (opening and closing cycles) and 1,000,000 irregular condensation load cycles.

An operational review was performed for MSRV actuations that concluded the total number of MSRV actuations, projected for 60 years, will not exceed the number analyzed for 40 years in either unit. The 60-year projection for Unit 1 is 211 actuations and for Unit 2 is 138 actuations, which are well below the 1100 actuations analyzed. No OBE or SSE event has occurred to-date and neither has a 60-year projection that exceeds the design limit of one event. The Fatigue Monitoring program is credited for managing fatigue of these components in accordance with 10 CFR 54.21 (c)(1)(iii) by ensuring that the

analyzed numbers of cycles are not exceeded during the period of extended operation.

The MSRV discharge lines were analyzed for significant thermal and pressure transients defined for the Main Steam system and for the same MSRV, chugging, OBE and SSE cycles described above for the downcomers. Each of these transients has been evaluated and shown to have 60-year projections that do not exceed the numbers of cycles analyzed. The Fatigue Monitoring program is credited for managing fatigue of these components in accordance with 10 CFR 54.21 (c)(1)(iii) by ensuring that the analyzed numbers of cycles are not exceeded during the period of extended operation.

A.4.6.9 Jet Pump Slip Joint Repair Clamps

Jet pump slip joint repair clamps have been designed and installed at LGS to minimize vibration and wear of the jet pump assemblies. The structural evaluation determined the loss of preload that would result from neutron fluence during the design life of the clamps. This analysis was identified as a TLAA. The maximum service life of the slip joint clamps from initial installation through the period of extended operation will be less than 40 years for the Unit 1 clamps and less than 45 years for the Unit 2 clamps. RAMA fluence projections for each unit have determined the maximum fluence the slip joint clamps can receive during their service life. These fluence values are less than the fluence value used to determine the loss of preload allowance applied in the structural evaluation of the clamps. Therefore, the jet pump slip joint clamp design analysis for loss of preload due to neutron fluence remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.4.6.10 Fuel Pool Girder Loss of Prestress

The design analysis of the LGS Fuel Pool Girders has been identified as a plant-specific TLAA because it includes a time-limited evaluation of loss of prestress of the fuel pool girders. The girder analysis used a 4% stress relaxation value that is based upon stress relaxation test data, projected for 1,000,000 hours (114 years), which is a time-limited assumption. The TLAA remains valid in accordance with 10 CFR 54.21(c)(1)(i) because the loss of prestress values used in the analysis were demonstrated to remain valid through the period of extended operation.

A.4.6.11 RHR and Core Spray Suction Strainer Fatigue Analyses

The design analyses for the RHR and Core Spray suction strainers have been identified as TLAAs because they include a time-limited fatigue analysis of the stainless steel bolting and stainless steel strainer assembly. These analyses were based upon 34,200 MSRV stress cycles (11,400 actuations), 10 SSE stress cycles (1 event), 50 OBE cycles (5 events), and condensation oscillation and chugging cycles that would result from LOCA events. These are the same types of transients analyzed for the downcomers described in LRA Section 4.6.8.

The Fatigue Monitoring program is credited for managing fatigue of the RHR and Core Spray strainer assemblies and bolting, in accordance with 10 CFR 54.21(c)(1)(iii).

Note: This table contains commitments related to the renewed LGS operating licenses. Because these commitments are contained within the UFSAR, any potential changes to these commitments require evaluation in accordance with 10 CFR 50.59 as defined per the Exelon commitment management process. In addition, that process must be followed to ensure that the commitment tracking database is updated with the latest commitment implementation information. Refer to PIMS AR A1813863 and Passport AR 1232104 for LGS license renewal commitment tracking data.

A.5 License Renewal Commitment List

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
1	ASME Section XI Inservice Inspection, Subsections IWB, IWC, and IWD	Existing program is credited.	Ongoing	Section A.2.1.1
2	Water Chemistry	Existing program is credited.	Ongoing	Section A.2.1.2
3	Reactor Head Closure Stud Bolting	Existing program is credited.	Ongoing	Section A.2.1.3

5	BWR Feedwater Nozzle	Existing program is credited.	Ongoing	Section A.2.1.5
6	BWR Control Rod Drive Return Line Nozzle	Existing program is credited.	Ongoing	Section A.2.1.6
7	BWR Stress Corrosion Cracking	Existing program is credited.	Ongoing	Section A.2.1.7
8	BWR Penetrations	Existing program is credited.	Ongoing	Section A.2.1.8

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
9	BWR Vessel Internals	BWR Vessel Internals is an existing program that will be enhanced to: 1. Perform an assessment of the susceptibility of reactor vessel internal components fabricated from Cast Austenitic Stainless Steel (CASS) to loss of fracture toughness due to thermal aging embrittlement. If material properties cannot be determined to perform the screening, they will be assumed susceptible to thermal aging for the purposes of determining program examination requirements. 2. Perform an assessment of the susceptibility of reactor vessel internal components fabricated from Cast Austenitic Stainless Steel (CASS) to loss of fracture toughness due to neutron irradiation embrittlement. 3. Specify the required periodic inspection of CASS components determined to be susceptible to loss of fracture toughness due to thermal aging and neutron irradiation embrittlement.	Program to be enhanced prior to the period of extended operation. The initial inspections will be performed either prior to or within 5 years after entering the period of extended operation.	Section A.2.1.9
10	Flow-Accelerated Corrosion	Existing program is credited.	Ongoing	Section A.2.1.10

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
11	Bolting Integrity	Bolting Integrity is an existing program that will be enhanced to: 1. Provide guidance to ensure proper specification of bolting material, lubricant and sealants, storage, and installation torque or tension to prevent or mitigate degradation and failure of closure bolting for pressure retaining components. 2. Prohibit the use of lubricants containing molybdenum disulfide for closure bolting for pressure retaining components. 3. Minimize the use of high strength bolting (actual measured yield strength equal to or greater than 150 ksi) for closure bolting for pressure retaining components. High strength bolting, if used, will be monitored for cracking. 4. Perform visual inspection of bolting for the Residual Heat Removal System, Core Spray System, High Pressure Coolant Injection System and Reactor Core Isolation Cooling System suppression pool suction strainers for loss of material and loss of preload during each ISI inspection interval.	Program to be enhanced prior to the period of extended operation.	Section A.2.1.11 LGS letter dated 3/12/2012 RAI 3.2.2.1.1-1
12	Open-Cycle Cooling Water System	Open-Cycle Cooling Water System is an existing program that will be enhanced to:	Program to be enhanced prior to the	Section A.2.1.12

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		1. Perform internal inspection of buried Safety Related Service Water Piping when it is accessible during maintenance and repair activities. 2. Perform periodic inspections for loss of material in the Nonsafety-Related Service Water System at a minimum of five locations on each unit once every refueling cycle. 3. Replace the supply and return piping for the Core Spray pump compartment unit coolers. 4. Replace degraded RHRSW piping in the pipe tunnel. 5. Perform periodic inspections for loss of material in the Safety Related Service Water System at a minimum of ten locations every two years. The Open-Cycle Cooling Water System aging management program also manages the loss of coating integrity in the service water side of the Main Control Room Chiller Condensers and Reactor Enclosure Cooling Water Heat Exchangers, and, in circulating water system piping. • As described below, baseline inspections will occur in the 10-year period prior to the period of extended operation. The maximum interval of subsequent	period of extended operation. Inspection schedule identified in commitment. 		coating inspections will comply with Table 4a of GALL Report AMP XI.M42 in draft LR-ISG-2013-01 dated January 6, 2014 (ADAMS Accession No. ML13262A442). • The inspection of the Main Control Room Chiller Condensers will be performed by inspectors qualified to ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II. • The inspection of the Reactor Enclosure Cooling Water Heat Exchangers will be performed by inspectors with a demonstrated working knowledge of EPRI Report 1019157, “Guideline on Nuclear Safety-Related Coatings”. • The inspection of 73 one-foot axial length circumferential segments of coated circulating water system piping will be performed by inspectors qualified to ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II. • The acceptance criteria for coating degradation and the requirements for physical inspections when degradation is identified will be in accordance with Element 6 of GALL Report AMP XI.M42 in draft LR-ISG-2013-01 dated January 6, 2014.		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
13	Closed Treated Water Systems	Closed Treated Water Systems is an existing program that will be enhanced to: 1. Perform condition monitoring and performance monitoring, including periodic testing and opportunistic and periodic NDE, to verify the effectiveness of water chemistry control to mitigate aging effects. A representative sample of piping and components will be selected based on likelihood of corrosion and inspected at an interval not to exceed once in 10 years during the period of extended operation. 2. Perform condition monitoring for the loss of material due to cavitation erosion in the reactor enclosure cooling water piping to the 2A Reactor Water Cleanup System (RWCU) non-regenerative heat exchanger. An initial inspection frequency of 4 years has been established. The inspection frequency will be re-evaluated and adjusted as necessary based on trend data.	Program to be enhanced prior to the period of extended operation. Inspection schedule identified in commitment.	Section A.2.1.13 LGS Letter dated 4/13/12 RAI B.2.1.13-2.1
14	Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems	Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems is an existing program that will be enhanced to: 1. Perform annual periodic inspections as defined in the appropriate ASME B30 series standard for all cranes, hoists, and equipment handling systems within the scope of license renewal. For handling systems that	Program to be enhanced prior to the period of extended operation.	Section A.2.1.14

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		are infrequently in service, such as those only used during refueling outages, annual periodic inspections may be deferred until just prior to use. 2. Perform inspections of structural components and bolting for loss of material due to corrosion, rails for loss of material due to wear and corrosion, and bolted connections for loss of preload. 3. Evaluate loss of material due to wear or corrosion and any loss of bolting preload on cranes, hoists, and equipment handling systems per the appropriate ASME B30 series standard. 4. Perform repairs to cranes, hoists, and equipment handling systems per the appropriate ASME B30 series standard.		
15	Compressed Air Monitoring	Compressed Air Monitoring is an existing program that will be enhanced to: 1. Perform periodic analysis and trending of air quality monitoring results.	Program to be enhanced prior to the period of extended operation.	Section A.2.1.15 LGS letter dated 2/15/12 RAI B.2.1.15-1
16	BWR Reactor Water Cleanup System	Existing program is credited.	Ongoing	Section A.2.1.16
17	Fire Protection	Fire Protection is an existing program that will be enhanced to:	Program to be enhanced prior to the	Section A.2.1.17

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		1. Provide additional inspection guidance to identify degradation of fire barrier walls, ceilings, and floors for aging effects such as cracking, spalling and loss of material. 2. Provide additional inspection guidance for identification of excessive loss of material due to corrosion on the external surfaces of the halon system.	period of extended operation.	
18	Fire Water System	Fire Water System is an existing program that will be enhanced to: 1. Replace sprinkler heads or perform 50-year sprinkler head testing using the guidance of NFPA 25 “Standard for the Inspection, Testing and Maintenance of Water-Based Fire Protection Systems” (2011 Edition), Section 5.3.1.1.1. This testing will be performed prior to the 50-year in-service date and every 10 years thereafter. 2. Inspect selected portions of the water based fire protection system piping located aboveground and exposed to the fire water internal environment by non-intrusive volumetric examinations. These inspections shall be performed prior to the period of extended operation and will be performed every 10 years thereafter.	Program to be enhanced prior to the period of extended operation. Inspection schedule identified in commitment.	Section A.2.1.18 LR-ISG-2012-02 review 03/12/2014 LGS Letter dated 3/14/14 RAI 3.0.3-1 LGS Letter dated 5/21/14 RAI 3.0.3.3.1-1 RAI 3.0.3.4-1

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		3. Inspect and clean line strainers for deluge systems after each actuation. Strainers for deluge systems subject to full flow testing will be inspected and cleaned on a frequency consistent with the deluge test frequency. 4. Inspect and clean the foam system water supply strainer after each system actuation and no less than once per refueling interval. 5. Perform external visual inspection of deluge piping and nozzles for the HVAC charcoal filters for signs of leakage, corrosion, physical damage, and correct orientation each time the charcoal is removed for replacement. 6. Perform flow tests for the hydraulically most remote hose stations once every five years, scheduling the testing so that some of the tests are performed in each year of the five year interval. 7. Perform a main drain test annually for the fire water piping in each of the following locations: Unit 1 Reactor Enclosure, Unit 2 Reactor Enclosure, Unit 1 Turbine Enclosure, Unit 2 Turbine Enclosure, Control Enclosure, and Radwaste Enclosure. Flow blockage or abnormal discharge identified during flow testing or any change in pressure during the		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		test greater than ten percent at a specific location is entered into the corrective action program for evaluation. 8. Perform charcoal filter deluge valve exercise testing and air flow testing each time the charcoal is removed for replacement and perform air flow testing for the deluge systems for the hydrogen seal oil units and lube oil reservoirs every two years. 9. Perform the following for Fire Water System sprinkler and deluge systems: • Perform visual internal inspections, consistent with NFPA 25, for corrosion and obstructions to flow on at least five wet pipe sprinkler systems every five years. • Collect and evaluate solids discharged from wet pipe sprinkler system flow testing. Flow testing through the inspector's test valve will be performed on an interval no greater than 18 months for each wet pipe system. • Perform visual internal inspections for corrosion and obstructions to flow for dry pipe preaction sprinkler systems of surfaces made accessible when preaction and water		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		deluge valves are serviced on an interval no greater than a refueling interval. • Perform visual internal inspections for corrosion and obstructions to flow for deluge systems of surfaces made accessible when deluge valves are serviced on at least ten deluge systems on an interval no greater than three years. To provide reasonable assurance of the presence of sufficient coating, two of the ten inspections will be associated with the galvanized transformer deluge system piping. • Perform a visual internal inspection for corrosion and obstructions to flow for any wet pipe, dry pipe preaction, or deluge system after any system actuation prior to return to service. • Perform an obstruction evaluation for conditions that indicate degraded flow. • Perform followup volumetric inspections for pipe wall thickness if internal visual inspections detect surface irregularities that could be indicative of wall loss below nominal wall thickness.		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		• Sprinkler and deluge systems that are normally dry but may be wetted as the result of testing or actuations will have augmented tests and inspections on piping segments that cannot be drained or piping segments that allow water to collect. These augmented inspections will be performed in each five year interval beginning five years prior to the period of extended operation and consist of either a flow test or flush sufficient to detect potential flow blockage or a visual inspection of 100 percent of the internal surface of piping segments that cannot be drained or piping segments that allow water to collect. In addition, in each five year interval of the period of extended operation, 20 percent of the length of piping segments that cannot be drained or piping segments that allow water to collect is subject to volumetric wall thickness inspections. 10. Perform wall thickness measurements using UT or other suitable techniques at five selected locations every year to identify loss of material in the carbon steel backup fire water piping. When these examinations identify pipe degradation, additional examinations will be performed in accordance with the following criteria:		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		• At least four additional locations will be examined if wall loss is greater than 50 percent of nominal wall thickness, • Two additional locations will be examined if wall loss is 30 percent to 50 percent of nominal wall thickness and the calculated remaining life is less than two years, • No additional examinations will be performed if wall loss is less than 30 percent of nominal wall thickness. The Fire Water System aging management program also manages the loss of coating integrity in the buried cement lined fire main header. • System flow testing activities measure system hydraulic resistance as a means of evaluating the internal piping condition. • Opportunistic internal inspections evaluate the condition of the cement lined fire main header. • Within 10 years prior to the PEO, five internal visual inspections of the cement lining in the fire main header will be performed.		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
19	Aboveground Metallic Tanks	Aboveground Metallic Tanks is an existing program that will be enhanced to: 1. Include UT measurements of the bottom of the Backup Water Storage Tank. Tank bottom UT inspections will be performed – within five years prior to entering the period of extended operation and every five years thereafter. If no tank bottom plate material loss is identified after the first two inspections, the remaining inspections will be performed whenever the tank is drained during the period of extended operation. 2. Provide visual inspections of the Backup Water Storage Tank external surfaces and include, on a sampling basis, removal of insulation to permit inspection of the tank surface. An inspection performed prior to entering the period of extended operation will include a minimum of 25 locations to demonstrate that the tank painted surface is not degraded under the insulation. Subsequent tank external surface visual inspection will be conducted on a two year frequency and include a minimum of four locations. Annual visual inspections will be performed of the tank insulation surface for degradation. Rips, tears, and gaps in the insulation skin will be repaired. Evidence of water intrusion beneath the insulation will be evaluated in accordance with the LGS corrective action program.	Program to be enhanced prior to the period of extended operation. Inspection schedule identified in commitment.	Section A.2.1.19 LGS Letter dated 2/15/12 RAI B.2.1.19-1 RAI B.2.1.19-2 LR-ISG-2012-02 review 03/12/2014 LGS Letter dated 5/21/14 RAI 3.0.3.3.3-1 RAI 3.0.3.3.3-2

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		3. Perform visual inspections of the Backup Water Storage Tank wetted and nonwetted internal surfaces. Tank internal inspections will be performed within five years prior to entering the period of extended operation and every five years thereafter. The tank bottom will be inspected for evidence of voids beneath the floor in accordance with NFPA 25, Section 9.2.6.5. Where pitting and general corrosion to below the nominal wall thickness occurs or any coating failure occurs in which bare metal is exposed, additional inspections and tests shall be performed in accordance with NFPA 25, Section 9.2.7. These tests include adhesion testing of the coating in the vicinity of the coating failure, dry film thickness measurements, spot wet sponge testing, and nondestructive examination to determine remaining wall thickness where bare metal has been exposed. Tank bottom weld seams in the area of degraded coating will be leak tested in accordance with NFPA 25, Section 9.2.7, by vacuum-box testing or magnetic particle (MT) examination. In addition, adhesion testing shall be performed in the vicinity of blisters even though bare metal may not be exposed.		
20	Fuel Oil Chemistry	Fuel Oil Chemistry is an existing program that will be enhanced to:	Program to be enhanced prior to the period of extended operation.	Section A.2.1.20

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		1. Periodically drain water from the Fire Pump Engine Diesel Oil Day Tank and the Fire Pump Diesel Engine Fuel Tank. 2. Perform internal inspections of the Fire Pump Engine Diesel Oil Day Tank, the Fire Pump Diesel Engine Fuel Tank, and the Diesel Generator Day Tanks, at least once during the 10-year period prior to the period of extended operation and at least once every 10 years during the period of extended operation. Each diesel fuel tank will be drained, cleaned and the internal surfaces either volumetrically or visually inspected. If evidence of degradation is observed during visual inspections, the diesel fuel tanks will require follow-up volumetric inspection. 3. Perform periodic analysis for total particulate concentration and microbiological organisms for the Fire Pump Engine Diesel Oil Day Tank and the Fire Pump Diesel Engine Fuel Tank. 4. Perform periodic analysis for water and sediment and microbiological organisms for the Diesel Generator Diesel Oil Storage Tanks. 5. Perform periodic analysis for water and sediment content, total particulate concentration, and the	Inspection schedule identified in commitment.	LGS Letter dated 3/14/14 RAI 3.0.3-1 LGS letter dated 05/21/14 RAI 3.0.3.4-1

		levels of microbiological organisms for the Diesel Generator Day Tanks. 6. Perform analysis of new fuel oil for water and sediment content, total particulate concentration and the levels of microbiological organisms for the Fire Pump Engine Diesel Oil Day Tank and the Fire Pump Diesel Engine Fuel Tank. 7. Perform analysis of new fuel oil for total particulate concentration and the levels of microbiological organisms for the Diesel Generator Diesel Oil Storage Tanks. The Fuel Oil Chemistry aging management program also manages the loss of coating integrity in the eight main fuel oil storage tanks. • Each fuel oil tank will be internally inspected at least once during the 10-year period prior to the period of extended operation and at least once every 10 years during the period of extended operation • The inspection of the eight main fuel oil storage tanks will be performed by inspectors qualified to ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		• The acceptance criteria for coating degradation and the requirements for physical inspections when degradation is identified will be in accordance with Element 6 of GALL Report AMP XI.M42 in draft LR-ISG-2013-01 dated January 6, 2014.		
21	Reactor Vessel Surveillance	Existing program is credited.	Ongoing	Section A.2.1.21
22	One-Time Inspection	One-Time Inspection is a new program that will be used to verify the system-wide effectiveness of the Water Chemistry, Fuel Oil Chemistry and Lubricating Oil Analysis programs.	Program to be implemented prior to the period of extended operation. One-time inspections will be performed within the 10 years prior to the period of extended operation.	Section A.2.1.22
23	Selective Leaching	Selective Leaching is a new program that will include one-time inspections of a representative sample of susceptible components to determine if loss of material due to selective leaching is occurring.	Program to be implemented prior to the period of extended operation. One-time inspections will be performed within the five years prior to the period of extended operation.	Section A.2.1.23

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
			Periodic inspections will be performed during the period of extended operations (PEO).	
24	One-Time Inspection of ASME Code Class 1 Small-Bore Piping	One-Time Inspection of ASME Code Class 1 Small-Bore Piping is a new program that will manage the aging effect of cracking in stainless steel and carbon steel Class 1 small-bore piping that is less than nominal pipe size (NPS) 4-inches, and greater than or equal to NPS 1-inch.	Program to be implemented prior to the period of extended operation. One-time Inspections will be performed within the six years prior to the period of extended operation.	Section A.2.1.24
25	External Surfaces Monitoring of Mechanical Components	External Surfaces Monitoring of Mechanical Components is a new program that manages aging effects of metallic and elastomeric materials through periodic visual inspection of external surfaces for evidence of loss of material. Visual inspections are augmented by physical manipulation as necessary to detect hardening and loss of strength of elastomers. A sample of outdoor component surfaces that are insulated and a sample of indoor insulated components	Program to be implemented prior to the period of extended operation.	Section A.2.1.25 LR-ISG-2012-02 review 03/12/2014

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		exposed to condensation (due to the in-scope component being operated below the dew point), are periodically inspected, under the insulation, every 10 years during the period of extended operation. Inspections subsequent to the initial inspection will consist of examination of the exterior surface of the insulation for indications of damage to the jacketing or protective outer layer of the insulation if the initial inspection verifies no loss of material beyond that which could have been present during initial construction. If the external visual inspections of the insulation reveal damage to the exterior surface of the insulation or if there is evidence of water intrusion through the insulation, then periodic inspections under insulation to detect corrosion under insulation will continue.		
26	Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components	Inspection of Internal Surfaces in Miscellaneous Piping and Ducting Components is a new program that manages aging effects of metallic and elastomeric materials through visual inspections of internal surfaces for evidence of loss of material. Visual inspections are augmented by physical manipulation as necessary to detect hardening and loss of strength of elastomers. This opportunistic approach is supplemented to ensure a representative sample of components within the scope of this program are inspected. At a minimum, in each 10-year period during the period of extended operation, a representative sample of 20 percent of the population	Program to be implemented prior to the period of extended operation.	Section A.2.1.26 LR-ISG-2012-02 review 03/12/2014 LGS letter dated 05/21/14 RAI 3.0.3.4-1

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		(defined as components having the same combination of material, environment, and aging effect) or a maximum of 25 components per population is inspected. Where practical, the inspections focus on the bounding or lead components most susceptible to aging because of time in service, and severity of operating conditions. Opportunistic inspections continue in each 10-year period despite meeting the sampling minimum requirement. For the waste water environment, a maximum of 25 components per population will be inspected. To provide reasonable assurance of the presence of sufficient coating, 10 of the 25 internal inspections will be of the normal waste, oily waste, sanitary waste and storm drain galvanized piping, and 15 of the internal inspections will be of the radioactive floor and equipment drain carbon steel piping.		
27	Lubricating Oil Analysis	Existing program is credited. The Lube Oil Analysis aging management program also manages the loss of coating integrity in the RCIC turbine bearing pedestals and HPCI turbine bearing pedestals and oil reservoir. • As described below, baseline inspections will occur in the 10-year period prior to the period of extended operation. The maximum interval of subsequent coating inspections will comply with Table 4a of GALL Report AMP XI.M42 in draft LR-ISG-2013-01	Ongoing	Section A.2.1.27 LGS Letter dated 3/14/14 RAI 3.0.3-1 LGS letter dated 05/21/14 RAI 3.0.3.4-1

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		dated January 6, 2014 (ADAMS Accession No. ML13262A442). • The inspection of the RCIC turbine bearing pedestals and HPCI turbine bearing pedestals and oil reservoir will be performed by inspectors qualified to ASTM D 4537-91 and ANSI N45.2.6-1978 to a minimum of level II. • The acceptance criteria for coating degradation and the requirements for physical inspections when degradation is identified will be in accordance with Element 6 of GALL Report AMP XI.M42 in draft LR-ISG-2013-01 dated January 6, 2014.		
28	Monitoring of Neutron-Absorbing Materials Other than Boraflex	Monitoring of Neutron-Absorbing Materials Other than Boraflex is an existing program that will be enhanced to: 1. Perform test coupon analysis on a ten-year frequency, beginning no earlier than 2020 for Unit 1 and 2021 for Unit 2. 2. Initiate corrective action if coupon test result data indicates that acceptance criteria will be exceeded prior to the next scheduled test coupon analysis. 3. Resume the accelerated exposure configuration for the Boral coupons (surrounded by freshly	Program to be enhanced prior to the period of extended operation. Inspection schedule identified in commitment.	Section A.2.1.28 LGS Letter dated 2/28/12 RAI B.2.1.28-1 LGS Letter dated 4/27/12 RAI B.2.1.28-2

		Table 1 of NACE SP0169-2007 or Section 3.4 of NACE RP0285-2002. 3. Perform direct visual inspections and volumetric inspections of the underground Emergency Diesel Generator System fuel oil piping and components during each 10-year period beginning 10 years prior to the entry into the period of extended operation. Prior to the period of extended operation all in scope Emergency Diesel Generator System fuel oil piping and components located in underground vaults will undergo a 100 percent visual inspection. Volumetric inspections will also be performed. After entering the period of extended operation, 2 percent of the linear length of in scope Emergency Diesel Generator System fuel oil piping and components located in underground vaults will undergo direct visual inspections and volumetric inspections every 10 years. Inspection locations after entering the period of extended operation will be selected based on susceptibility to degradation and consequences of failure. Visual inspections will be performed by a NACE Coating Inspector Program Level 2 or 3 qualified inspector or an individual that has attended the EPRI Comprehensive Coatings Course and completed the EPRI Buried Pipe Condition Assessment and Repair Training Computer Based Training Course.		8/6/13 RAI B.2.1.29-4

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		4. Perform two sets of volumetric inspections of the Safety Related Service Water System underground piping and components during each 10-year period beginning 10 years prior to the entry into the period of extended operation. Each set of volumetric inspections will assess either the entire length of a run of in scope Safety Related Service Water System piping and components in the underground vault or a minimum of 10 feet of the linear length of in scope Safety Related Service Water System piping and components in the underground vault. Inspection locations will be selected based on susceptibility to degradation and consequences of failure. 5. Specify that visual inspections of Safety Related Service Water System underground piping and components will be performed by a NACE Coating Inspector Program Level 2 or 3 qualified inspector or an individual that has attended the EPRI Comprehensive Coatings Course and completed the EPRI Buried Pipe Condition Assessment and Repair Training Computer Based Training Course. 6. Perform trending of the cathodic protection testing results to identify changes in the effectiveness of the system and to ensure that the rectifiers remain operational at least 85% of the time, and cathodic protection effectiveness will be maintained greater		

	PROGRAM OR TOPIC	COMMITMENT	IMPLEMENTATION SCHEDULE	SOURCE
		than 80%. Cathodic Protection operational and effectiveness requirements shall be met for the 10 years prior to the period of extended operation (PEO), and throughout the PEO. 7. Modify the yearly cathodic protection survey acceptance criterion to meet NACE SP0169-2007 standards and add a statement that if negative polarized potential exceeds -1100mV relative to copper/copper sulfate electrode an issue report will be entered into the corrective action program. In performing cathodic protection surveys, the polarized potential criterion of -850mV for copper/copper sulfate reference electrodes (CSEs) will be used to determine cathodic protection system effectiveness. Other standard reference electrodes may be substituted for the CSEs; however their voltage measurements must be converted to the CSE equivalents in accordance with NACE RP0285-2002. 8. Whenever pipe is excavated and damage to the coating is significant and the damage was caused by non-conforming backfill, an extent of condition evaluation should be conducted to ensure that the as-left condition of backfill in the vicinity of observed damage will not lead to further degradation. Visual inspection of coatings will be performed by a NACE Coating Inspector Program Level 2 or 3 qualified

2.0 INTRODUCTION

The fuel cladding, reactor pressure vessel and primary system piping are the principal barriers to the release of radioactive materials to the environs. Safety Limits are established to protect the integrity of these barriers during normal plant operations and anticipated transients. The Technical Specification Safety Limit is set generically on a fuel product Minimum Critical Power Ration (MCPR) correlation basis as the MCPR which corresponds to a 95% probability at a 95% confidence level that transition boiling will not occur, referred to as SLMCPR(95/95). The fuel cladding integrity Safety Limit is set such that no significant fuel damage is calculated to occur if the limit is not violated. Because fuel damage is not directly observable, a step-back approach is used to establish a Safety Limit such that the MCPR is not less than the limit specified in Specification 2.1.2. MCPR greater than the specified limit represents a conservative margin relative to the conditions required to maintain fuel cladding integrity. The fuel cladding is one of the physical barriers which separate the radioactive materials from the environs. The integrity of this cladding barrier is related to its relative freedom from perforations or cracking. Although some corrosion or use related cracking may occur during the life of the cladding, fission product migration from this source is incrementally cumulative and continuously measurable. Fuel cladding perforations, however, can result from thermal stresses which occur from reactor operation significantly above design conditions and the Limiting Safety System Settings. While fission product migration from cladding perforation is just as measurable as that from use related cracking, the thermally caused cladding perforations signal a threshold beyond which still greater thermal stresses may cause gross rather than incremental cladding deterioration. Therefore, the fuel cladding Safety Limit is defined with a margin to the conditions which would produce onset of transition boiling, MCPR of 1.0. These conditions represent a significant departure from the condition intended by design for planned operation. This is accomplished by having a Safety Limit Minimum Critical Power Ratio (SLMCPR) design basis, referred to as SLMCPR(95/95), which corresponds to a 95% probability at a 95% confidences level (the 95/95 MCPR criterion) that transition boiling will not occur.

2.1.1 THERMAL POWER, Low Pressure or Low Flow

GNF critical power correlation for GNF3 is applicable for all critical power calculations at pressures ≥ 700 psia and core flows ≥ 10% of rated flow (Ref. 3). For operation at low pressures or low flows, another basis is used. This is done by establishing a limiting condition on core THERMAL POWER with the following basis. Since the pressure drop in the bypass region is essentially all elevation head, the core pressure drop at low power and flows will always be greater than 4.5 psi. Analyses show that with a bundle flow of 28×10^3 lb/hr, bundle pressure drop is nearly independent of bundle power and has a value of 3.5 psi. Thus, the bundle flow with a 4.5 psi driving head will be greater than 28×10^3 lb/hr. Full scale ATLAS test data taken at pressures from 14.7 psia to 800 psia indicate that the fuel assembly critical power at this flow is approximately 3.35 MWt. With the design peaking factors, this corresponds to a THERMAL POWER of more than 50% of RATED THERMAL POWER. Thus, a THERMAL POWER limit of 25% of RATED THERMAL POWER for reactor pressure below 700 psia is conservative.

2.1.2 THERMAL POWER, High Pressure and High Flow

The fuel cladding integrity Safety Limit is set such that no fuel damage is calculated to occur if the limit is not violated. Since the parameters which result in fuel damage are not directly observable during reactor operation, the thermal and hydraulic conditions resulting in a departure from nucleate boiling have been used to mark the beginning of the region where fuel damage could occur. Although it is recognized that a departure from nucleate boiling would not necessarily result in damage to BWR fuel rods, the critical power at which boiling transition is calculated to occur has been adopted as a convenient limit. The Technical Specification Safety Limit value is dependent on the fuel product line and the corresponding MCPR correlation, which is cycle independent. The value is based on the Critical Power Ratio (CPR) data statistics and a 95% probability with 95% confidence that rods are not susceptible to boiling transition, referred to as MCPR(95/95).

The Safety Limit is based on GNF3 fuel. For cores with a single fuel product line, the SLMCPR(95/95) is the MCPR(95/95) for the fuel type. For cores loaded with a mix of applicable fuel types, the SLMCPR(95/95) is based on the largest (i.e., most limiting) of the MCPR values for the fuel product lines that are fresh or once-burnt at the start of the cycle.

LEFT INTENTIONALLY BLANK

2.1.3 REACTOR COOLANT SYSTEM PRESSURE

The Safety Limit for the reactor coolant system pressure has been selected such that it is at a pressure below which it can be shown that the integrity of the system is not endangered. The reactor pressure vessel is designed to Section III of the ASME Boiler and Pressure Vessel Code 1968 Edition, including Addenda through Summer 1969, which permits a maximum pressure transient of 110%, 1375 psig, of design pressure 1250 psig. The Safety Limit of 1325 psig, as measured by the reactor vessel steam dome pressure indicator, is equivalent to 1375 psig at the lowest elevation of the reactor coolant system. The reactor coolant system is designed to the ASME Boiler and Pressure Vessel Code, 1977 Edition, including Addenda through Summer 1977 for the reactor recirculation piping, which permits a maximum pressure transient of 110%, 1375 psig of design pressure, 1250 psig for suction piping and 1500 psig for discharge piping. The pressure Safety Limit is selected to be the lowest transient overpressure allowed by the ASME Boiler and Pressure Vessel Code Section III, Class I.

2.1.4 REACTOR VESSEL WATER LEVEL

With fuel in the reactor vessel during periods when the reactor is shutdown, consideration must be given to water level requirements due to the effect of decay heat. If the water level should drop below the top of the active irradiated fuel during this period, the ability to remove decay heat is reduced. This reduction in cooling capability could lead to elevated cladding temperatures and clad perforation in the event that the water level became less than two-thirds of the core height. The Safety Limit has been established at the top of the active irradiated fuel to provide a point which can be monitored and also provide adequate margin for effective action.

2.2.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS

The Reactor Protection System instrumentation setpoints specified in Table 2.2.1-1 are the values at which the reactor trips are set for each parameter. The Trip Setpoints have been selected to ensure that the reactor core and reactor coolant system are prevented from exceeding their Safety Limits during normal operation and design basis anticipated operational occurrences and to assist in mitigating the consequences of accidents. Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is equal to or less than the drift allowance assumed for each trip in the safety analyses.

1. Intermediate Range Monitor, Neutron Flux - High

The IRM system consists of 8 chambers, 4 in each of the reactor trip systems. The IRM is a 5 decade 10 range instrument. The trip setpoint of 120 divisions of scale is active in each of the 10 ranges. Thus as the IRM is ranged up to accommodate the increase in power level, the trip setpoint is also ranged up. The IRM instruments provide for overlap with both the APRM and SRM systems.

The most significant source of reactivity changes during the power increase is due to control rod withdrawal. In order to ensure that the IRM provides the required protection, a range of rod withdrawal accidents have been analyzed. The results of these analyses are in Section 15.4 of the FSAR. The most severe case involves an initial condition in which THERMAL POWER is at approximately 1% of RATED THERMAL POWER. Additional conservatism was taken in this analysis by assuming the IRM channel closest to the control rod being withdrawn is bypassed. The results of this analysis show that the reactor is shutdown and peak power is limited to 21% of RATED THERMAL POWER with the peak fuel enthalpy well below the fuel failure threshold of 170 cal/gm. Based on this analysis, the IRM provides protection against local control rod errors and continuous withdrawal of control rods in sequence and provides backup protection for the APRM.

2. Average Power Range Monitor

The APRM system is divided into four APRM channels and four 2-Out-Of-4 Voter channels. The four voter channels are divided into two groups of two each, with each group of two providing inputs to one RPS trip system. All four voters will trip (full scram) when any two unbypassed APRM channels exceed their trip setpoints.

APRM trip Functions 2.a, 2.b, 2.c, and 2.d are voted independently from OPRM Upscale Function 2.f. Therefore, any Function 2.a, 2.b, 2.c, or 2.d trip from any two unbypassed APRM channels will result in a full trip in each of the four voter channels. Similarly, a Function 2.f trip from any two unbypassed APRM channels will result in a full trip from each of the four voter channels.

For operation at low pressure and low flow during STARTUP, the APRM Neutron Flux-Upscale (Setdown) scram setting of 15% of RATED THERMAL POWER provides adequate thermal margin between the setpoint and the Safety Limits. The margin accommodates the anticipated maneuvers associated with power plant startup. Effects of increasing pressure at zero or low void content are minor and cold water from sources available during startup is not much colder than that already in the system. Temperature coefficients are small and control rod patterns are constrained by the RWM. Of all the possible sources of reactivity input, uniform control rod withdrawal is the most probable cause of significant power increase.

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

Average Power Range Monitor (Continued)

Because the flux distribution associated with uniform rod withdrawals does not involve high local peaks and because several rods must be moved to change power by a significant amount, the rate of power rise is very slow. Generally the heat flux is in near equilibrium with the fission rate. In an assumed uniform rod withdrawal approach to the trip level, the rate of power rise is not more than 5% of RATED THERMAL POWER per minute and the APRM system would be more than adequate to assure shutdown before the power could exceed the Safety Limit. The 15% Neutron Flux - Upscale (Setdown) trip remains active until the mode switch is placed in the Run position.

The APRM trip system is calibrated using heat balance data taken during steady state conditions. Fission chambers provide the basic input to the system and therefore the monitors respond directly and quickly to changes due to transient operation for the case of the Neutron Flux - Upscale setpoint; i.e., for a power increase, the THERMAL POWER of the fuel will be less than that indicated by the neutron flux due to the time constants of the heat transfer associated with the fuel. For the Simulated Thermal Power - Upscale setpoint, a time constant of 6 ± 0.6 seconds is introduced into the flow-biased APRM in order to simulate the fuel thermal transient characteristics. A more conservative maximum value is used for the flow-biased setpoint as shown in Table 2.2.1-1.

A reduced Trip Setpoint and Allowable Value is provided for the Simulated Thermal Power - Upscale Function, applicable when the plant is operating in Single Loop Operation (SLO) per LCO 3.4.1.1. In SLO, the drive flow values (W) used in the Trip Setpoint and Allowable Value equations is reduced by 7.6%. The 7.6% value is established to conservatively bound the inaccuracy created in the core flow/drive flow correlation due to back flow in the jet pumps associated with the inactive recirculation loop. The Trip Setpoint and Allowable Value thus maintain thermal margins essentially unchanged from those for two-loop operation. The Trip Setpoint and Allowable Value equations for single loop operation are only valid for flows down to W = 7.6%. The Trip Setpoint and Allowable Value do not go below 61.5% and 62.0% RATED THERMAL POWER, respectively. This is acceptable because back flow in the inactive recirculation loop is only an issue with drive flows of approximately 40% or greater (Reference 1).

The APRM setpoints were selected to provide adequate margin for the Safety Limits and yet allow operating margin that reduces the possibility of unnecessary shutdown.

The APRM channels also include an Oscillation Power Range Monitor (OPRM) Upscale Function. The OPRM Upscale Function provides compliance with GDC 10 and GDC 12, thereby providing protection from exceeding the fuel MCPR Safety Limit due to anticipated thermal-hydraulic power oscillations. The OPRM Upscale Function receives input signals from the local power range monitors (LPRMs) within the reactor core, which are combined into “cells” for evaluation by the OPRM algorithms.

References 2, 3 and 4 describe three algorithms for detecting thermal-hydraulic instability related neutron flux oscillations: the period based detection algorithm, the amplitude based algorithm, and the growth rate algorithm. All three are implemented in the OPRM Upscale Function, but the safety analysis takes credit only for the period based detection algorithm. The remaining algorithms provide defense in depth and additional protection against unanticipated oscillations. OPRM Upscale Function OPERABILITY for Technical Specification purposes is based only on the period based detection algorithm.

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

Average Power Range Monitor (Continued)

The OPRM Upscale trip output shall be automatically enabled (not bypassed) when APRM Simulated Thermal Power is ≥ 29.5% and recirculation drive flow is < 60% as indicated by APRM measured recirculation drive flow. (NOTE: 60% recirculation drive flow is the recirculation drive flow that corresponds to 60% of rated core flow. Refer to TS Bases 3/4.3.1 for further discussion concerning the recirculation drive flow/core flow relationship.) This is the operating region where actual thermal-hydraulic instability and related neutron flux oscillations may occur. See Reference 5 for additional discussion of OPRM Upscale trip enable region limits. These setpoints, which are sometimes referred to as the "auto-bypass" setpoints, establish the boundaries of the OPRM Upscale trip enabled region. The APRM Simulated Thermal Power auto-enable setpoint has 1% deadband while the drive flow setpoint has a 2% deadband. The deadband for these setpoints is established so that it increases the enabled region.

An OPRM Upscale trip is issued from an APRM channel when the period based detection algorithm in that channel detects oscillatory changes in the neutron flux, indicated by the combined signals of the LPRM detectors in a cell, with period confirmations and relative cell amplitude exceeding specified setpoints. One or more cells in a channel exceeding the trip conditions will result in a channel trip. An OPRM Upscale trip is also issued from the channel if either the growth rate or amplitude based algorithms detect oscillatory changes in the neutron flux for one or more cells in that channel.

There are four "sets" of OPRM related setpoints or adjustment parameters: a) OPRM trip auto-enable setpoints for APRM Simulated Thermal Power (29.5%) and recirculation drive flow (60%); b) period based detection algorithm (PBDA) confirmation count and amplitude setpoints; c) period based detection algorithm tuning parameters; and d) growth rate algorithm (GRA) and amplitude based algorithm (ABA) setpoints.

The first set, the OPRM auto-enable region setpoints, are treated as nominal setpoints with no additional margins added as discussed in Reference 5. The settings, 29.5% APRM Simulated Thermal Power and 60% recirculation drive flow, are defined (limit values) in a note to Table 2.2.1-1. The second set, the OPRM PBDA trip setpoints, are established in accordance with methodologies defined in Reference 4, and are documented in the COLR. There are no allowable values for these setpoints. The third set, the OPRM PBDA "tuning" parameters, are established or adjusted in accordance with and controlled by station procedures. The fourth set, the GRA and ABA setpoints, in accordance with References 2 and 3, are established as nominal values only, and controlled by station procedures.

3. Reactor Vessel Steam Dome Pressure-High

High pressure in the nuclear system could cause a rupture to the nuclear system process barrier resulting in the release of fission products. A pressure increase while operating will also tend to increase the power of the reactor by compressing voids thus adding reactivity. The trip will quickly reduce the neutron flux, counteracting the pressure increase. The trip setting is slightly higher than the operating pressure to permit normal operation without spurious trips. The setting provides for a wide margin to the maximum allowable design pressure and takes into account the location of the pressure measurement compared to the highest pressure that occurs in the system during a transient. This trip setpoint is effective at low power/flow conditions when the turbine stop valve and control fast closure trips are bypassed. For a turbine trip or load rejection under these conditions, the transient analysis indicated an adequate margin to the thermal hydraulic limit.

INTENTIONALLY LEFT BLANK

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

4. Reactor Vessel Water Level-Low

The reactor vessel water level trip setpoint has been used in transient analyses dealing with coolant inventory decrease. The scram setting was chosen far enough below the normal operating level to avoid spurious trips but high enough above the fuel to assure that there is adequate protection for the fuel and pressure limits.

5. Main Steam Line Isolation Valve-Closure

The main steam line isolation valve closure trip was provided to limit the amount of fission product release for certain postulated events. The MSIVs are closed automatically from measured parameters such as high steam flow, low reactor water level, high steam tunnel temperature, and low steam line pressure. The MSIVs closure scram anticipates the pressure and flux transients which could follow MSIV closure and thereby protects reactor vessel pressure and fuel thermal/hydraulic Safety Limits.

6. DELETED

7 Drywell Pressure-High

High pressure in the drywell could indicate a break in the primary pressure boundary systems or a loss of drywell cooling. The reactor is tripped in order to minimize the possibility of fuel damage and reduce the amount of energy being added to the coolant and to the primary containment. The trip setting was selected as low as possible without causing spurious trips.

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

8. Scram Discharge Volume Water Level-High

The scram discharge volume receives the water displaced by the motion of the control rod drive pistons during a reactor scram. Should this volume fill up to a point where there is insufficient volume to accept the displaced water at pressures below 65 psig, control rod insertion would be hindered. The reactor is therefore tripped when the water level has reached a point high enough to indicate that it is indeed filling up, but the volume is still great enough to accommodate the water from the movement of the rods at pressures below 65 psig when they are tripped. The trip setpoint for each scram discharge volume is equivalent to a contained volume of 25.45 gallons of water.

9. Turbine Stop Valve-Closure

The turbine stop valve closure trip anticipates the pressure, neutron flux, and heat flux increases that would result from closure of the stop valves. With a trip setting of 5% of valve closure from full open, the resultant increase in heat flux is such that adequate thermal margins are maintained during the worst design basis transient.

10. Turbine Control Valve Fast Closure, Trip Oil Pressure-Low

The turbine control valve fast closure trip anticipates the pressure, neutron flux, and heat flux increase that could result from fast closure of the turbine control valves due to load rejection with or without coincident failure of the turbine bypass valves. The Reactor Protection System initiates a trip when fast closure of the control valves is initiated by the fast acting solenoid valves and in less than 30 milliseconds after the start of control valve fast closure. This is achieved by the action of the fast acting solenoid valves in rapidly reducing hydraulic trip oil pressure at the main turbine control valve actuator disc dump valves. This loss of pressure is sensed by pressure switches whose contacts form the one-out-of-two-twice logic input to the Reactor Protection System. This trip setting, a faster closure time, and a different valve characteristic from that of the turbine stop valve, combine to produce transients which are very similar to that for the stop valve. Relevant transient analyses are discussed in Section 15.2.2 of the Final Safety Analysis Report.

11. Reactor Mode Switch Shutdown Position

The reactor mode switch Shutdown position is a redundant channel to the automatic protective instrumentation channels and provides additional manual reactor trip capability.

12. Manual Scram

The Manual Scram is a redundant channel to the automatic protective instrumentation channels and provides manual reactor trip capability.

BASES FOR

SECTIONS 3.0 AND 4.0

LIMITING CONDITIONS FOR OPERATION

AND

SURVEILLANCE REQUIREMENTS

INTENTIONALLY LEFT BLANK

NOTE

The BASES contained in succeeding pages summarize the reasons for the Specifications in Sections 3.0 and 4.0, but in accordance with 10 CFR 50.36 are not part of these Technical Specifications.

THIS PAGE INTENTIONALLY LEFT BLANK

BASES

Specifications 3.0.1 through 3.0.9 establish the general requirements applicable to Limiting Conditions for Operation. These requirements are based on the requirements for Limiting Conditions for Operation stated in the Code of Federal Regulations, 10 CFR 50.36(c)(2):

> "Limiting Conditions for operation are the lowest functional capability or performance levels of equipment required for safe operation of the facility. When a limiting condition for operation of a nuclear reactor is not met, the licensee shall shut down the reactor or follow any remedial action permitted by the technical specification until the condition can be met."

Specification 3.0.1 establishes the Applicability statement within each individual specification as the requirement for when (i.e., in which OPERATIONAL CONDITIONS or other specified conditions) conformance to the Limiting Conditions for Operation is required for safe operation of the facility. The ACTION requirements establish those remedial measures that must be taken within specified time limits when the requirements of a Limiting Condition for Operation are not met. The ACTIONS for not meeting a single LCO adequately manage any increase in plant risk, provided any unusual external conditions (e.g., severe weather, offsite power instability) are considered. In addition, the increased risk associated with simultaneous removal of multiple structures, systems, trains or components from service is assessed and managed in accordance with 10 CFR 50.65(a)(4).

There are two basic types of ACTION requirements. The first specifies the remedial measures that permit continued operation of the facility which is not further restricted by the time limits of the ACTION requirements. In this case, conformance to the ACTION requirements provides an acceptable level of safety for unlimited continued operation as long as the ACTION requirements continue to be met. The second type of ACTION requirement specifies a time limit in which conformance to the conditions of the Limiting Condition for Operation must be met. This time limit is the allowable outage time to restore an inoperable system or component to OPERABLE status or for restoring parameters within specified limits. If these actions are not completed within the allowable outage time limits, a shutdown is required to place the facility in an OPERATIONAL CONDITION or other specified condition in which the specification no longer applies.

The specified time limits of the ACTION requirements are applicable from the point of time it is identified that a Limiting Condition for Operation is not met. The time limits of the ACTION requirements are also applicable when a system or component is removed from service for surveillance testing or investigation of operational problems. Individual specifications may include a specified time limit for the completion of a Surveillance Requirement when equipment is removed from service. In this case, the allowable outage time limits of the ACTION requirements are applicable when this limit expires if the surveillance has not been completed. When a shutdown is required to comply with ACTION requirements, the plant may have entered an OPERATIONAL CONDITION in which a new specification becomes applicable. In this case, the time limits of the ACTION requirements would apply from the point in time that the new specification becomes applicable if the requirements of the Limiting Condition for Operation are not met.

Specification 3.0.2 establishes that noncompliance with a specification exists when the requirements of the Limiting Condition for Operation are not met and the associated ACTION requirements have not been implemented within the specified time interval, unless otherwise specified. The purpose of this specification is to clarify that (1) implementation of the ACTION requirements within the specified time interval constitutes compliance with a specification and (2) completion of the remedial measures of the ACTION requirements is not required when compliance with a Limiting Condition of Operation is restored within the time interval specified in the associated ACTION requirements.

Specification 3.0.3 establishes the shutdown ACTION requirements that must be implemented when a Limiting Condition for Operation is not met and the condition is not specifically addressed by the associated ACTION requirements or the required ACTION is not met. The purpose of this specification is to delineate the time limits for placing the unit in a safe shutdown CONDITION when plant operation cannot be maintained within the limits defined by the Limiting Conditions for Operation and its ACTION requirements. Planned entry into LCO 3.0.3 should be avoided. If it is not practicable to avoid planned entry into LCO 3.0.3, plant risk should be assessed and managed in accordance with 10 CFR 50.65(a)(4), and the planned entry into LCO 3.0.3 should have less effect on plant safety than other practicable alternatives.

Upon entering LCO 3.0.3, a risk assessment addressing inoperable systems and components must be completed and appropriate risk management actions must be implemented within 6 hours. The risk assessment must consider all inoperable equipment regardless of whether the equipment is included in the normal 10 CFR 50.65(a)(4) risk assessment scope. The risk assessments will be conducted using the procedures and guidance endorsed by Regulatory Guide 1.160, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." Regulatory Guide 1.160 endorses the guidance in Section 11 of NUMARC 93-01, “Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants.” All relevant elements of the risk assessment description in Section 11 will be included. These documents address general guidance for conduct of the risk assessment, quantitative and qualitative guidelines for establishing risk management actions, and example risk management actions. These include actions to plan and conduct other activities in a manner that controls overall risk, increased risk awareness by shift and management personnel, actions to reduce the duration of the condition, actions to minimize the magnitude of risk increases (establishment of backup success paths or compensatory measures). A formal cause or apparent cause evaluation is not required because of the limited time available, but the likely cause of the conditions that resulted in LCO 3.0.3 entry are considered. If the extent of condition is unknown, the risk assessment will consider the possibility of common cause failure either numerically or through risk management actions.

Continuing operation for a limited time is acceptable if the risk assessment determines that for the current plant configuration, the Incremental Core Damage Probability (ICDP) is less than 1E-5, and the Incremental Large Early Release Probability (ILERP) is less than 1E-6. Non-quantifiable factors will also be assessed. In addition, the configuration-specific Core Damage Frequency (CDF) and Large Early Release Frequency (LERF) will be evaluated to identify high-risk situations. A configuration-specific CDF in excess of 1E-3/year or LERF in excess of 1E-4/year does not support continuing operation. The impact on plant risk is evaluated from the baseline, zero-maintenance, condition.

Whenever practicable, a quantitative value for risk will be determined. If determination of a quantitative value for risk is not practicable, a qualitative assessment of risk may be used with appropriate consideration of the plant conditions and uncertainties to determine whether continued operation for a limited time is acceptable.

If during the 24-hour period the plant configuration changes such that plant risk may be increased, the risk must be reassessed. If the configuration no longer supports continuing plant operation, action must be initiated to shut down the unit in accordance with the LCO 3.0.3 requirements.

Appropriate risk management actions are implemented in accordance with the Maintenance Rule procedures that are appropriate for the current plant condition and the inoperable equipment. Risk management actions are used to address non-quantifiable factors, increase risk awareness, and reduce the risk magnitude and duration.

If the risk assessment determines that continuing operation is acceptable, that the appropriate risk management actions are implemented, and that entry into LCO 3.0.3 was unplanned, action to shut down the unit must be initiated within 24 hours of entry into LCO 3.0.3. It is not necessary for the planned restoration of compliance with the LCO or ACTIONS to be within 24 hours as other actions are available, such as regulatory relief or an orderly shutdown. The 24-hour provision may not be used if the LCO 3.0.3 entry is planned, such as intentionally removing a train from service when the redundant train is inoperable. However, it may be used for emergent conditions that occur in parallel with other planned or unplanned inoperabilities.

The determination that continuing operation is acceptable will be documented in sufficient detail to allow a knowledgeable individual to understand the basis for the determination.

If the risk assessment determines that continuing operation is not acceptable, if the risk assessment was not completed, the appropriate risk management actions were not implemented, or if entry into LCO 3.0.3 was planned, action to shut down the unit must be initiated following the 6 hour time period provided to perform the risk assessment and implement risk management actions.

All times for completing actions and entering OPERATIONAL CONDITIONS are determined from entry into LCO 3.0.3.

The time limits specified to enter lower CONDITIONS of operation permit the shutdown to proceed in a controlled and orderly manner that is well within the specified maximum cooldown rate and within the cooldown capabilities of the facility assuming only the minimum required equipment is OPERABLE. This reduces thermal stresses on components of the primary coolant system and the potential for a plant upset that could challenge safety systems under conditions for which this specification applies.

If remedial measures permitting limited continued operation of the facility under the provisions of the ACTION requirements are completed, the shutdown may be terminated. The time limits of the ACTION requirements are applicable from the point in time there was a failure to meet a Limiting Condition for Operation. Therefore, the shutdown may be terminated if the ACTION requirements have been met, the ACTION is no longer applicable, or time limits of the ACTION requirements have not expired, thus providing an allowance for the completion of the required actions.

The time limits of Specification 3.0.3 allow 36 hours for the plant to be in COLD SHUTDOWN after a shutdown is initiated during POWER operation. If the plant is in a lower CONDITION of operation when a shutdown is initiated, the time limit for entering the next lower CONDITION of operation applies. However, if a lower CONDITION of operation is entered in less time than allowed, the total allowable time to enter COLD SHUTDOWN, or other OPERATIONAL CONDITION, is not reduced. For example, if HOT SHUTDOWN is entered 10 hours after a shutdown is initiated, the time allowed to enter COLD SHUTDOWN is the next 26 hours because the total time to enter COLD SHUTDOWN is not reduced from the allowable limit of 36 hours after a shutdown is initiated. Therefore, if remedial measures are completed that would permit a return to POWER operation, a penalty is not incurred by having to enter a lower CONDITION of operation in less than the total time allowed.

The same principle applies with regard to the allowable outage time limits of the ACTION requirements, if compliance with the ACTION requirements for one specification results in entry into an OPERATIONAL CONDITION or condition of operation for another specification in which the requirements of the Limiting Condition for Operation are not met. If the new specification becomes applicable in less time than specified, the difference may be added to the allowable outage time limits of the second specification. However, the allowable outage time limits of ACTION requirements for a higher CONDITION of operation may not be used to extend the allowable outage time that is applicable when a Limiting Condition for Operation is not met in a lower CONDITION of operation.

The shutdown requirements of Specification 3.0.3 do not apply in CONDITIONS 4 and 5, because the ACTION requirements of individual specifications define the remedial measures to be taken.

Specification 3.0.4 establishes limitations on changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability when a Limiting Condition for Operation is not met. It allows placing the unit in an OPERATIONAL CONDITION or other specified condition stated in that Applicability (e.g., the Applicability desired to be entered) when unit conditions are such that the requirements of the Limiting Condition for Operation would not be met, in accordance with either Specification 3.0.4.a, Specification 3.0.4.b, or Specification 3.0.4.c.

Specification 3.0.4.a allows entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met when the associated ACTION requirements to be entered following entry into the OPERATIONAL CONDITION or other specified condition in the Applicability will permit continued operation within the MODE or other specified condition for an unlimited period of time. Compliance with ACTIONS that permit continued operation of the unit for an unlimited period of time in an OPERATIONAL CONDITION or other specified condition provides an acceptable level of safety for continued operation. This is without regard to the status of the unit before or after the OPERATIONAL CONDITION change. Therefore, in such cases, entry into an OPERATIONAL CONDITION or other specified condition in the Applicability may be made and the Required Actions followed after entry into the Applicability.

For example, LCO 3.0.4.a may be used when the Required Action to be entered states that an inoperable instrument channel must be placed in the trip condition within the Completion Time. Transition into a MODE or other specified condition in the Applicability may be made in accordance with LCO 3.0.4 and the channel is subsequently placed in the tripped condition within the Completion Time, which begins when the Applicability is entered. If the instrument channel cannot be placed in the tripped condition and the subsequent default ACTION ("Required Action and associated Completion Time not met") allows the OPERABLE train to be placed in operation, use of LCO 3.0.4.a is acceptable because the subsequent ACTIONS to be entered following entry into the MODE include ACTIONS (place the OPERABLE train in operation) that permit safe plant operation for an unlimited period of time in the MODE or other specified condition to be entered.

Specification 3.0.4.b allows entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, consideration of the results, determination of the acceptability of entering the OPERATIONAL CONDITION or other specified condition in the Applicability, and establishment of risk management actions, if appropriate.

The risk assessment may use quantitative, qualitative, or blended approaches, and the risk assessment will be conducted using the plant program, procedures, and criteria in place to implement 10 CFR 50.65(a)(4), which requires that risk impacts of maintenance activities be assessed and managed. The risk assessment, for the purposes of Specification 3.0.4.b, must take into account all inoperable Technical Specification equipment regardless of whether the equipment is included in the normal 10 CFR 50.65(a)(4) risk assessment scope. The risk assessments will be conducted using the procedures and guidance endorsed by Regulatory Guide 1.182, "Assessing and Managing Risk Before Maintenance Activities at Nuclear Power Plants." Regulatory Guide 1.182 endorses the guidance in Section 11 of NUMARC 93-01, "Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." These documents address general guidance for conduct of the risk assessment, quantitative and qualitative guidelines for establishing risk management actions, and example risk management actions. These include actions to plan and conduct other activities in a manner that controls overall risk, increased risk awareness by shift and management personnel, actions to reduce the duration of the condition, actions to minimize the magnitude of risk increases (establishment of backup success paths or compensatory measures), and determination that the proposed OPERATIONAL CONDITION change is acceptable. Consideration should also be given to the probability of completing restoration such that the requirements of the Limiting Condition for Operation would be met prior to the expiration of the ACTION requirement's specified time interval that would require exiting the Applicability.

Specification 3.0.4.b may be used with single, or multiple systems and components unavailable. NUMARC 93-01 provides guidance relative to consideration of simultaneous unavailability of multiple systems and components.

The results of the risk assessment shall be considered in determining the acceptability of entering the OPERATIONAL CONDITION or other specified condition in the Applicability, and any corresponding risk management actions. The Specification 3.0.4.b risk assessments do not have to be documented.

The Technical Specifications allow continued operation with equipment unavailable in OPERATIONAL CONDITION 1 for the duration of the specified time interval. Since this is allowable, and since in general the risk impact in that particular OPERATIONAL CONDITION bounds the risk of transitioning into and through the applicable OPERATIONAL CONDITIONS or other specified conditions in the Applicability of the Limiting Condition for Operation, the use of the Specification 3.0.4.b allowance should be generally acceptable, as long as the risk is assessed and managed as stated above. However, there is a small subset of systems and components that have been determined to be more important to risk and use of the Specification 3.0.4.b allowance is prohibited. The Limiting Condition for Operations governing these system and components contain Notes prohibiting the use of Specification 3.0.4.b by stating that Specification 3.0.4.b is not applicable.

Specification 3.0.4.c allows entry into a OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met based on a Note in the Specification which states Specification 3.0.4.c is applicable. These specific allowances permit entry into OPERATIONAL CONDITIONS or other specified conditions in the Applicability when the associated ACTION requirements to be entered do not provide for continued operation for an unlimited period of time and a risk assessment has not been performed. This allowance may apply to all the ACTION requirements or to a specific ACTION requirement of a Specification. The risk assessments performed to justify the use of Specification 3.0.4.b usually only consider systems and components. For this

reason, Specification 3.0.4.c is typically applied to Specifications which describe values and parameters (e.g., Reactor Coolant Specific Activity), and may be applied to other Specifications based on NRC plant-specific approval.

The provisions of this Specification should not be interpreted as endorsing the failure to exercise the good practice of restoring systems or components to OPERABLE status before entering an associated OPERATIONAL CONDITION or other specified condition in the Applicability.

The provisions of Specification 3.0.4 shall not prevent changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability that are required to comply with ACTION requirements. In addition, the provisions of Specification 3.0.4 shall not prevent changes in OPERATIONAL CONDITIONS or other specified

INTENTIONALLY LEFT BLANK

conditions in the Applicability that result from any unit shutdown. In this context, a unit shutdown is defined as a change in OPERATIONAL CONDITION or other specified condition in the Applicability associated with transitioning from OPERATIONAL CONDITION 1 to OPERATIONAL CONDITION 2, OPERATIONAL CONDITION 2 to OPERATIONAL CONDITION 3, and OPERATIONAL CONDITION 3 to OPERATIONAL CONDITION 4.

Upon entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met, Specification 3.0.1 and Specification 3.0.2 require entry into the applicable Conditions and ACTION requirements until the Condition is resolved, until the Limiting Condition for Operation is met, or until the unit is not within the Applicability of the Technical Specification.

Surveillances do not have to be performed on the associated inoperable equipment (or on variables outside the specified limits), as permitted by Specification 4.0.1. Therefore, utilizing Specification 3.0.4 is not a violation of Specification 4.0.1 or Specification 4.0.4 for any Surveillances that have not been performed on inoperable equipment. However, SRs must be met to ensure OPERABILITY prior to declaring the associated equipment OPERABLE (or variable within limits) and restoring compliance with the affected Limiting Condition for Operation.

Specification 3.0.5 establishes the allowance for restoring equipment to service under administrative controls when it has been removed from service or declared inoperable to comply with ACTIONs. The sole purpose of this Specification is to provide an exception to Specifications 3.0.1 and 3.0.2 (e.g., to not comply with the applicable ACTION(s)) to allow the performance of required testing to demonstrate:

a. The OPERABILITY of the equipment being returned to service, or

b. The OPERABILITY of other equipment.

The administrative controls ensure the time the equipment is returned to service in conflict with the requirements of the ACTIONs is limited to the time necessary to perform the required testing to demonstrate OPERABILITY. This Specification does not provide time to perform any other preventive or corrective maintenance. LCO 3.0.5 should not be used in lieu of other practicable alternatives that comply with Required Actions and that do not require changing the MODE or other specified conditions in the Applicability in order to demonstrate equipment is OPERABLE. LCO 3.0.5 is not intended to be used repeatedly.

An example of demonstrating equipment is OPERABLE with the Required Actions not met is opening a manual valve that was closed to comply with Required Actions to isolate a flowpath with excessive Reactor Coolant System (RCS) Pressure Isolation Valve (PIV) leakage in order to perform testing to demonstrate that RCS PIV leakage is now within limit.

Examples of demonstrating equipment OPERABILITY include instances in which it is necessary to take an inoperable channel or trip system out of a tripped condition that was directed by a Required Action, if there is no Required Action Note for this purpose. An example of verifying OPERABILITY of equipment removed from service is taking a tripped channel out of the tripped condition to permit the logic to function and indicate the appropriate response during performance of required testing on the inoperable channel.

Examples of demonstrating the OPERABILITY of other equipment are taking an inoperable channel or trip system out of the tripped condition 1) to prevent the trip function from occurring during the performance of required testing on another channel in the other trip system, or 2) to permit the logic to function and indicate the appropriate response during the performance of required testing on another channel in the same trip system.

The administrative controls in LCO 3.0.5 apply in all cases to systems or components in Chapter 3 of the Technical Specifications, as long as the testing could not be conducted while complying with the Required Actions. This includes the realignment or repositioning of redundant or alternate equipment or trains previously manipulated to comply with ACTIONS, as well as equipment removed from service or declared inoperable to comply with ACTIONS.

INTENTIONALLY LEFT BLANK

Specification 3.0.6 establishes an exception to Specifications 3.0.1 and 3.0.2 for supported systems that have a support system Limiting Condition for Operation specified in the Technical Specifications (TS). The exception to Specification 3.0.1 is provided because Specification 3.0.1 would require that the ACTIONs of the associated inoperable supported system Limiting Condition for Operation be entered solely due to the inoperability of the support system. This exception is justified because the actions that are required to ensure the plant is maintained in a safe condition are specified in the support system Limiting Condition for Operation's ACTIONs. These ACTIONs may include entering the supported system's ACTIONs or may specify other ACTIONs. The exception to Specification 3.0.2 is provided because Specification 3.0.2 would consider not entering into the ACTIONs for the supported system within the specified time intervals as a TS noncompliance.

When a support system is inoperable and there is a Limiting Condition for Operation specified for it in the TS, the supported system(s) are required to be declared inoperable if determined to be inoperable as a result of the support system inoperability. However, it is not necessary to enter into the supported systems' ACTIONs unless directed to do so by the support system's ACTIONs. The potential confusion and inconsistency of requirements related to the entry into multiple support and supported systems' Limiting Condition for Operations' ACTIONs are eliminated by providing all the actions that are necessary to ensure the plant is maintained in a safe condition in the support system's ACTIONs.

However, there are instances where a support system's ACTION may either direct a supported system to be declared inoperable or direct entry into ACTIONS for the supported system. This may occur immediately or after some specified delay to perform some other ACTION. Regardless of whether it is immediate or after some delay, when a support system's ACTION directs a supported system to be declared inoperable or directs entry into ACTIONs for a supported system, the applicable ACTIONs shall be entered in accordance with Specification 3.0.1.

Specification 6.17, "Safety Function Determination Program (SFDP)," ensures loss of safety function is detected and appropriate actions are taken. Upon entry into Specification 3.0.6, an evaluation shall be made to determine if loss of safety function exists. Additionally, other limitations, remedial actions, or compensatory actions may be identified as a result of the support system inoperability and corresponding exception to entering supported system ACTIONs. The SFDP implements the requirements of Specification 3.0.6.

The following examples use Figure B 3.0-1 to illustrate loss of safety function conditions that may result when a TS support system is inoperable. In this figure, the fifteen systems that comprise Train A are independent and redundant to the fifteen systems that comprise Train B. To correctly use the figure to illustrate the SFDP provisions for a cross train check, the figure establishes a relationship between support and supported systems as follows: the figure shows System 1 as a support system for System 2 and System 3; System 2 as a support system for System 4 and System 5; and System 4 as a support system for System 8 and System 9. Specifically, a loss of safety function may exist when a support system is inoperable and:

a. A system redundant to system(s) supported by the inoperable support system is also inoperable (EXAMPLE B 3.0.6-1),

b. A system redundant to system(s) in turn supported by the inoperable supported system is also inoperable (EXAMPLE B 3.0.6-2), or

c. A system redundant to support system(s) for the supported systems (a) and (b) above is also inoperable (EXAMPLE B 3.0.6-3).

For the following examples, refer to Figure B 3.0-1.

EXAMPLE B 3.0.6-1
If System 2 of Train A is inoperable and System 5 of Train B is inoperable, a loss of safety function exists in Systems 5, 10, and 11.

EXAMPLE B 3.0.6-2

If System 2 of Train A is inoperable, and System 11 of Train B is inoperable, a loss of safety function exists in System 11.

EXAMPLE B 3.0.6-3

If System 2 of Train A is inoperable, and System 1 of Train B is inoperable, a loss of safety function exists in Systems 2, 4, 5, 8, 9, 10 and 11.

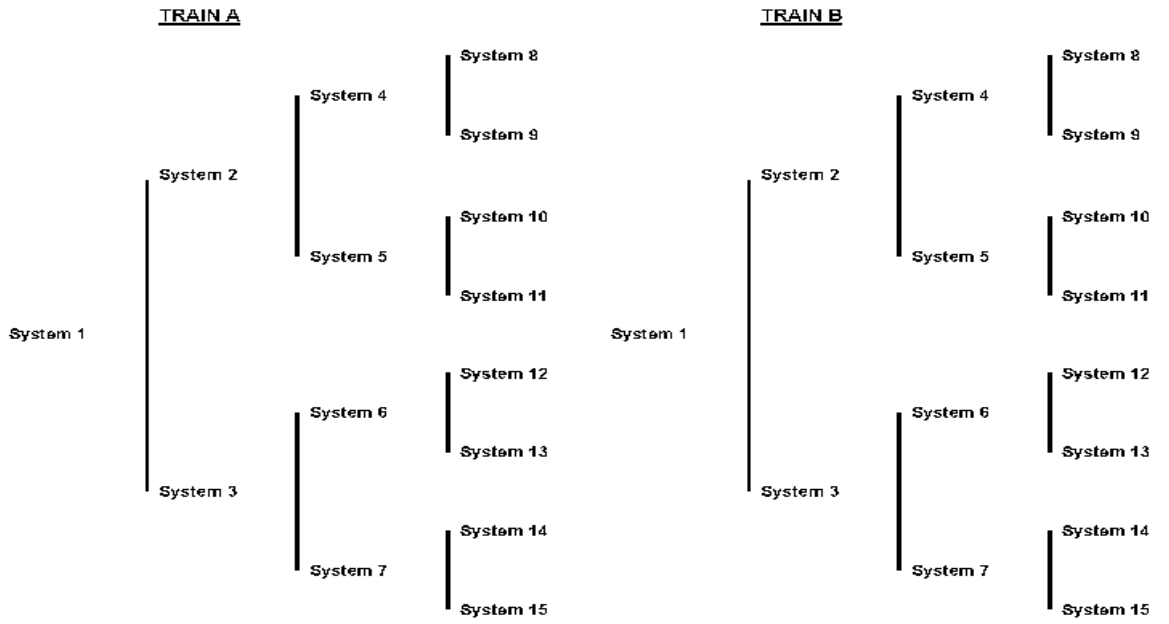

Figure B 3.0-1
Configuration of Trains and Systems

If an evaluation determines that a loss of safety function exists, the appropriate ACTIONs of the Limiting Condition for Operation in which the loss of safety function exists are required to be entered. This loss of safety function does not require the assumption of additional single failures or loss of offsite power. Since operations are being restricted in accordance with the ACTIONs of the support system, any resulting temporary loss of redundancy or single failure protection is taken into account.

When loss of safety function is determined to exist, and the SFDP requires entry into the appropriate ACTIONs of the Limiting Condition for Operation in which the loss of safety function exists, consideration must be given to the specific type of function affected. Where a loss of function is solely due to a single Technical Specification support system (e.g., loss of automatic start due to inoperable instrumentation, or loss of pump suction source due to low tank level), the appropriate Limiting Condition for Operation is the Limiting Condition for Operation for the support system. The ACTIONs for a support system Limiting Condition for Operation adequately address the inoperabilities of that system without reliance on entering its supported system Limiting Condition for Operation. When the loss of function is the result of multiple support systems, the appropriate Limiting Condition for Operation is the Limiting Condition for Operation for the supported system.

Specification 3.0.7 - Not Used

Specification 3.0.8 establishes conditions under which systems are considered to remain capable of performing their intended safety function when associated snubbers are not capable of providing their associated support function(s). This Specification states that the supported system is not considered to be inoperable solely due to one or more snubbers not capable of performing their associated support function(s). This is appropriate because a limited length of time is allowed for maintenance, testing, or repair of one or more snubbers not capable of performing their associated support function(s) and appropriate compensatory measures are specified in the snubber requirements, which are located outside of the Technical Specifications (TS) under licensee control. The snubber requirements do not meet the criteria in 10 CFR 50.36(c)(2)(ii), and, as such, are appropriate for control by the licensee.

If the allowed time expires and the snubber(s) are unable to perform their associated support function(s), the affected supported system's Limiting Condition for Operation must be declared not met and the associated ACTION requirements shall be met in accordance with Specification 3.0.1.

Specification 3.0.8.a applies when one or more snubbers are not capable of providing their associated support function(s) to a single train or subsystem of a multiple train or subsystem supported system or to a single train or subsystem supported system. Specification 3.0.8.a allows 72 hours to restore the snubber(s) before declaring the supported system inoperable. The 72-hour Completion Time is reasonable based on the low probability of a seismic event concurrent with an event that would require operation of the supported system occurring while the snubber(s) are not capable of performing their associated support function and due to the availability of the redundant train of the supported system.

Specification 3.0.8.b applies when one or more snubbers are not capable of providing their associated support function(s) to more than one train or subsystem of a multiple train or subsystem supported system. Specification 3.0.8.b allows 12 hours to restore the snubber(s) before declaring the supported system inoperable. The 12-hour Completion Time is reasonable based on the low probability of a seismic event concurrent with an event that would require operation of the supported system occurring while the snubber(s) are not capable of performing their associated support function.

The following configuration restrictions shall be applied to the use of Specification 3.0.8:

(1) Specification 3.0.8.a can only be used if one of the following two means of heat removal is available:

a. At least one high pressure makeup path (e.g., using High Pressure Coolant Injection (HPCI) or Reactor Core Isolation Cooling (RCIC) or its equivalent) and heat removal capability (e.g., suppression pool cooling), including a minimum set of supporting equipment required for success, not associated with the inoperable snubber(s), or

b. At least one low pressure makeup path (e.g., Low Pressure Coolant Injection (LPCI) or Core Spray (CS)) and heat removal capability (e.g., suppression pool cooling or shutdown cooling), including a minimum set of supporting equipment required for success, not associated with the inoperable snubber(s).

(2) Specification 3.0.8.b can only be used following verification that at least one success path exists, using equipment not associated with the inoperable snubber(s), to provide makeup and core cooling needed to mitigate Loss of Offsite Power (LOOP) accident sequences (i.e., initiated by a seismically-induced LOOP event with concurrent loss of all safety system trains supported by the out-of-service snubbers).

Specification 3.0.8 only applies to the seismic function of snubbers; it does not apply to the non-seismic functions of snubbers. Therefore, each use of Specification 3.0.8 for seismic snubbers that also have non-seismic functions requires confirmation that at least one train (or subsystem) of systems supported by the inoperable snubbers would remain capable of performing their required safety or support functions for postulated design loads other than seismic loads. In addition, a record of the design function of the inoperable snubber (i.e., seismic vs. non-seismic), implementation and compliance with the configuration restrictions defined above, and the associated plant configuration shall be available on a recoverable basis for NRC inspection.

Specification 3.0.8 requires that risk be assessed and managed. Industry and NRC guidance on the implementation of 10 CFR 50.65(a)(4) (i.e., the Maintenance Rule) does not address seismic risk. However, use of Specification 3.0.8 should be considered with respect to other plant maintenance activities, and integrated into the existing Maintenance Rule process to the extent possible so that maintenance on any unaffected train or subsystem is properly controlled, and emergent issues are properly addressed. The risk assessment need not be quantified, but may be a qualitative awareness of the vulnerability of systems and components when one or more snubbers are not able to perform their associated support function.

Specification 3.0.9 establishes conditions under which systems described in the Technical Specifications are considered to remain OPERABLE when required barriers are not capable of providing their related support function(s).

Barriers are doors, walls, floor plugs, curbs, hatches, installed structures or components, or other devices, not explicitly described in Technical Specifications, that support the performance of the safety function of systems described in the Technical Specifications. This Limiting Condition for Operation states that the supported system is not considered to be inoperable

solely due to required barriers not capable of performing their related support function(s) under the described conditions. Limiting Condition for Operation 3.0.9 allows 30 days before declaring the supported system(s) inoperable and the Limiting Conditions for Operation associated with the supported system(s) not met. A maximum time is placed on each use of this allowance to ensure that as required barriers are found or are otherwise made unavailable, they are restored. However, the allowable duration may be less than the specified maximum time based on the risk assessment.

If the allowed time expires and the barriers are unable to perform their related support function(s), the supported system's Limiting Conditions for Operation must be declared not met and the Conditions and Required Actions entered in accordance with Limiting Condition for Operation 3.0.2.

This provision does not apply to barriers which support ventilation systems or to fire barriers. The Technical Specifications for ventilation systems provide specific Conditions for inoperable barriers. Fire barriers are addressed by other regulatory requirements and associated plant programs. This provision does not apply to barriers which are not required to support system OPERABILITY (see NRC Regulatory Issue Summary 2001-09, "Control of Hazard Barriers," dated April 2, 2001).

The provisions of Limiting Condition for Operation 3.0.9 are justified because of the low risk associated with required barriers not being capable of performing their related support function. This provision is based on consideration of the following initiating event categories:

- Loss of coolant accidents;
- High energy line breaks;
- Feedwater line breaks;
- Internal flooding;
- External flooding;
- Turbine missile ejection; and
- Tornado or high wind.

The risk impact of the barriers which cannot perform their related support function(s) must be addressed pursuant to the risk assessment and management provision of the Maintenance Rule, 10 CFR 50.65 (a)(4), and the associated implementation guidance, Regulatory Guide 1.160, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." Regulatory Guide 1.160 endorses the guidance in Section 11 of NUMARC 93-01, "Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." This guidance provides for the consideration of dynamic plant configuration issues, emergent conditions, and other aspects pertinent to plant operation with the barriers unable to perform their related support function(s). These considerations may result in risk management and other compensatory actions being required during the period that barriers are unable to perform their related support function(s).

Limiting Condition for Operation 3.0.9 may be applied to one or more trains or subsystems of a system supported by barriers that cannot provide their related support function(s), provided that risk is assessed and managed (including consideration of the effects on Large Early Release and from external events). If applied concurrently to more than one train or subsystem of a multiple train or subsystem supported system, the barriers supporting each of these trains or subsystems must provide their related support function(s) for different categories of initiating events. For example, Limiting Condition for Operation 3.0.9 may be applied for up to 30 days for more than one train of a multiple train supported system if the affected barrier for one train protects against internal flooding and the affected barrier for the other train protects against tornado missiles. In this example, the affected barrier may be the same physical barrier but serve different protection functions for each train.

The HPCI and RCIC systems are single train systems for injecting makeup water into the reactor during an accident or transient event. For the purposes of Limiting Condition for Operation 3.0.9, the HPCI system, the RCIC system, and the ADS are considered independent subsystems of a single system and Limiting Condition for Operation 3.0.9 can be used on these single train systems in a manner similar to multiple train or subsystem systems.

If during the time that Limiting Condition for Operation 3.0.9 is being used, the required OPERABLE train or subsystem becomes inoperable, it must be restored to OPERABLE status within 24 hours. Otherwise, the train(s) or subsystem(s) supported by barriers that cannot perform their related support function(s) must be declared inoperable and the associated Limiting Conditions for Operation declared not met. This 24 hour period provides time to respond to emergent conditions that would otherwise likely lead to entry into Limiting Condition for Operation 3.0.3 and a rapid plant shutdown, which is not justified given the low probability of an initiating event which would require the barrier(s) not capable of performing their related support function(s). During this 24 hour period, the plant risk associated with the existing conditions is assessed and managed in accordance with 10 CFR 50.65(a)(4).

Specification 4.0.1 through 4.0.5 establish the general requirements applicable to Surveillance Requirements. SR 4.0.2 and SR 4.0.3 apply in Section 6, Administrative Controls, only when invoked by a Section 6 Specification. These requirements are based on the Surveillance Requirements stated in the Code of Federal Regulations 10 CFR 50.36(c)(3):

"Surveillance requirements are requirements relating to test, calibration, or inspection to ensure that the necessary quality of systems and components is maintained, that facility operation will be within safety limits, and that the limiting conditions of operation will be met."

Specification 4.0.1 establishes the requirement that SRs must be met during the OPERATIONAL CONDITIONS or other specified conditions in the Applicability for which the requirements of the Limiting Condition for Operation apply, unless otherwise specified in the individual SRs. This Specification is to ensure that Surveillances are performed to verify the OPERABILITY of systems and components, and that variables are within specified limits. Failure to meet a Surveillance within the specified Surveillance time interval and allowed extension, in accordance with Specification 4.0.2, constitutes a failure to meet the Limiting Condition for Operation.

Systems and components are assumed to be OPERABLE when the associated SRs have been met. Nothing in this Specification, however, is to be construed as implying that systems or components are OPERABLE when:

a. The systems or components are known to be inoperable, although still meeting the SRs; or

b. The requirements of the Surveillance(s) are known to be not met between required Surveillance performances.

Surveillances do not have to be performed when the unit is in an OPERATIONAL CONDITION or other specified condition for which the requirements of the associated Limiting Condition for Operation are not applicable, unless otherwise specified. The SRs associated with a Special Test Exception Limiting Condition for Operation are only applicable when the Special Test Exception Limiting Condition for Operation is used as an allowable exception to the requirements of a Specification.

Unplanned events may satisfy the requirements (including applicable acceptance criteria) for a given SR. In this case, the unplanned event may be credited as fulfilling the performance of the SR. This allowance includes those SRs whose performance is normally precluded in a given OPERATIONAL CONDITION or other specified condition.

Surveillances, including Surveillances invoked by ACTION requirements, do not have to be performed on inoperable equipment because the ACTIONS define the remedial measures that apply. Surveillances have to be met and performed in accordance with Specification 4.0.2, prior to returning equipment to OPERABLE status.

Upon completion of maintenance, appropriate post maintenance testing is required to declare equipment OPERABLE. This includes ensuring applicable Surveillances are not failed and their most recent performance is in accordance with Specification 4.0.2. Post maintenance testing may not be possible in the current OPERATIONAL CONDITION or other specified conditions in the Applicability due to the necessary unit parameters not having been established. In these situations, the equipment may be considered OPERABLE provided testing has been satisfactorily completed to the extent possible and the equipment is not otherwise believed to be incapable of performing its function. This will allow operation to proceed to an OPERATIONAL CONDITION or other specified condition where other necessary post maintenance tests can be completed.

Some examples of this process are:

a. Control Rod Drive maintenance during refueling that requires scram testing at > 950 psi. However, if other appropriate testing is satisfactorily completed and the scram time testing of Specification 4.1.3.2 is satisfied, the control rod can be considered OPERABLE. This allows startup to proceed to reach 950 psi to perform other necessary testing.

b. High pressure coolant injection (HPCI) maintenance during shutdown that requires system functional tests at a specified pressure. Provided other appropriate testing is satisfactorily completed, startup can proceed with HPCI considered OPERABLE. This allows operation to reach the specified pressure to complete the necessary post maintenance testing.

Specification 4.0.2 establishes the limit for which the specified time interval for Surveillance Requirements may be extended. It permits an allowable extension of the normal surveillance interval to facilitate surveillance scheduling and consideration of plant operating conditions that may not be suitable for conducting the surveillance; e.g., transient conditions or other ongoing surveillance or maintenance activities. It also provides flexibility to accommodate the length of a fuel cycle for surveillances that are performed at each refueling outage and are specified with an 24-month surveillance interval. It is not intended that this provision be used repeatedly to extend the surveillance intervals beyond that specified for surveillances that are not performed during refueling outages. Likewise, it is not the intent that REFUELING INTERVAL surveillances be performed during power operation unless it is consistent with safe plant operation. The limitation of Specification 4.0.2 is based on engineering judgment and the recognition that the most probable result of any particular surveillance being performed is the verification of conformance with the Surveillance Requirements. This provision is sufficient to ensure that the reliability ensured through surveillance activities is not significantly degraded beyond that obtained from the specified surveillance interval.

Specification 4.0.3 establishes the flexibility to defer declaring affected equipment inoperable or an affected variable outside the specified limits when a Surveillance has not been performed within the specified Surveillance time interval and allowed extension. A delay period of up to 24 hours or up to the limit of the specified Surveillance time interval, whichever is greater, applies from the point in time that it is discovered that the Surveillance has not been performed in accordance with Specification 4.0.2, and not at the time that the specified Surveillance time interval and allowed extension was not met.

When a Section 6.8, ‘Procedures and Programs,” specification states that the provisions of SR 4.0.3 are applicable, it permits the flexibility to defer declaring the testing requirement not met in accordance with SR 4.0.3 when the testing has not been completed within the testing interval (including the allowance of SR 4.0.2 if invoked by the Section 6.8 specification).

This delay period provides adequate time to perform Surveillances that have been missed. This delay period permits the performance of a Surveillance before complying with ACTION requirements or other remedial measures that might preclude performance of the Surveillance.

The basis for this delay period includes consideration of unit conditions, adequate planning, availability of personnel, the time required to perform the Surveillance, the safety significance of the delay in completing the required Surveillance, and the recognition that the most probable result of any particular Surveillance being performed is the verification of conformance with the requirements. When a Surveillance with a Surveillance time interval based not on time intervals, but upon specified unit conditions, operating situations, or requirements of regulations (e.g., prior to entering OPERATIONAL CONDITION 1 after each fuel loading, or in accordance with 10 CFR 50, Appendix J, as modified by approved exemptions, etc.) is discovered to have not been performed when specified, Specification 4.0.3 allows for the full delay period of up to the specified Surveillance time interval to perform the Surveillance. However, since there is not a time interval specified, the missed Surveillance should be performed at the first reasonable opportunity.

Specification 4.0.3 provides a time limit for, and allowances for the performance of, Surveillances that become applicable as a consequence of OPERATIONAL CONDITION changes imposed by ACTION requirements.

BASES

Specification 4.0.3 (Continued)
SR 4.0.3 is only applicable if there is a reasonable expectation the associated equipment is OPERABLE or that variables are within limits, and it is expected that the Surveillance will be met when performed. Many factors should be considered, such as the period of time since the Surveillance was last performed, or whether the Surveillance, or a portion thereof, has ever been performed, and any other indications, tests, or activities that might support the expectation that the Surveillance will be met when performed. An example of the use of SR 4.0.3 would be a relay contact that was not tested as required in accordance with a particular SR, but previous successful performances of the SR included the relay contact; the adjacent, physically connected relay contacts were tested during the SR performance; the subject relay contact has been tested by another SR; or historical operation of the subject relay contact has been successful. It is not sufficient to infer the behavior of the associated equipment from the performance of similar equipment. The rigor of determining whether there is a reasonable expectation a Surveillance will be met when performed should increase based on the length of time since the last performance of the Surveillance. If the Surveillance has been performed recently, a review of the Surveillance history and equipment performance may be sufficient to support a reasonable expectation that the Surveillance will be met when performed. For Surveillances that have not been performed for a long period or that have never been performed, a rigorous evaluation based on objective evidence should provide a high degree of confidence that the equipment is OPERABLE. The evaluation should be documented in sufficient detail to allow a knowledgeable individual to understand the basis for the determination.

Failure to comply with specified Surveillance time intervals and allowed extensions for SRs is expected to be an infrequent occurrence. Use of the delay period established by Specification 4.0.3 is a flexibility which is not intended to be used repeatedly to extend Surveillance intervals.

INTENTIONALLY LEFT BLANK

While up to 24 hours or the limit of the specified Surveillance time interval is provided to perform the missed Surveillance, it is expected that the missed Surveillance will be performed at the first reasonable opportunity. The determination of the first reasonable opportunity should include consideration of the impact on plant risk (from delaying the Surveillance as well as any plant configuration changes required or shutting the plant down to perform the Surveillance) and impact on any analysis assumptions, in addition to unit conditions, planning, availability of personnel, and the time required to perform the Surveillance. This risk impact should be managed through the program in place to implement 10 CFR 50.65(a)(4) and its implementation guidance, NRC Regulatory Guide 1.182, 'Assessing and Managing Risk Before Maintenance Activities at Nuclear Power Plants.' This Regulatory Guide addresses consideration of temporary and aggregate risk impacts, determination of risk management action thresholds, and risk management action up to and including plant shutdown. The missed Surveillance should be treated as an emergent condition as discussed in the Regulatory Guide. The risk evaluation may use quantitative, qualitative, or blended methods. The degree of depth and rigor of the evaluation should be commensurate with the importance of the component. Missed Surveillances for important components should be analyzed quantitatively. If the results of the risk evaluation determine the risk increase is significant, this evaluation should be used to determine the safest course of action. All missed Surveillances will be placed in the Corrective Action Program.

If a Surveillance is not completed within the allowed delay period, then the equipment is considered inoperable or the variable is considered outside the specified limits and the ACTION requirements for the applicable Limiting Condition for Operation begin immediately upon expiration of the delay period. If a Surveillance is failed within the delay period or the variable is outside the specified limits, then the equipment is inoperable and the Completion Times of the Required Actions for the applicable LCO Conditions begin immediately upon the failure of the Surveillance.

Completion of the Surveillance within the delay period allowed by this Specification, or within the allowed times specified in the ACTION requirements, restores compliance with Specification 4.0.1.

Specification 4.0.4 establishes the requirement that all applicable SRs must be met before entry into an OPERATIONAL CONDITION or other specified condition in the Applicability.

This Specification ensures that system and component OPERABILITY requirements and variable limits are met before entry into OPERATIONAL CONDITIONS or other specified conditions in the Applicability for which these systems and components ensure safe operation of the unit. The provisions of this Specification should not be interpreted as endorsing the failure to exercise the good practice of restoring systems or components to OPERABLE status before entering an associated OPERATIONAL CONDITION or other specified condition in the Applicability.

A provision is included to allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability when a Limiting Condition for Operation is not met due to a Surveillance not being met in accordance with Specification 3.0.4.

However, in certain circumstances, failing to meet an SR will not result in Specification 4.0.4 restricting an OPERATIONAL CONDITION change or other specified condition change. When a system, subsystem, division, component, device, or variable is inoperable or outside its specified limits, the associated

BASES

SR(s) are not required to be performed, per Specification 4.0.1, which states that surveillances do not have to be performed on inoperable equipment. When equipment is inoperable, Specification 4.0.4 does not apply to the associated SR(s) since the requirement for the SR(s) to be performed is removed. Therefore, failing to perform the Surveillance(s) within the specified Surveillance time interval does not result in a Specification 4.0.4 restriction to changing OPERATIONAL CONDITIONS or other specified conditions of the Applicability. However, since the Limiting Condition for Operation is not met in this instance, Specification 3.0.4 will govern any restrictions that may (or may not) apply to OPERATIONAL CONDITION or other specified condition changes. Specification 4.0.4 does not restrict changing OPERATIONAL CONDITIONS or other specified conditions of the Applicability when a Surveillance has not been performed within the specified Surveillance time interval, provided the requirement to declare the Limiting Condition for Operation not met has been delayed in accordance with Specification 4.0.3.

The provisions of Specification 4.0.4 shall not prevent entry into OPERATIONAL CONDITIONS or other specified conditions in the Applicability that are required to comply with ACTION requirements. In addition, the provisions of Specification 4.0.4 shall not prevent changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability that result from any unit shutdown. In this context, a unit shutdown is defined as a change in OPERATIONAL CONDITION or other specified condition in the Applicability associated with transitioning from OPERATIONAL CONDITION 1 to OPERATIONAL CONDITION 2, OPERATIONAL CONDITION 2 to OPERATIONAL CONDITION 3, and OPERATIONAL CONDITION 3 to OPERATIONAL CONDITION 4.

Specification 4.0.5 establishes the requirement that inservice inspection of ASME Code Class 1, 2 and 3 components and inservice testing of ASME Code Class 1, 2 and 3 pumps and valves shall be performed in accordance with a periodically updated version of Section XI of the ASME Boiler and Pressure Vessel Code and Addenda, and the ASME Code for Operation and Maintenance of Nuclear Power Plants (ASME OM Code) and applicable Addenda as required by 10 CFR 50.55a. The provisions of SR 4.0.2 and SR 4.0.3 do not apply to the INSERVICE TESTING PROGRAM unless there is a specific SR referencing usage of the program.

Limerick Generating Station has received a license amendment to implement 10 CFR 50.69, “Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors,” and may voluntarily comply with the requirements of 10 CFR 50.69 as an alternative to compliance with the following requirements for structures, systems, and components (SSCs) that have a Risk-Informed Safety Class (RISC) of RISC-3:

(1) The INSERVICE TESTING PROGRAM requirements of 10 CFR 50.55a(f), and
(2) The inservice inspection, and repair and replacement (with the exception of fracture toughness), requirements for ASME Class 2 and Class 3 SSCs in 10 CFR 50.55a(g).

Therefore, SSCs that have been categorized as RISC-3 in accordance with 10 CFR 50.69 may be removed from the INSERVICE TESTING [IST] PROGRAM and the Inservice Inspection (ISI) Program in accordance with 10 CFR 50.69(b)(1)(v).

RISC-3 SSCs with technical specification surveillance requirements referencing Technical Specification 4.0.5, which have been removed from the IST/ISI programs, are subject to the alternative treatment requirements of 10 CFR 50.69(d)(2). The SSCs must continue to meet the acceptance criteria specified in associated technical specification surveillance requirements, as applicable; however, the surveillance frequency is determined as part of the alternative treatment.

3/4.1.1 SHUTDOWN MARGIN

A sufficient SHUTDOWN MARGIN ensures that (1) the reactor can be made subcritical from all operating conditions, (2) the reactivity transients associated with postulated accident conditions are controllable within acceptable limits, and (3) the reactor will be maintained sufficiently subcritical to preclude inadvertent criticality in the shutdown condition.

Since core reactivity values will vary through core life as a function of fuel depletion and poison burnup, the demonstration of SHUTDOWN MARGIN will be performed in the cold, xenon-free condition and shall show the core to be subcritical by at least R + 0.38% Δ k/k or R + 0.28% Δ k/k, as appropriate. The 0.38% Δ k/k includes uncertainties and calculation biases. The value of R in units of % Δ k/k is the difference between the calculated value of minimum shutdown margin during the operating cycle and the calculated shutdown margin at the time of the shutdown margin test at the beginning of cycle. The value of R must be positive or zero and must be determined for each fuel loading cycle.

Two different values are supplied in the Limiting Condition for Operation to provide for the different methods of demonstration of the SHUTDOWN MARGIN. The highest worth rod may be determined analytically or by test. The SHUTDOWN MARGIN is demonstrated by (an insequence) control rod withdrawal at the beginning of life fuel cycle conditions, and, if necessary, at any future time in the cycle if the first demonstration indicates that the required margin could be reduced as a function of exposure. Observation of subcriticality in this condition assures subcriticality with the most reactive control rod fully withdrawn.

This reactivity characteristic has been a basic assumption in the analysis of plant performance and can be best demonstrated at the time of fuel loading, but the margin must also be determined anytime a control rod is incapable of insertion.

3/4.1.2 REACTIVITY ANOMALIES

Since the SHUTDOWN MARGIN requirement for the reactor is small, a careful check on actual conditions to the predicted conditions is necessary, and the changes in reactivity can be inferred from these comparisons of core $k_{effective}$ (k_{eff}). Since the comparisons are easily done, frequent checks are not an imposition on normal operations. A 1% change is larger than is expected for normal operation so a change of this magnitude should be thoroughly evaluated. A change as large as 1% would not exceed the design conditions of the reactor and is on the safe side of the postulated transients.

3/4.1.3 CONTROL RODS

The specification of this section ensure that (1) the minimum SHUTDOWN MARGIN is maintained, (2) the control rod insertion times are consistent with those used in the accident analysis, and (3) the potential effects of the rod drop accident are limited. The ACTION statements permit variations from the basic requirements but at the same time impose more restrictive criteria for continued operation. A limitation on inoperable rods is set such that the resultant effect on total rod worth and scram shape will be kept to a minimum. The requirements for the various scram time measurements ensure that any indication of systematic problems with rod drives will be investigated on a timely basis.

Damage within the control rod drive mechanism could be a generic problem, therefore with a control rod immovable because of excessive friction or mechanical interference, operation of the reactor is limited to a time period which is reasonable to determine the cause of the inoperability and at the same time prevent operation with a large number of inoperable control rods.

Control rods that are inoperable for other reasons are permitted to be taken out of service provided that those in the nonfully-inserted position are consistent with the SHUTDOWN MARGIN requirements.

With two or more withdrawn control rods immovable, the reactor must be brought to HOT SHUTDOWN. The occurrence of more than one control rod immovable at a withdrawn position increases the probability that the reactor cannot be shut down if required. Insertion of all insertable control rods eliminates the possibility of an additional failure of a control rod to insert.

The number of control rods permitted to be inoperable could be more than the eight allowed by the specification, but the occurrence of eight inoperable rods could be indicative of a generic problem and the reactor must be shutdown for investigation and resolution of the problem.

The control rod system is designed to bring the reactor subcritical at a rate fast enough to prevent the MCPR from becoming less than the fuel cladding safety limit during the limiting power transient analyzed in Section 15.2 of the FSAR. This analysis shows that the negative reactivity rates resulting from the scram with the average response of all the drives as given in the specifications, provided the required protection and MCPR remains greater than the fuel cladding safety limit. The occurrence of scram times longer then those specified should be viewed as an indication of a systemic problem with the rod drives and therefore the surveillance interval is reduced in order to prevent operation of the reactor for long periods of time with a potentially serious problem.

Scram time testing at zero psig reactor coolant pressure is adequate to ensure that the control rod will perform its intended scram function during startup of the plant until scram time testing at 950 psig reactor coolant pressure is performed prior to exceeding 40% rated core thermal power.

The scram discharge volume is required to be OPERABLE so that it will be available when needed to accept discharge water from the control rods during a reactor scram and will isolate the reactor coolant system from the containment when required.

CONTROL RODS (Continued)

The OPERABILITY of all SDV vent and drain valves ensures that the SDV vent and drain valves will close during a scram to contain reactor water discharged to the SDV piping. The SDV has one common drain line and one common vent line. Since the vent and drain lines are provided with two valves in series, the single failure of one valve in the open position will not impair the isolation function of the system. Additionally, the valves are required to open on scram reset to ensure that a path is available for the SDV piping to drain freely at other times.

When one SDV vent or drain valve is inoperable in one or more lines, the valves must be restored to OPERABLE status within 7 days. The allowable outage time is reasonable, given the level of redundancy in the lines and the low probability of a scram occurring while the valve(s) are inoperable. The SDV is still isolable since the redundant valve in the affected line is OPERABLE. During these periods, the single failure criterion may not be preserved, and a higher risk exists to allow reactor water out of the primary system during a scram.

If both valves in a line are inoperable, the line must be isolated to contain the reactor coolant during a scram. When a line is isolated, the potential for an inadvertent scram due to high SDV level is increased. The associated ACTION is modified by a note ("****") that allows periodic draining and venting of the SDV when a line is isolated. During these periods, the line may be unisolated under administrative control. This allows any accumulated water in the line to be drained, to preclude a reactor scram on SDV high level. This is acceptable since the administrative controls ensure the valve can be closed quickly, by a dedicated operator, if a scram occurs with the valve open. The 8 hour allowable outage time to isolate the line is based on the low probability of a scram occurring while the line is not isolated and the unlikelihood of significant CRD seal leakage.

Control rods with inoperable accumulators are declared inoperable and Specification 3.1.3.1 then applies. This prevents a pattern of inoperable accumulators that would result in less reactivity insertion on a scram than has been analyzed even though control rods with inoperable accumulators may still be inserted with normal drive water pressure. The drive water pressure normal operating range is specified in system operating procedures which provide ranges for system alignment and control rod motion (exercising). Operability of the accumulator ensures that there is a means available to insert the control rods even under the most unfavorable depressurization of the reactor. A control rod is considered trippable if it is capable of fully inserting as a result of a scram signal.

THIS PAGE INTENTIONALLY LEFT BLANK

CONTROL RODS (Continued)

Control rod coupling integrity is required to ensure compliance with the analysis of the rod drop accident in the FSAR. The overtravel position feature provides the only positive means of determining that a rod is properly coupled and therefore this check must be performed prior to achieving criticality after completing CORE ALTERATIONS that could have affected the control rod coupling integrity. The subsequent check is performed as a backup to the initial demonstration.

In order to ensure that the control rod patterns can be followed and therefore that other parameters are within their limits, the control rod position indication system must be OPERABLE.

The control rod housing support restricts the outward movement of a control rod to less than 3 inches in the event of a housing failure. The amount of rod reactivity which could be added by this small amount of rod withdrawal is less than a normal withdrawal increment and will not contribute to any damage to the primary coolant system. The support is not required when there is no pressure to act as a driving force to rapidly eject a drive housing.

The required surveillances are adequate to determine that the rods are OPERABLE and not so frequent as to cause excessive wear on the system components.

3/4.1.4 CONTROL ROD PROGRAM CONTROLS

Control rod withdrawal and insertion sequences are established to assure that the maximum insequence individual control rod or control rod segments which are withdrawn at any time during the fuel cycle could not be worth enough to result in a peak fuel enthalpy greater than 280 cal/gm in the event of a control rod drop accident. The specified sequences are characterized by homogeneous, scattered patterns of control rod withdrawal. When THERMAL POWER is greater than 10% of RATED THERMAL POWER, there is no possible rod worth which, if dropped at the design rate of the velocity limiter, could result in a peak enthalpy of 280 cal/gm. Thus requiring the RWM to be OPERABLE when THERMAL POWER is less than or equal to 10% of RATED THERMAL POWER provides adequate control.

The RWM provides automatic supervision to assure that out-of-sequence rods will not be withdrawn or inserted.

The analysis of the rod drop accident is presented in Section 15.4.9 of the FSAR and the techniques of the analysis are presented in a topical report, Reference 1, and two supplements, References 2 and 3. Additional pertinent analysis is also contained in Amendment 17 to the Reference 4 topical report.

The RBM is designed to automatically prevent fuel damage in the event of erroneous rod withdrawal from locations of high power density over the range of power operation. Two channels are provided. Tripping one of the channels will block erroneous rod withdrawal to prevent fuel damage. This system backs up the written sequence used by the operator for withdrawal of control rods. RBM OPERABILITY is required when the limiting condition described in Specification 3.1.4.3 exists.

3/4.1.5 STANDBY LIQUID CONTROL SYSTEM

The standby liquid control system provides a backup capability for bringing the reactor from full power to a cold, Xenon-free shutdown, assuming that the withdrawn control rods remain fixed in the rated power pattern. To meet this objective it is necessary to inject a quantity of boron which produces a concentration of 660 ppm in the reactor core and other piping systems connected to the reactor vessel. To allow for potential leakage and improper mixing, this concentration is increased by 25%. The required concentration is achieved by having available a minimum quantity of 3,160 gallons of sodium pentaborate solution containng a minimum of 3,754 lbs of sodium pentaborate having the requisite Boron-10 atom % enrichment of 29% as determined from Reference 5. This quantity of solution is a net amount which is above the pump suction shutoff level setpoint thus allowing for the portion which cannot be injected.

The above quantities calculated at 29% Boron-10 enrichment have been demonstrated by analysis to provide a Boron-10 weight equivalent of 185 lbs in the sodium pentaborate solution. Maintaining this Boron-10 weight in the net tank contents ensures a sufficient quantity of boron to bring the reactor to a cold, Xenon-free shutdown.

The pumping rate of 37.0 gpm provides a negative reactivity insertion rate over the permissible solution volume range, which adequately compensates for the positive reactivity effects due to elimination of steam voids, increased water density from hot to cold, reduced doppler effect in uranium, reduced neutron leakage from boiling to cold, decreased control rod worth as the moderator cools, and xenon decay. The temperature requirement ensures that the sodium pentaborate always remains in solution.

With redundant pumps and explosive injection valves and with a highly reliable control rod scram system, operation of the reactor is permitted to continue for short periods of time with the system inoperable or for longer periods of time with one of the redundant components inoperable.

The SLCS system consists of three separate and independent pumps and explosive valves. Two of the separate and independent pumps and explosive valves are required to meet the minimum requirements of this technical specification and, where applicable, satisfy the single failure criterion. To ensure that SLCS pump discharge pressure does not exceed the SLCS relief valve setpoint during operation following an anticipated transient without scram (ATWS) event, no more than two pumps shall be aligned for automatic operation in OPERATIONAL CONDITIONS 1, 2, and 3. This maintains the equivalent control capacity to satisfy 10 CFR 50.62 (Requirements for reduction of risk from anticipated transients without scram (ATWS). With three pumps aligned for automatic operation, the system is inoperable and ACTION statement (b) applies.

The SLCS must have an equivalent control capacity of 86 gpm of 13% weight sodium pentaborate in order to satisfy 10 CFR 50.62. As part of the ARTS/MELLL program the ATWS analysis was updated to reflect the new rod line. As a result of this it was determined that the Boron 10 enrichment was required to be increased to 29% to prevent exceeding a suppression pool temperature of 190°F. This equivalency requirement is fulfilled by having a system which satisfies the equation given in 4.1.5.b.2.

The upper limit concentration of 13.8% has been established as a reasonable limit to prevent precipitation of sodium pentaborate in the event of a loss of tank heating, which allow the solution to cool. A SLCS Pump flowrate of 37.0 gpm (minimum) and a Sodium Pentaborate Solution concentration of 9% by weight (minimum) will require a Boron-10 enrichment of 49 atom % to be added to the tank. The decreased pump flowrate and increased solution enrichment are acceptable because the results of the ATWS Rule Equation will remain > 1.0.

STANDBY LIQUID CONTROL SYSTEM (Continued)

Surveillance requirements are established on a frequency that assures a high reliability of the system. Once the solution is established, boron concentration will not vary unless more boron or water is added, thus a check on the temperature and volume assures that the solution is available for use.

Replacement of the explosive charges in the valves will assure that these valves will not fail because of deterioration of the charges.

The Standby Liquid Control System also has a post-DBA LOCA safety function to buffer Suppression Pool pH in order to maintain bulk pH above 7.0. The buffering of Suppression Pool pH is necessary to prevent iodine re-evolution to satisfy the methodology for Alternative Source Term. Manual initiation is used, and the minimum amount of total boron required for Suppression Pool pH buffering is 256 lbs. Given that at least 185 lbs of Boron-10 is maintained in the tank, the total boron in the tank will be greater than 256 lbs for the range of enrichments from 29% to 62%.

ACTION Statement (a) applies only to OPERATIONAL CONDITIONS 1 and 2 because a single pump can satisfy both the reactor control function and the post-DBA LOCA function to control Suppression Pool pH since boron injection is not required until 13 hours post-LOCA. ACTION Statement (b) applies to OPERATIONAL CONDITIONS 1, 2 and 3 to address the post-LOCA safety function of the SLC system.

3/4.2.1 AVERAGE PLANAR LINEAR HEAT GENERATION RATE

This specification assures that the peak cladding temperature (PCT) following the postulated design basis Loss-of-Coolant Accident (LOCA) will not exceed the limits specified in 10 CFR 50.46 and that the fuel design analysis limits specified in NEDE-24011-P-A (Reference 2) will not be exceeded.

Mechanical Design Analysis: NRC approved methods (specified in Refer-ence 2) are used to demonstrate that all fuel rods in a lattice operating at the bounding power history, meet the fuel design limits specified in Reference 2. No single fuel rod follows, or is capable of following, this bounding power history. This bounding power history is used as the basis for the fuel design analysis MAPLHGR limit.

LOCA Analysis: A LOCA analysis is performed in accordance with 10 CFR 50 Appendix K to demonstrate that the permissible planar power (MAPLHGR) limits comply with the ECCS limits specified in 10 CFR 50.46. The analysis is performed for the most limiting break size, break location, and single failure combination for the plant, using the evaluation model described in Reference 9.

The MAPLHGR limit as show in the CORE OPERATING LIMITS REPORT is the most limiting composite of the fuel mechanical design anaylsis MAPLHGR and the ECCS MAPLHGR limit.

Only the most limiting MAPLHGR values are shown in the CORE OPERATING LIMITS REPORT for multiple lattice fuel. Compliance with the specific lattice MAPLHGR operating limits, which are available in Reference 3, is ensured by use of the process computer.

As a result of no longer utilizing an APRM trip setdown requirement, additional constraints are placed on the MAPLHGR limits to assure adherence to the fuel-mechanical design bases. These constraints are introduced through the MAPFAC(P) and MAPFAC(F) factors as defined in the COLR.

3/4.2.2 (DELETED)

INFORMATION CONTAINED ON

THIS PAGE HAS BEEN

DELETED

LEFT INTENTIONALLY BLANK

3/4.2.3 MINIMUM CRITICAL POWER RATIO

The required operating limit MCPRs at steady-state operating conditions as specified in Specification 3.2.3 are derived from the established fuel cladding integrity MCPR(99.9%), and an analysis of abnormal operational transients. For any abnormal operating transient analysis evaluation with the initial condition of the reactor being at the steady-state operating limit, it is required that less than 0.1% of fuel rods in the core are susceptible to transition boiling or that the resulting MCPR does not decrease below the operating limit MCPR at any time during the transient assuming instrument trip setting given in Specification 2.2.

To assure that the fuel cladding integrity Safety Limit is not exceeded during any anticipated abnormal operational transient, the most limiting transients have been analyzed to determine which result in the largest reduction in CRITICAL POWER RATIO (CPR). The type of transients evaluated were loss of flow, increase in pressure and power, positive reactivity insertion, and coolant temperature decrease.

The evaluation of a given transient begins with the system initial parameters shown in FSAR Table 15.0-2 that are input to a BWR system dynamic behavior transient computer program. The codes used to evaluate transients are discussed in Reference 2.

MCPR(99.9%) is determined to ensure more than 99.9% of the fuel rods in the core are not susceptible to boiling transition using a statistical model that combines all the uncertainties in operating parameters and the procedures used to calculate critical power. The probability of the occurrence of boiling transition is determined using the approved Critical Power correlations. Details of the MCPR(99.9%) calculation are given in Reference 2. Reference 2 also includes a tabulation of the uncertainties and the nominal values $MCPR_{99.9\%}$ statistical analysis.

The MCPR operating limits are derived from the MCPR(99.9%) value and the transient analysis and are dependent on the operating core flow and power state (MCPR(F), and MCPR(P), respectively) to ensure adherence to fuel design limits during the worst transient that occurs with moderate frequency (Ref. 6). Flow dependent MCPR limits (MCPR(F)) are determined by steady state thermal hydraulic methods with key physics response inputs benchmarked using the three dimensional BWR simulator code (Ref. 7) to analyze slow flow runout transients.

Power dependent MCPR limits (MCPR(P)) are determined by approved transient analysis (Reference 2). Due to the sensitivity of the transient response to initial core flow levels at power levels below those at which the turbine stop valve closure and turbine control valve fast closure scrams are bypassed, high and low flow MCPR(P), operating limits are provided for operating between 25% RTP and 30% RTP.

The MCPR operating limits specified in the COLR (MCPR(99.9%) value, MCPR(F), and MCPR(P) values) are the result of the Design Basis Accident (DBA) and transient analysis. The operating limit MCPR is determined by the larger of the MCPR(F), and MCPR(P) limits, which are based on the MCPR(99.9%) limit specified in the COLR.

MINIMUM CRITICAL POWER RATIO (Continued)

At THERMAL POWER levels less than or equal to 25% of RATED THERMAL POWER, the reactor will be operating at minimum recirculation pump speed and the moderator void content will be very small. For all designated control rod patterns which may be employed at this point, operating plant experience indicates that the resulting MCPR value is in excess of requirements by a considerable margin. During initial start-up testing of the plant, a MCPR evaluation will be made at 25% of RATED THERMAL POWER level with minimum recirculation pump speed. The MCPR margin will thus be demonstrated such that future MCPR evaluation below this power level will be shown to be unnecessary. The daily requirement for calculating MCPR when THERMAL POWER is greater than or equal to 25% of RATED THERMAL POWER is sufficient since power distribution shifts are very slow when there have not been significant power or control rod changes. The requirement for calculating MCPR when a limiting control rod pattern is approached ensures that MCPR will be known following a change in THERMAL POWER or power shape, regardless of magnitude, that could place operation at a thermal limit.

3/4.2.4 LINEAR HEAT GENERATION RATE

This specification assures that the Linear Heat Generation Rate (LHGR) in any rod is less than the design linear heat generation even if fuel pellet densification is postulated.

PAGE INTENTIONALLY LEFT BLANK

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION

The reactor protection system automatically initiates a reactor scram to:

a. Preserve the integrity of the fuel cladding.

b. Preserve the integrity of the reactor coolant system.

c. Minimize the energy which must be adsorbed following a loss-of-coolant accident, and

d. Prevent inadvertent criticality.

This specification provides the limiting conditions for operation necessary to preserve the ability of the system to perform its intended function even during periods when instrument channels may be out of service because of maintenance. When necessary, one channel may be made inoperable for brief intervals to conduct required surveillance.

The reactor protection system is made up of two independent trip systems. There are usually four channels to monitor each parameter with two channels in each trip system. The outputs of the channels in a trip system are combined in a logic so that either channel will trip that trip system. The tripping of both trip systems will produce a reactor scram. The APRM system is divided into four APRM channels and four 2-Out-Of-4 Voter channels. Each APRM channel provides inputs to each of the four voter channels. The four voter channels are divided into two groups of two each, with each group of two providing inputs to one RPS trip system. The system is designed to allow one APRM channel, but no voter channels, to be bypassed.

The system meets the intent of IEEE-279 for nuclear power plant protection systems. Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30851P-A, "Technical Specification Improvement Analyses for BWR Reactor Protection System" and NEDC-32410P-A, “Nuclear Measurement Analysis and Control Power Range Neutron Monitor (NUMAC PRNM) Retrofit Plus Option III Stability Trip Function.” The bases for the trip settings of the RPS are discussed in the bases for Specification 2.2.1.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

The APRM Functions include five Functions accomplished by the four APRM channels (Functions 2.a, 2.b, 2.c, 2.d, and 2.f) and one accomplished by the four 2-Out-Of-4 Voter channels (Function 2.e). Two of the five Functions accomplished by the APRM channels are based on neutron flux only (Functions 2.a and 2.c), one Function is based on neutron flux and recirculation drive flow (Function 2.b) and one is based on equipment status (Function 2.d). The fifth Function accomplished by the APRM channels is the Oscillation Power Range Monitor (OPRM) Upscale trip Function 2.f, which is based on detecting oscillatory characteristics in the neutron flux. The OPRM Upscale Function is also dependent on average neutron flux (Simulated Thermal Power) and recirculation drive flow, which are used to automatically enable the output trip.

The Two-Out-Of-Four Logic Module includes 2-Out-Of-4 Voter hardware and the APRM Interface hardware. The 2-Out-Of-4 Voter Function 2.e votes APRM Functions 2.a, 2.b, 2.c, and 2.d independently of Function 2.f. This voting is accomplished by the 2-Out-Of-4 Voter hardware in the Two-Out-Of-Four Logic Module. The voter includes separate outputs to RPS for the two independently voted sets of Functions, each of which is redundant (four total outputs). The analysis in Reference 2 took credit for this redundancy in the justification of the 12-hour allowed out-of-service time for

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

Action b, so the voter Function 2.e must be declared inoperable if any of its functionality is inoperable. The voter Function 2.e does not need to be declared inoperable due to any failure affecting only the APRM Interface hardware portion of the Two-Out-Of-Four Logic Module.

Three of the four APRM channels and all four of the voter channels are required to be OPERABLE to ensure that no single failure will preclude a scram on a valid signal. To provide adequate coverage of the entire core, consistent with the design bases for the APRM Functions 2.a, 2.b, and 2.c, at least 20 LPRM inputs, with at least three LPRM inputs from each of the four axial levels at which the LPRMs are located, must be operable for each APRM channel. In addition, no more than 9 LPRMs may be bypassed between APRM calibrations (weekly gain adjustments). For the OPRM Upscale Function 2.f, LPRMs are assigned to "cells" of 3 or 4 detectors. A minimum of 23 cells (Reference 9), each with a minimum of 2 OPERABLE LPRMs, must be OPERABLE for each APRM channel for the OPRM Upscale Function 2.f to be OPERABLE in that channel. LPRM gain settings are determined from the local flux profiles measured by the TIP system. This establishes the relative local flux profile for appropriate representative input to the APRM System. The 2000 EFPH frequency is based on operating experience with LPRM sensitivity changes.

References 4, 5 and 6 describe three algorithms for detecting thermal-hydraulic instability related neutron flux oscillations: the period based detection algorithm, the amplitude based algorithm, and the growth rate algorithm. All three are implemented in the OPRM Upscale Function, but the safety analysis takes credit only for the period based detection algorithm. The remaining algorithms provide defense in depth and additional protection against unanticipated oscillations. OPRM Upscale Function OPERABILITY for Technical Specification purposes is based only on the period based detection algorithm.

An OPRM Upscale trip is issued from an APRM channel when the period based detection algorithm in that channel detects oscillatory changes in the neutron flux, indicated by the combined signals of the LPRM detectors in any cell, with period confirmations and relative cell amplitude exceeding specified setpoints. One or more cells in a channel exceeding the trip conditions will result in a channel trip. An OPRM Upscale trip is also issued from the channel if either the growth rate or amplitude based algorithms detect growing oscillatory changes in the neutron flux for one or more cells in that channel.

The OPRM Upscale Function is required to be OPERABLE when the plant is at $\geq$ 25% RATED THERMAL POWER. The 25% RATED THERMAL POWER level is selected to provide margin in the unlikely event that a reactor power increase transient occurring while the plant is operating below 29.5% RATED THERMAL POWER causes a power increase to or beyond the 29.5% RATED THERMAL POWER OPRM Upscale trip auto-enable point without operator action. This OPERABILITY requirement assures that the OPRM Upscale trip automatic-enable function will be OPERABLE when required.

Actions a, b and c define the Action(s) required when RPS channels are discovered to be inoperable. For those Actions, separate entry condition is allowed for each inoperable RPS channel. Separate entry means that the allowable time clock(s) for Actions a, b or c start upon discovery of inoperability for that specific channel. Restoration of an inoperable RPS channel satisfies only the action statements for that particular channel. Action statement(s) for remaining inoperable channel(s) must be met according to their original entry time.

A Note has been provided to modify the Actions when Functional Unit 2.b and 2.c channels are inoperable due to failure of SR 4.3.1.1 and gain adjustments are necessary. The Note allows entry into associated Actions to be delayed for up to 2 hours if the APRM is indicating a lower power value than the calculated power (i.e., the gain adjustment factor (GAF) is high (non-conservative)). The GAF for any channel is defined as the power value determined by the heat balance divided by the APRM reading for that channel. Upon completion of the gain adjustment, or

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

expiration of the allowed time, the channel must be returned to OPERABLE status or the applicable Actions taken. This Note is based on the time required to perform gain adjustments on multiple channels.

Because of the diversity of sensors available to provide trip signals and the redundancy of the RPS design, an allowable out of service time of 12 hours has been shown to be acceptable (NEDC-30851P-A and NEDC-32410P-A) to permit restoration of any inoperable channel to OPERABLE status. However, this out of service time is only acceptable provided that the associated Function's (identified as a "Functional Unit" in Table 3.3.1-1) inoperable channel is in one trip system and the Function still maintains RPS trip capability. Alternatively, an allowable out-of-service time can be determined in accordance with the Risk Informed Completion Time Program.

The requirements of Action a are intended to ensure that appropriate actions are taken if multiple, inoperable, untripped channels within the same trip system for the same Function result in the Function not maintaining RPS trip capability. A Function is considered to be maintaining RPS trip capability when sufficient channels are OPERABLE or in trip (or the associated trip system is in trip), such that both trip systems will generate a trip signal from the given Function on a valid signal. For the typical Function with one-out-of-two taken twice logic, including the IRM Functions and APRM Function 2.e (trip capability associated with APRM Functions 2.a, 2.b, 2.c, 2.d, and 2.f are discussed below), this would require both trip systems to have one channel OPERABLE or in trip (or the associated trip system in trip).

For Function 5 (Main Steam Isolation Valve--Closure), this would require both trip systems to have each channel associated with the MSIVs in three main steam lines (not necessarily the same main steam lines for both trip systems) OPERABLE or in trip (or the associated trip system in trip).

For Function 9 (Turbine Stop Valve-Closure), this would require both trip systems to have three channels, each OPERABLE or in trip (or the associated trip system in trip).

The completion time to satisfy the requirements of Action a is intended to allow the operator time to evaluate and repair any discovered inoperabilities. The 1 hour Completion Time is acceptable because it minimizes risk while allowing time for restoration or tripping of channels. Alternatively, the completion time can be determined in accordance with the Risk Informed Completion Time Program.

With trip capability maintained, i.e., Action a satisfied, Actions b and c as applicable must still be satisfied. If the inoperable channel cannot be restored to OPERABLE status within the allowable out of service time, Action b requires that the channel or the associated trip system must be placed in the tripped condition. Placing the inoperable channel in trip (or the associated trip system in trip) would conservatively compensate for the inoperability, restore capability to accommodate a single failure, and allow operation to continue.

As noted, placing the trip system in trip is not applicable to satisfy Action b for APRM functions 2.a, 2.b, 2.c, 2.d, or 2.f. Inoperability of one required APRM channel affects both trip systems. For that condition, the Action b requirements can only be satisfied by placing the inoperable APRM channel in trip. Restoring OPERABILITY or placing the inoperable APRM channel in trip are the only actions that will restore capability to accommodate a single APRM channel failure. Inoperability of more than one required APRM channel of the same trip function results in loss of trip capability and the requirement to satisfy Action a.

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

The requirements of Action c must be satisfied when, for any one or more Functions, at least one required channel is inoperable in each trip system. In this condition, provided at least one channel per trip system is OPERABLE, normally the RPS still maintains trip capability for that Function, but cannot accommodate a single failure in either trip system (see additional bases discussion above related to loss of trip capability and the requirements of Action a, and special cases for Functions 2.a, 2.b, 2.c, 2.d, 2.f, 5 and 9).

The requirements of Action c limit the time the RPS scram logic, for any Function, would not accommodate single failure in both tip systems (e.g., one-out-of-one and one-out-of-one arrangement for a typical four channel Function). The reduced reliability of this logic arrangement was not evaluated in NEDC-3Ø851P-A for the 12 hour Completion Time. Within the 6 hour allowance, the associated Function must have all required channels OPERABLE or in trip (or any combination) in one trip system.

Completing the actions required by Action c restores RPS to a reliability level equivalent to that evaluated in NEDC-3Ø851P-A, which justified a 12 hour allowable out of service time as allowed by Action b. To satisfy the requirements of Action c, the trip system in the more degraded state should be placed in trip or, alternatively, all the inoperable channels in that trip system should be placed in trip (e.g., a trip system with two inoperable channels could be in a more degraded state than a trip system with four inoperable channels if the two inoperable channels are in the same Function while the four inoperable channels are all in different Functions). The decision of which trip system is in the more degraded state should be based on prudent judgment and take into account current plant conditions (i.e., what OPERATIONAL CONDITION the plant is in). If this action would result in a scram or RPT, it is permissible to place the other trip system or its inoperable channels in trip.

The 6 hour allowable out of service time is judged acceptable based on the remaining capability to trip, the diversity of the sensors available to provide the trip signals, the low probability of extensive numbers of inoperabilities affecting all diverse Functions, and the low probability of an event requiring the initiation of a scram.

As noted, Action c is not applicable for APRM Functions 2.a, 2.b, 2.c, 2.d, or 2.f. Inoperability of an APRM channel affects both trip systems and is not associated with a specific trip system as are the APRM 2-Out-Of-4 voter and other non-APRM channels for which Action c applies. For an inoperable APRM channel, the requirements of Action b can only be satisfied by tripping the inoperable APRM channel. Restoring OPERABILITY or placing the inoperable APRM channel in trip are the only actions that will restore capability to accommodate a single APRM channel failure.

If it is not desired to place the channel (or trip system) in trip to satisfy the requirements of Action a, Action b or Action c (e.g., as in the case where placing the inoperable channel in trip would result in a full scram), Action d requires that the Action defined by Table 3.3.1-1 for the applicable Function be initiated immediately upon expiration of the allowable out of service time.

Table 3.3.1-1, Function 2.f, references Action 1Ø, which defines the action required if OPRM Upscale trip capability is not maintained. Action 1Øb is required to address identified equipment failures. Action 1Øa is to address common mode vendor/industry identified issues that render all four OPRM channels inoperable at once. For this condition, References 2 and 3 justified use of alternate methods to

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

detect and suppress oscillations for a limited period of time, up to 120 days. The alternate methods are procedurally established consistent with the guidelines identified in Reference 7 requiring manual operator action to scram the plant if certain predefined events occur. The 12-hour allowed completion time to implement the alternate methods is based on engineering judgment to allow orderly transition to the alternate methods while limiting the period of time during which no automatic or alternate detect and suppress trip capability is formally in place. The 120-day period during which use of alternate methods is allowed is intended to be an outside limit to allow for the case where design changes or extensive analysis might be required to understand or correct some unanticipated characteristic of the instability detection algorithms or equipment. The evaluation of the use of alternate methods concluded, based on engineering judgment, that the likelihood of an instability event that could not be adequately handled by the alternate methods during the 120-day period was negligibly small. Plant startup may continue while operating within the allowed completion time of Action 10a. The primary purpose of this is to allow an orderly completion, without undue impact on plant operation, of design and verification activities in the event of a required design change to the OPRM Upscale function. This exception is not intended as an alternative to restoring inoperable equipment to OPERABLE status in a timely manner.

Action 10a is not intended and was not evaluated as a routine alternative to returning failed or inoperable equipment to OPERABLE status. Correction of routine equipment failure or inoperability is expected to be accomplished within the completion times allowed for LCO 3.3.1 Action a or Action b, as applicable. Action 10b applies when routine equipment OPERABILITY cannot be restored within the allowed completion times of LCO 3.3.1 Actions a or b, or if a common mode OPRM deficiency cannot be corrected and OPERABILITY of the OPRM Upscale Function restored within the 120-day allowed completion time of Action 10a.

The OPRM Upscale trip output shall be automatically enabled (not-bypassed) when APRM Simulated Thermal Power is $\geq$ 29.5% and recirculation drive flow is $<$ 60% as indicated by APRM measured recirculation drive flow. NOTE: 60% recirculation drive flow is the recirculation drive flow that corresponds to 60% of rated core flow. This is the operating region where actual thermal-hydraulic instability and related neutron flux oscillations may occur. As noted in Table 4.3.1.1-1, Note c, CHANNEL CALIBRATION for the OPRM Upscale trip Function 2.f includes confirming that the auto-enable (not-bypassed) setpoints are correct. Other surveillances ensure that the APRM Simulated Thermal Power properly correlates with THERMAL POWER (Table 4.3.1.1-1, Note d) and that recirculation drive flow properly correlates with core flow (Table 4.3.1.1-1, Note g).

If any OPRM Upscale trip auto-enable setpoint is exceeded and the OPRM Upscale trip is not enabled, i.e., the OPRM Upscale trip is bypassed when APRM Simulated Thermal Power is $\geq$ 29.5% and recirculation drive flow is $<$ 60%, then the affected channel is considered inoperable for the OPRM Upscale Function. Alternatively, the OPRM Upscale trip auto-enable setpoint(s) may be adjusted to place the channel in the enabled condition (not-bypassed). If the OPRM Upscale trip is placed in the enabled condition, the surveillance requirement is met and the channel is considered OPERABLE.

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

As noted in Table 4.3.1.1-1, Note g, CHANNEL CALIBRATION for the APRM Simulated Thermal Power - Upscale Function 2.b and the OPRM Upscale Function 2.f, includes the recirculation drive flow input function. The APRM Simulated Thermal Power - Upscale Function and the OPRM Upscale Function both require a valid drive flow signal. The APRM Simulated Thermal Power - Upscale Function uses drive flow to vary the trip setpoint. The OPRM Upscale Function uses drive flow to automatically enable or bypass the OPRM Upscale trip output to RPS. A CHANNEL CALIBRATION of the APRM recirculation drive flow input function requires both calibrating the drive flow transmitters and establishing a valid drive flow / core flow relationship. The drive flow / core flow relationship is established once per refuel cycle, while operating within 10% of rated core flow and within 10% of RATED THERMAL POWER. Plant operational experience has shown that this flow correlation methodology is consistent with the guidance and intent in Reference 8. Changes throughout the cycle in the drive flow / core flow relationship due to the changing thermal hydraulic operating conditions of the core are accounted for in the margins included in the bases or analyses used to establish the setpoints for the APRM Simulated Thermal Power - Upscale Function and the OPRM Upscale Function.

For the Simulated Thermal Power - Upscale Function (Function 2.b), the CHANNEL CALIBRATION surveillance requirement is modified by two Notes. The first Note requires evaluation of channel performance for the condition where the as-found setting for the channel setpoint is outside its as-found tolerance but conservative with respect to the Allowable Value. Evaluation of channel performance will verify that the channel will continue to behave in accordance with safety analysis assumptions and the channel performance assumptions in the setpoint methodology. The purpose of the assessment is to ensure confidence in the channel performance prior to returning the channel to service. For channels determined to be OPERABLE but degraded, after returning the channel to service the performance of these channels will be evaluated under the plant Corrective Action Program. Entry into the Corrective Action Program will ensure required review and documentation of the condition. The second Note requires that the as-left setting for the channel be within the as-left tolerance of the Trip Setpoint. The as-left and as-found tolerances, as applicable, will be applied to the surveillance procedure setpoint. This will ensure that sufficient margin to the Safety Limit and/or Analytical Limit is maintained. If the as-left channel setting cannot be returned to a setting within the as-left tolerance of the Trip Setpoint, then the channel shall be declared inoperable. The as-left tolerance for this function is calculated using the square-root-sum-of-squares of the reference accuracy and the measurement and test equipment error (including readability). The as-found tolerance for this function is calculated using the square-root-sum-of-squares of the reference accuracy, instrument drift, and the measurement and test equipment error (including readability).

To ensure that the APRMs are accurately indicating the true core average power, the APRMs are adjusted to the reactor power calculated from a heat balance if the heat balance calculated reactor power exceeds the APRM channel output by more than 2% RTP.

This Surveillance does not preclude making APRM channel adjustments, if desired, when the heat balance calculated reactor power is less than the APRM channel output. To provide close agreement between the APRM indicated power and to preserve operating margin, the APRM channels are normally adjusted to within +/- 2% of the heat balance calculated reactor power. However, this agreement is not required for OPERABILITY when APRM output indicates a higher reactor power than the heat balance calculated reactor power.

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

As noted in Table 3.3.1-2, Note "*", the redundant outputs from the 2-Out-Of-4 Voter channel are considered part of the same channel, but the OPRM and APRM outputs are considered to be separate channels, so N = 8 to determine the interval between tests for application of Specification 4.3.1.3 (REACTOR PROTECTION SYSTEM RESPONSE TIME). The note further requires that testing of OPRM and APRM outputs shall be alternated.

Each test of an OPRM or APRM output tests each of the redundant outputs from the 2-Out-Of-4 Voter channel for that function, and each of the corresponding relays in the RPS. Consequently, each of the RPS relays is tested every fourth cycle. This testing frequency is twice the frequency justified by References 2 and 3.

Automatic reactor trip upon receipt of a high-high radiation signal from the Main Steam Line Radiation Monitoring System was removed as the result of an analysis performed by General Electric in NEDO-31400A. The NRC approved the results of this analysis as documented in the SER (letter to George J. Beck, BWR Owner's Group from A.C. Thadani, NRC, dated May 15, 1991).

The measurement of response time at the frequencies specified in the Surveillance Frequency Control Program provides assurance that the protective functions associated with each channel are completed within the time limit assumed in the safety analyses. No credit was taken for those channels with response times indicated as not applicable except for the APRM Simulated Thermal Power - Upscale and Neutron Flux - Upscale trip functions and the OPRM Upscale trip function (Table 3.3.1-2, Items 2.b, 2.c, and 2.f). Response time may be demonstrated by any series of sequential, overlapping or total channel test measurement, provided such tests demonstrate the total channel response time as defined. Sensor response time verification may be demonstrated by either (1) inplace, onsite or offsite test measurements, or (2) utilizing replacement sensors with certified response times. Response time testing for the sensors as noted in Table 3.3.1-2 is not required based on the analysis in NEDO-32291-A. Response time testing for the remaining channel components is required as noted. For the digital electronic portions of the APRM functions, performance characteristics that determine response time are checked by a combination of automatic self-test, calibration activities, and response time tests of the 2-Out-Of-4 Voter (Table 3.3.1-2, Item 2.e).

3/4.3.2 ISOLATION ACTUATION INSTRUMENTATION

This specification ensures the effectiveness of the instrumentation used to mitigate the consequences of accidents by prescribing the OPERABILITY trip setpoints and response times for isolation of the reactor systems. When necessary, one channel may be inoperable for brief intervals to conduct required surveillance.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30851P, Supplement 2, "Technical Specification Improvement Analysis for BWR Instrumentation Common to RPS and ECCS Instrumentation" as approved by the NRC and documented in the NRC Safety Evaluation Report (SER) (letter to D.N. Grace from C.E. Rossi dated January 6, 1989) and NEDC-31677P-A, "Technical Specification Improvement Analysis for BWR Isolation Actuation Instrumentation," as approved by the NRC and documented in the NRC SER (letter to S.D. Floyd from C.E. Rossi dated June 18, 1990).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Automatic closure of the MSIVs upon receipt of a high-high radiation signal from the Main Steam Line Radiation Monitoring System was removed as the result of an analysis performed by General Electric in NEDO-31400A. The NRC approved the results of this analysis as documented in the SER (letter to George J. Beck, BWR Owner's Group from A.C. Thadani, NRC, dated May 15, 1991).

Some of the trip settings may have tolerances explicitly stated where both the high and low values are critical and may have a substantial effect on safety. The setpoints of other instrumentation, where only the high or low end of the setting have a direct bearing on safety, are established at a level away from the normal operating range to prevent inadvertent actuation of the systems involved.

Except for the MSIVs, the safety analysis does not address individual sensor response times or the response times of the logic systems to which the sensors are connected. For D.C. operated valves, a 3 second delay is assumed before the valve starts to move. For A.C. operated valves, it is assumed that the A.C. power supply is lost and is restored by startup of the emergency diesel generators. In this event, a time of 13 seconds is assumed before the valve starts to move. In addition to the pipe break, the failure of the D.C. operated valve is assumed; thus the signal delay (sensor response) is concurrent with the 10-second diesel startup and the 3 second load center loading delay. The safety analysis considers an allowable inventory loss in each case which in turn determines the valve speed in conjunction with the 13-second delay. It follows that checking the valve speeds and the 13-second time for emergency power establishment will establish the response time for the isolation functions.

Response time testing for sensors are not required based on the analysis in NEDO 32291-A. Response time testing of the remaining channel components is required as noted in Table 3.3.2-3.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses. Primary containment isolation valves that are actuated by the isolation signals specified in Technical Specification Table 3.3.2-1 are identified in Technical Requirements Manual Table 3.6.3-1.

The opening of a containment isolation valve that was locked or sealed closed to satisfy Technical Specification 3.3.2 Action statements, may be reopened on an intermittent basis under administrative controls. These controls consist of stationing a dedicated individual at the controls of the valve, who is in continuous communication with the control room. In this way, the penetration can be rapidly isolated when a need for primary containment isolation is indicated.

3/4.3.3 EMERGENCY CORE COOLING SYSTEM ACTUATION INSTRUMENTATION

The emergency core cooling system actuation instrumentation is provided to initiate actions to mitigate the consequences of accidents that are beyond the ability of the operator to control. This specification provides the OPERABILITY requirements, trip setpoints and response times that will ensure effectiveness of the systems to provide the design protection. Although the instruments are listed by system, in some cases the same instrument may be used to send the actuation signal to more than one system at the same time.

3/4.3.3 EMERGENCY CORE COOLING ACTUATION INSTRUMENTATION (Continued)

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30936P, Parts 1 and 2, "Technical Specification Improvement Methodology (with Demonstration for BWR ECCS Actuation Instrumentation)," as approved by the NRC and documented in the SER (letter to D. N. Grace from A. C. Thadani dated December 9, 1988 (Part 1) and letter to D. N. Grace from C. E. Rossi dated December 9, 1988 (Part 2)).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Successful operation of the required safety functions of the Emergency Core Cooling Systems (ECCS) is dependent upon the availability of adequate power for energizing various components such as pump motors, motor operated valves, and the associated control components. If the loss of power instrumentation detects that voltage levels are too low, the buses are disconnected from the offsite power sources and connected to the onsite diesel generator (DG) power sources. The loss of power relays in each channel have sufficient overlapping detection characteristics and functionality to permit operation subject to the conditions in Action Statement 37. Bases 3/4.8.1, 3/4.8.2, and 3/4.8.3 provide discussion regarding parametric bounds for determining operability of the offsite sources. Those Bases assume that the loss of power relays are operable. With an inoperable 127Z-11X00X relay, the grid voltage is monitored to 230kV (for the 101 Safeguard Bus Source) or 525kV (for the 201 Safeguard Bus Source) to increase the margin for the operation of the 127Z-11X00X relay.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.3.A REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC) INSTRUMENTATION

The RPV contains penetrations below the top of the active fuel (TAF) that have the potential to drain the reactor coolant inventory to below the TAF. If the water level should drop below the TAF, the ability to remove decay heat is reduced, which could lead to elevated cladding temperatures and clad perforation. Safety Limit 2.1.4 requires the RPV water level to be above the top of the active irradiated fuel at all times to prevent such elevated cladding temperatures.

Technical Specifications are required by 10 CFR 50.36 to include limiting safety system settings (LSSS) for variables that have significant safety functions. LSSS are defined by the regulation as "Where a LSSS is specified for a variable on which a safety limit has been placed, the setting must be chosen so that automatic protective actions will correct the abnormal situation before a Safety Limit (SL) is exceeded." The Analytical Limit is the limit of the process variable at which a safety action is initiated to ensure that a SL is not exceeded. Any automatic protection action that occurs on reaching the Analytical Limit therefore ensures that the SL is not exceeded. However, in practice, the actual settings for automatic protection channels must be chosen to be more conservative than the Analytical Limit to account for instrument loop uncertainties related to the setting at which the automatic protective action would actually occur. The actual settings for the automatic isolation channels are the same as those established for the same functions in OPERATIONAL CONDITIONS 1, 2, and 3 in Table 3.3.2-2, "ISOLATION ACTUATION INSTRUMENTATION SETPOINTS."

With the unit in OPERATIONAL CONDITION 4 or 5, RPV water inventory control is not required to mitigate any events or accidents evaluated in the safety analyses. RPV water inventory control is required in OPERATIONAL CONDITIONS 4 and 5 to protect Safety Limit 2.1.4 and the fuel cladding barrier to prevent the release of radioactive material should a draining event occur. Under the definition of DRAIN TIME, some penetration flow paths may be excluded from the DRAIN TIME calculation if they will be isolated by valves that will close

3/4.3.3.A RPV WATER INVENTORY CONTROL (WIC) INSTRUMENTATION (Continued)

automatically without offsite power prior to the RPV water level being equal to the TAF when actuated by RPV water level isolation instrumentation.

The purpose of the RPV Water Inventory Control Instrumentation is to support the requirements of LCO 3.5.2, "Reactor Pressure Vessel (RPV) Water Inventory Control (WIC)," and the definition of DRAIN TIME. There are functions that support automatic isolation of Residual Heat Removal (RHR) subsystem and Reactor Water Cleanup (RWCU) system penetration flow path(s) on low RPV water level.

A double-ended guillotine break of the Reactor Coolant System (RCS) is not considered in OPERATIONAL CONDITIONS 4 and 5 due to the reduced RCS pressure, reduced piping stresses, and ductile piping systems. Instead, an event is considered in which an initiating event allows draining of the RPV water inventory through a single penetration flow path with the highest flow rate, or the sum of the drain rates through multiple penetration flow paths susceptible to a common mode failure. It is assumed, based on engineering judgment, that while in OPERATIONAL CONDITIONS 4 and 5, one low pressure ECCS injection/spray subsystem can be manually initiated to maintain adequate reactor vessel water level.

As discussed in References 1, 2, 3, 4, and 5, operating experience has shown RPV water inventory to be significant to public health and safety. Therefore, RPV Water Inventory Control satisfies Criterion 4 of 10 CFR 50.36(c)(2)(ii).

Permissive and interlock setpoints are generally considered as nominal values without regard to measurement accuracy.

The specific Applicable Safety Analyses, LCO, and Applicability discussions are listed below on a Function-by-Function basis.

3/4.3.3.A RPV WATER INVENTORY CONTROL (WIC) INSTRUMENTATION (Continued)

RHR System Isolation - Reactor Vessel Water Level Low - Level 3

The definition of DRAIN TIME allows crediting the closing of penetration flow paths that are capable of being isolated by valves that will close automatically without offsite power prior to the RPV water level being equal to the TAF when actuated by RPV water level isolation instrumentation. The Reactor Vessel Water Level Low - Level 3 Function associated with RHR System isolation may be credited for automatic isolation of penetration flow paths associated with the RHR System.

Reactor Vessel Water Level Low - Level 3 signals are initiated from four level transmitters that sense the difference between the pressure due to a constant column of water (reference leg) and the pressure due to the actual water level (variable leg) in the vessel. While four channels (two channels per trip system) of the Reactor Vessel Water Level Low - Level 3 Function are available, only two channels (all in the same trip system) are required to be OPERABLE.

The Reactor Vessel Water Level Low - Level 3 Allowable Value was chosen to be the same as the Primary Containment Isolation Instrumentation Reactor Vessel Water Level Low - Level 3 Allowable Value (Table 3.3.2-2), since the capability to cool the fuel may be threatened.

The Reactor Vessel Water Level Low - Level 3 Function is only required to be OPERABLE when automatic isolation of the associated penetration flow path is credited in calculating DRAIN TIME. This Function isolates the Group 2 valves.

Reactor Water Cleanup (RWCU) System Isolation - Reactor Vessel Water Level - Low, Low - Level 2

The definition of DRAIN TIME allows crediting the closing of penetration flow paths that are capable of being isolated by valves that will close automatically without offsite power prior to the RPV water level being equal to the TAF when actuated by RPV water level isolation instrumentation. The Reactor

3/4.3.3.A RPV WATER INVENTORY CONTROL (WIC) INSTRUMENTATION (Continued)

Vessel Water Level - Low, Low - Level 2 Function associated with RWCU System isolation may be credited for automatic isolation of penetration flow paths associated with the RWCU System. Reactor Vessel Water Level - Low, Low - Level 2 signals are initiated from four level transmitters that sense the difference between the pressure due to a constant column of water (reference leg) and the pressure due to the actual water level (variable leg) in the vessel. While four channels (two channels per trip system) of the Reactor Vessel Water Level - Low, Low - Level 2 Function are available, only two channels (all in the same trip system) are required to be OPERABLE.

The Reactor Vessel Water Level - Low, Low - Level 2 Allowable Value was chosen to be the same as the Primary Containment Isolation Instrumentation Reactor Vessel Water Level - Low, Low Level 2 Allowable Value (Table 3.3.2-2), since the capability to cool the fuel may be threatened.

The Reactor Vessel Water Level - Low, Low Level 2 Function is only required to be OPERABLE when automatic isolation of the associated penetration flow path is credited in calculating DRAIN TIME. This Function isolates the Group 3 valves.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Actions

A note has been provided to modify the ACTIONs related to RPV Water Inventory Control instrumentation channels. The ACTIONs for inoperable RPV Water Inventory Control instrumentation channels provide appropriate compensatory measures for each inoperable RPV Water Inventory Control instrumentation channel.

ACTION a. directs taking the appropriate ACTION referenced in Table 3.3.3.A-1. The applicable ACTION referenced in the table is Function dependent.

RHR System Shutdown Cooling Mode Isolation, Reactor Vessel Water Level Low - Level 3, and Reactor Water Cleanup System Isolation, Reactor Vessel Water Level - Low, Low - Level 2 functions are applicable when automatic isolation of the associated penetration flow path is credited in calculating DRAIN TIME. If the instrumentation is inoperable, ACTION 38 directs immediate action to place the channel in trip. With the inoperable channel in the tripped condition, the remaining channel will isolate the penetration flow path on low water level. If both channels are inoperable and placed in trip, the penetration flow path will be isolated. Alternatively, ACTION 38 requires the associated penetration flow path(s) to be immediately declared incapable of automatic isolation and directs initiating action to calculate of DRAIN TIME. The calculation cannot credit automatic isolation of the affected penetration flow paths.

3/4.3.3.4 RECIRCULATION PUMP TRIP ACTUATION INSTRUMENTATION

The anticipated transient without scram (ATWS) recirculation pump trip system provides a means of limiting the consequences of the unlikely occurrence of a failure to scram during an anticipated transient. The response of the plant to this postulated event falls within the envelope of study events in General Electric Company Topical Report NEDO-1Ø349, dated March 1971, NEDO-24222, dated December 1979, and Section 15.8 of the FSAR.

The end-of-cycle recirculation pump trip (EOC-RPT) system is a supplement to the reactor trip. During turbine trip and generator load rejection events, the EOC-RPT will reduce the likelihood of reactor vessel level decreasing to level 2. Each EOC-RPT system trips both recirculation pumps, reducing coolant flow in order to reduce the void collapse in the core during two of the most limiting pressurization events. The two events for which the EOC-RPT protective feature will function are closure of the turbine stop valves and fast closure of the turbine control valves.

A fast closure sensor from each of two turbine control valves provides input to the EOC-RPT system; a fast closure sensor from each of the other two turbine control valves provides input to the second EOC-RPT system. Similarly, a position switch for each of two turbine stop valves provides input to one EOC-RPT system; a position switch from each of the other two stop valves provides input to the other EOC-RPT system. For each EOC-RPT system, the sensor relay contacts are arranged to form a 2-out-of-2 logic for the fast closure of turbine control valves and a 2-out-of-2 logic for the turbine stop valves. The operation of either logic will actuate the EOC-RPT system and trip both recirculation pumps.

3/4.3.4 RECIRCULATION PUMP TRIP ACTUATION INSTRUMENTATION (Continued)

Each EOC-RPT system may be manually bypassed by use of a keyswitch which is administratively controlled. The manual bypasses and the automatic Operating Bypass at less than 29.5% of RATED THERMAL POWER are annunciated in the control room.

The EOC-RPT system response time is the time assumed in the analysis between initiation of valve motion and complete suppression of the electric arc, i.e., 175 ms. Included in this time are: the response time of the sensor, the time allotted for breaker arc suppression, and the response time of the system logic.

3/4.3.4 RECIRCULATION PUMP TRIP ACTUATION INSTRUMENTATION (Continued)

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with GENE-770-06-1, "Bases for Changes to Surveillance Test Intervals and Allowed Out-of-Service Times for Selected Instrumentation Technical Specifications," as approved by the NRC and documented in the SER (letter to R.D. Binz, IV, from C.E. Rossi dated July 21, 1992).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.5 REACTOR CORE ISOLATION COOLING SYSTEM ACTUATION INSTRUMENTATION

The reactor core isolation cooling system actuation instrumentation is provided to initiate actions to assure adequate core cooling in the event of reactor isolation from its primary heat sink and the loss of feedwater flow to the reactor vessel. This instrumentation does not provide actuation of any of the emergency core cooling equipment.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been specified in accordance with recommendations made by GE in their letter to the BWR Owner's Group dated August 7, 1989, SUBJECT: "Clarification of Technical Specification changes given in ECCS Actuation Instrumentation Analysis."

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.6 CONTROL ROD BLOCK INSTRUMENTATION

The control rod block functions are provided consistent with the requirements of the specifications in Section 3/4.1.4, Control Rod Program Controls and Section 3/4.2 Power Distribution Limits and Section 3/4.3 Instrumentation. The trip logic is arranged so that a trip in any one of the inputs will result in a control rod block.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30851P, Supplement 1, "Technical Specification Improvement Analysis for BWR Control Rod Block Instrumentation," as approved by the NRC and documented in the SER (letter to D. N. Grace from C. E. Rossi dated September 22, 1988).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.7 MONITORING INSTRUMENTATION

3/4.3.7.1 RADIATION MONITORING INSTRUMENTATION

The OPERABILITY of the radiation monitoring instrumentation ensures that: (1) the radiation levels are continually measured in the areas served by the individual channels, and (2) the alarm or automatic action is initiated when the radiation level trip setpoint is exceeded, and (3) sufficient information is available on selected plant parameters to monitor and assess these variables following an accident. This capability is consistent with 10 CFR Part 50, Appendix A, General Design Criteria 19, 41, 60, 61, 63, and 64.

The surveillance interval for the Main Control Room Normal Fresh Air Supply Radiation Monitor is determined in accordance with the Surveillance Frequency Control Program.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

3/4.3.7.2 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE UFSAR.

3/4.3.7.3 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM.

3/4.3.7.4 REMOTE SHUTDOWN SYSTEM

The OPERABILITY of the remote shutdown system ensures that sufficient capability is available to permit shutdown and maintenance of HOT SHUTDOWN of the unit from locations outside of the control room. This capability is required in the event control room habitability is lost and is consistent with General Design Criterion 19 of 10 CFR Part 50, Appendix A.

The systems/functions for which the RSP provides remote instrumentation and controls to accomplish this purpose are as follows:

- Reactor Core Isolation Cooling (RCIC) system to maintain reactor vessel water level.
- Main steam line safety/relief valves (manual actuation) to reduce reactor vessel pressure.
- Nuclear boiler instrumentation to monitor reactor vessel pressure and level.
- Residual Heat Removal (RHR) system for suppression pool cooling and shutdown cooling.
- RHR Service Water system to supply cooling water to the RHR heat exchanger.
- Emergency Service Water (ESW) system to supply cooling water to RCIC and RHR room coolers, RHR motor oil and seal coolers, and the emergency diesel generator.
- Containment and suppression pool system monitoring instrumentation.
- Standby AC power that supplies power to the above systems.

3/4.3.7.5 ACCIDENT MONITORING INSTRUMENTATION

The OPERABILITY of the accident monitoring instrumentation ensures that sufficient information is available on selected plant parameters to monitor and assess important variables following an accident. This capability is consistent with the recommendations of Regulatory Guide 1.97, "Instrumentation for Light Water Cooled Nuclear Power Plants to Assess Plant Conditions During and Following an Accident," December 1975 and NUREG-0737, "Clarification of TMI Action Plan Requirements," November 1980.

Table 3.3.7.5-1, Accident Monitoring Instrumentation, Item 2, requires two OPERABLE channels of Reactor Vessel Water Level monitoring from each of two overlapping instrumentation loops to ensure monitoring of Reactor Vessel Water Level over the range of -350 inches to +60 inches. Each channel is comprised of one OPERABLE Wide Range Level instrument loop (-150 inches to +60 inches) and one OPERABLE Fuel Zone Range instrument loop (-350 inches to -100 inches). Both instrument loops, Wide Range and Fuel Zone Range, are required by Tech. Spec. 3.3.7.5 to provide sufficient overlap to bound the required range as described in UFSAR Section 7.5. Action 80 is applicable if the required number of instrument loops per channel (Wide Range and Fuel Zone Range) is not maintained.

3/4.3.7.5 ACCIDENT MONITORING INSTRUMENTATION (continued)

Table 3.3.7.5-1, Accident Monitoring Instrumentation, Item 13, requires two OPERABLE channels of Neutron Flux monitoring from each of three overlapping instrumentation loops to ensure monitoring of Neutron Flux over the range of 10^{-6}% to 100% full power. Each channel is comprised of one OPERABLE SRM (10^{-9}% to 10^{-3}% power), one OPERABLE IRM (10^{-4}% to 40% power) and one OPERABLE APRM (0% to 125% power). All three instrument loops, SRM, IRM and APRM, are required by Tech. Spec. 3.3.7.5 to provide sufficient overlap to bound the required range as described in UFSAR Section 7.5. Action 80 is applicable if the required number of instrument loops per channel (SRM, IRM, and APRM) is not maintained.

3/4.3.7.6 SOURCE RANGE MONITORS

The source range monitors provide the operator with information of the status of the neutron level in the core at very low power levels during startup and shutdown. At these power levels, reactivity additions shall not be made without this flux level information available to the operator. When the intermediate range monitors are on scale, adequate information is available without the SRMs and they can be retracted.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

3/4.3.7.8 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4.3.7.9 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

(INTENTIONALLY LEFT BLANK)

3/4.3.7.10 (Deleted)

3/4.3.7.11 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM.

3/4.3.7.12 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM AND THE TRM.

3/4.3.8 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE UFSAR.

3/4.3.9 FEEDWATER/MAIN TURBINE TRIP SYSTEM ACTUATION INSTRUMENTATION

The feedwater/main turbine trip system actuation instrumentation is provided to initiate action of the feedwater system/main turbine trip system in the event of failure of feedwater controller under maximum demand.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

APRM CONFIGURATION

(INTENTIONALLY LEFT BLANK)

3/4.4.1 RECIRCULATION SYSTEM

The impact of single recirculation loop operation upon plant safety is assessed and shows that single-loop operation is permitted if the MCPR(99.9%) is increased as noted in the COLR, APRM scram and control rod block setpoints are adjusted as noted in Tables 2.2.1-1 and 3.3.6-2, respectively.

An inoperable jet pump is not, in itself, a sufficient reason to declare a recirculation loop inoperable, but it does, in case of a design-basis-accident, increase the blowdown area and reduce the capability of reflooding the core; thus, the requirement for shutdown of the facility with a jet pump inoperable. Jet pump failure can be detected by monitoring jet pump performance on a prescribed schedule for significant degradation.

Additionally, surveillance on the pump speed of the operating recirculation loop is imposed to exclude the possibility of excessive internals vibration. The surveillance on differential temperatures below 30% RATED THERMAL POWER or 50% rated recirculation loop flow is to mitigate the undue thermal stress on vessel nozzles, recirculation pump and vessel bottom head during the extended operation of the single recirculation loop mode.

Surveillance of recirculation loop flow, total core flow, and diffuser-to-lower plenum differential pressure is designed to detect significant degradation in jet pump performance that precedes jet pump failure. This surveillance is required to be performed only when the loop has forced recirculation flow since surveillance checks and measurements can only be performed during jet pump operation. The jet pump failure of concern is a complete mixer displacement due to jet pump beam failure. Jet pump plugging is also of concern since it adds flow resistance to the recirculation loop. Significant degradation is indicated if the specified criteria confirm unacceptable deviations from established patterns or relationships. Since refueling activities (fuel assembly replacement or shuffle, as well as any modifications to fuel support orifice size or core plate bypass flow) can affect the relationship between core flow, jet pump flow, and recirculation loop flow, these relationships may need to be re-established each cycle. Similarly, initial entry into extended single loop operation may also require establishment of these relationships. During the initial weeks of operation under such conditions, while base-lining new "established patterns," engineering judgment of the daily surveillance results is used to detect significant abnormalities which could indicate a jet pump failure.

The recirculation pump speed operating characteristics (pump flow and loop flow versus pump speed) are determined by the flow resistance from the loop suction through the jet pump nozzles. A change in the relationship indicates a plug, flow restriction, loss in pump hydraulic performance, leakage, or new flow path between the recirculation pump discharge and jet pump nozzle. For this criterion, the pump flow and loop flow versus pump speed relationship must be verified.

3/4.4.1 RECIRCULATION SYSTEM (continued)

Individual jet pumps in a recirculation loop normally do not have the same flow. The unequal flow is due to the drive flow manifold, which does not distribute flow equally to all risers. The flow (or jet pump diffuser to lower plenum differential pressure) pattern or relationship of one jet pump to the loop average is repeatable. An appreciable change in this relationship is an indication that increased (or reduced) resistance has occurred in one of the jet pumps. This may be indicated by an increase in the relative flow for a jet pump that has experienced beam cracks.

The deviations from normal are considered indicative of a potential problem in the recirculation drive flow or jet pump system. Normal flow ranges and established jet pump flow and differential pressure patterns are established by plotting historical data.

Recirculation pump speed mismatch limits are in compliance with the ECCS LOCA analysis design criteria for two recirculation loop operation. The limits will ensure an adequate core flow coastdown from either recirculation loop following a LOCA. In the case where the mismatch limits cannot be maintained during two loop operation, continued operation is permitted in a single recirculation loop mode.

In order to prevent undue stress on the vessel nozzles and bottom head region, the recirculation loop temperatures shall be within 50°F of each other prior to startup of an idle loop. The loop temperature must also be within 50°F of the reactor pressure vessel coolant temperature to prevent thermal shock to the recirculation pump and recirculation nozzles. Sudden equalization of a temperature difference > 145°F between the reactor vessel bottom head coolant and the coolant in the upper region of the reactor vessel by increasing core flow rate would cause undue stress in the reactor vessel bottom head.

3/4.4.2 SAFETY/RELIEF VALVES

The safety valve function of the safety/relief valves operates to prevent the reactor coolant system from being pressurized above the Safety Limit of 1325 psig in accordance with the ASME Code. A total of 12 OPERABLE safety/relief valves is required to limit reactor pressure to within ASME III allowable values for the worst case upset transient.

Demonstration of the safety/relief valve lift settings will occur only during shutdown. The safety/relief valves will be removed and either set pressure tested or replaced with spares which have been previously set pressure tested and stored in accordance with manufacturers recommendations at the frequency specified in the Surveillance Frequency Control Program.

3/4.4.3 REACTOR COOLANT SYSTEM LEAKAGE

3/4.4.3.1 LEAKAGE DETECTION SYSTEMS

BACKGROUND

UFSAR Safety Design Basis (Ref. 1), requires means for detecting and, to the extent practical, identifying the location of the source of Reactor Coolant System (RCS) PRESSURE BOUNDARY LEAKAGE. Regulatory Guide 1.45, Revision 0, (Ref. 2) describes acceptable methods for selecting leakage detection systems.

Limits on leakage from the reactor coolant pressure boundary (RCPB) are required so that appropriate action can be taken before the integrity of the RCPB is impaired (Ref. 2). Leakage detection systems for the RCS are provided to alert the operators when leakage rates above normal background levels are detected and also to supply quantitative measurement of leakage rates. In addition to meeting the OPERABILITY requirements, the monitors are typically set to provide the most sensitive response without causing an excessive number of spurious alarms.

Systems for quantifying the leakage are necessary to provide prompt and quantitative information to the operators to permit them to take immediate corrective action. Leakage from the RCPB inside the drywell is detected by at least one of four (4) independently monitored variables which include drywell sump flow monitoring equipment with the required RCS leakage detection instrumentation (i.e., the drywell floor drain sump flow monitoring system, or, the drywell equipment drain sump monitoring system with the drywell floor drain sump overflowing to the drywell equipment drain sump), drywell gaseous radioactivity, drywell unit cooler condensate flow rate and drywell pressure/temperature levels. The primary means of quantifying leakage in the drywell is the drywell sump monitoring system for UNIDENTIFIED LEAKAGE and the drywell equipment drain tank flow monitoring system for IDENTIFIED LEAKAGE. IDENTIFIED leakage is not germane to this Tech Spec and the associated drywell equipment drain tank flow monitoring system is not included.

The drywell floor drain sump flow monitoring system monitors UNIDENTIFIED LEAKAGE collected in the floor drain sump. UNIDENTIFIED LEAKAGE consists of leakage from RCPB components inside the drywell which are not normally subject to leakage and otherwise routed to the drywell equipment drain sump. The primary containment floor drain sump has transmitters that supply level indication to the main control room via the plant monitoring system. The floor drain sump level transmitters are associated with High/Low level switches that open/close the sump tank drain valves automatically. The level instrument processing unit calculates an average leak rate (gpm) for a given measurement period which resets whenever the sump drain valve closes. The level processing unit provides an alarm to the main control room each time the average leak rate changes by a predetermined value since the last time the alarm was reset. For the drywell floor drain sump flow monitoring system, the setpoint basis is a 1 gpm change in UNIDENTIFIED LEAKAGE.

An alternate to the drywell floor drain sump flow monitoring system for quantifying UNIDENTIFIED LEAKAGE is the drywell equipment drain sump monitoring system, if the drywell floor drain sump is overflowing to the drywell equipment drain sump. In this configuration, the drywell equipment drain sump collects all leakage into the drywell equipment drain sump and the overflow from the drywell floor drain sump. Therefore, if the drywell floor drain sump is overflowing to the drywell equipment drain sump, the drywell equipment drain sump monitoring system can be used to quantify UNIDENTIFIED LEAKAGE. In this condition, all leakage measured by the drywell equipment drain sump monitoring system is assumed to be UNIDENTIFIED LEAKAGE. The leakage determination process, including the transition to and use of the alternate method is described in station procedures. The alternate method would only be used when the drywell floor drain sump flow monitoring system is unavailable.

In addition to the drywell sump monitoring system described above, the discharge of each sump is monitored by an independent flow element. The measured flow rate from the flow element is integrated and recorded. A main control room alarm is also provided to indicate an excessive sump discharge rate measured via the flow element. This system, referred to as the “drywell floor drain flow totalizer”, is not credited for drywell floor drain sump flow monitoring system operability.

BACKGROUND (Continued)

The primary containment atmospheric gaseous radioactivity monitoring system continuously monitors the primary containment atmosphere for gaseous radioactivity levels. A sudden increase of radioactivity, which may be attributed to RCPB steam or reactor water leakage, is annunciated in the main control room.

Condensate from the eight drywell air coolers is routed to the drywell floor drain sump and is monitored by a series of flow transmitters that provide indication and alarms in the main control room. The outputs from the flow transmitters are added together by summing units to provide a total continuous condensate drain flow rate. The high flow alarm setpoint is based on condensate drain flow rate in excess of 1 gpm over the currently identified preset leak rate. The drywell air cooler condensate flow rate monitoring system serves as an added indicator, but not quantifier, of RCS UNIDENTIFIED LEAKAGE (Ref. 4).

The drywell temperature and pressure monitoring systems provide an indirect method for detecting RCPB leakage. A temperature and/or pressure rise in the drywell above normal levels may be indicative of a reactor coolant or steam leakage (Ref. 5).

APPLICABLE SAFETY ANALYSES

A threat of significant compromise to the RCPB exists if the barrier contains a crack that is large enough to propagate rapidly. Leakage rate limits are set low enough to detect the leakage emitted from a single crack in the RCPB (Refs. 6 and 7).

A control room alarm allows the operators to evaluate the significance of the indicated leakage and, if necessary, shut down the reactor for further investigation and corrective action. The allowed leakage rates are well below the rates predicted for critical crack sizes (Ref. 7). Therefore, these actions provide adequate responses before a significant break in the RCPB can occur.

RCS leakage detection instrumentation satisfies Criterion 1 of the NRC Policy Statement.

LIMITING CONDITION FOR OPERATION (LCO)

This LCO requires instruments of diverse monitoring principles to be OPERABLE to provide confidence that small amounts of UNIDENTIFIED LEAKAGE are detected in time to allow actions to place the plant in a safe condition, when RCS leakage indicates possible RCPB degradation.

The LCO requires four instruments to be OPERABLE.

The required instrumentation to quantify UNIDENTIFIED LEAKAGE from the RCS consists of either the drywell floor drain sump flow monitoring system, or, the drywell equipment drain sump monitoring system with the drywell floor drain sump overflowing to the drywell equipment drain sump. For either system to be considered operable, the flow monitoring portion of the system must be operable. The identification of an increase in UNIDENTIFIED LEAKAGE will be delayed by the time required for the UNIDENTIFIED LEAKAGE to travel to the drywell floor drain sump and it may take longer than one hour to detect a 1 gpm increase in UNIDENTIFIED LEAKAGE, depending on the origin and magnitude of the leakage. This sensitivity is acceptable for containment sump monitor OPERABILITY.

The reactor coolant contains radioactivity that, when released to the primary containment, can be detected by the gaseous primary containment atmospheric radioactivity monitor. A radioactivity detection system is included for monitoring gaseous activities because of its sensitivity and rapid response to RCS leakage, but it has recognized limitations. Reactor coolant radioactivity levels will be low during initial reactor startup and for a few weeks thereafter, until activated corrosion products have been formed and fission products appear from fuel element cladding contamination or cladding defects. If there are few fuel element cladding defects and low levels of activation products, it may not be possible for the gaseous primary

LIMITING CONDITION FOR OPERATION (LCO) (Continued)

containment atmospheric radioactivity monitor to detect a 1 gpm increase within 1 hour during normal operation. However, the gaseous primary containment atmospheric radioactivity monitor is OPERABLE when it is capable of detecting a 1 gpm increase in UNIDENTIFIED LEAKAGE within 1 hour given an RCS activity equivalent to that assumed in the design calculations for the monitors (Reference 9).

The LCO is satisfied when monitors of diverse measurement means are available. Thus, the drywell floor drain sump monitoring system in combination with a gaseous primary containment atmospheric radioactivity monitor, a primary containment air cooler condensate flow rate monitoring system, and a primary containment pressure and temperature monitoring system provides an acceptable minimum.

APPLICABILITY

In OPERATIONAL CONDITIONS 1, 2, and 3, leakage detection systems are required to be OPERABLE to support LCO 3.4.3.2. This applicability is consistent with that for LCO 3.4.3.2.

ACTIONS

A. With the primary containment atmosphere gaseous monitoring system inoperable, grab samples of the primary containment atmosphere must be taken and analyzed to provide periodic leakage information. [Provided a sample is obtained and analyzed once every 12 hours, the plant may be operated for up to 30 days to allow restoration of the radioactivity monitoring system. The plant may continue operation since other forms of drywell leakage detection are available.]

   The 12 hour interval provides periodic information that is adequate to detect leakage. The 30 day Completion Time for Restoration recognizes other forms of leakage detection are available.

B. With required drywell sump monitoring system inoperable, no other form of sampling can provide the equivalent information to quantify leakage at the required 1 gpm/hour sensitivity. However, the primary containment atmospheric gaseous monitor [and the primary containment air cooler condensate flow rate monitor] will provide indication of changes in leakage.

   With required drywell sump monitoring system inoperable, drywell condensate flow rate monitoring frequency increased from 12 to every 8 hours, and UNIDENTIFIED LEAKAGE and total leakage being determined every 8 hours (Ref. SR 4.4.3.2.1.b) operation may continue for 30 days. To the extent practical, the surveillance frequency change associated with the drywell condensate flow rate monitoring system, makes up for the loss of the drywell floor drain monitoring system which had a normal surveillance requirement to monitor leakage every 8 hours. Also note that in this instance, the drywell floor drain tank flow totalizer will be used to comply with SR 4.4.3.2.1.b. The 30 day Completion Time of the required ACTION is acceptable, based on operating experience, considering the multiple forms of leakage detection that are still available.

C. With the required primary containment air cooler condensate flow rate monitoring system inoperable, SR 4.4.3.1.a must be performed every 8 hours to provide periodic information of activity in the primary containment of more frequent interval than the routine frequency of every 12 hours. The 8 hour interval provides periodic information that is adequate to detect leakage and recognizes that other forms of leakage detection are available. The required ACTION has been clarified to state

ACTIONS (Continued)

that the additional surveillance requirement is not applicable if the required primary containment atmosphere gaseous radioactivity monitoring system is also inoperable. Consistent with SR 4.0.3, surveillances are not required to be performed on inoperable equipment. In this case, ACTION Statement A. and E. requirements apply.

D. With the primary containment pressure and temperature monitoring system inoperable, operation may continue for up to 30 days given the system's indirect capability to detect RCS leakage. However, other more limiting Tech Spec requirements associated with the primary containment pressure/temperature monitoring system will still apply.

E. With both the primary containment atmosphere gaseous radioactivity monitor and the primary containment air cooler condensate flow rate monitor inoperable, the only means of detecting leakage is the drywell floor drain sump monitor and the drywell pressure/temperature instrumentation. This condition does not provide the required diverse means of leakage detection. The required ACTION is to restore either of the inoperable monitors to OPERABLE status within 30 days to regain the intended leakage detection diversity. The 30 day Completion Time ensures that the plant will not be operated in a degraded configuration for a lengthy time period. While the primary containment atmosphere gaseous radioactivity monitor is INOPERABLE, primary containment atmospheric grab samples will be taken and analyzed every 12 hours since ACTION Statement A. requirements also apply.

F. With the drywell floor drain sump monitoring system inoperable and the drywell unit coolers condensate flow rate monitoring system inoperable, one of the two remaining means of detecting leakage is the primary containment atmospheric gaseous radiation monitor. The primary containment atmospheric gaseous radiation monitor typically cannot detect a 1 gpm leak within one hour when RCS activity is low. Indirect methods of monitoring RCS leakage must be implemented. Grab samples of the primary containment atmosphere must be taken and analyzed and monitoring of RCS leakage by administrative means must be performed every 12 hours to provide alternate periodic information.

Administrative means of monitoring RCS leakage include monitoring and trending parameters that may indicate an increase in RCS leakage. There are diverse alternative mechanisms from which appropriate indicators may be selected based on plant conditions. It is not necessary to utilize all of these methods, but a method or methods should be selected considering the current plant conditions and historical or expected sources of UNIDENTIFIED LEAKAGE. The administrative methods are the drywell cooling fan inlet/outlet temperatures, drywell equipment drain sump temperature indicator, drywell equipment drain tank hi temperature indicator, and drywell equipment drain tank flow indicator. These indications, coupled with the atmospheric grab samples, are sufficient to alert the operating staff to an unexpected increase in UNIDENTIFIED LEAKAGE.

In addition to the primary containment atmospheric gaseous radiation monitor and indirect methods of monitoring RCS leakage, the primary containment pressure and temperature monitoring system is also available to alert the operating staff to an unexpected increase in UNIDENTIFIED LEAKAGE.

ACTIONS (Continued)

The 12 hour interval is sufficient to detect increasing RCS leakage. The Required Action provides 7 days to restore another RCS leakage monitor to OPERABLE status to regain the intended leakage detection diversity. The 7-day Completion Time ensures that the plant will not be operated in a degraded configuration for a lengthy time period.

G. If any required ACTION of Conditions A, B, C, D, E or F cannot be met within the associated Completion Time, the plant must be brought to an OPERATIONAL CONDITION in which the LCO does not apply. To achieve this status, the plant must be brought to at least HOT SHUTDOWN within 12 hours and COLD SHUTDOWN within the next 24 hours. The allowed Completion Times are reasonable, based on operating experience, to perform the ACTIONS in an orderly manner and without challenging plant systems.

SURVEILLANCE REQUIREMENTS

SR 4.4.3.1.a
This SR is for the performance of a CHANNEL CHECK of the required primary containment atmospheric monitoring system. The check gives reasonable confidence that the channel is operating properly.

SR 4.4.3.1.b
This SR is for the performance of a CHANNEL FUNCTIONAL TEST of the required RCS leakage detection instrumentation. The test ensures that the monitors can perform their function in the desired manner. The test also verifies the alarm setpoint and relative accuracy of the instrument string. A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

SR 4.4.3.1.c
The SR is for the performance of a CHANNEL CALIBRATION of required leakage detection instrumentation channels. The calibration verifies the accuracy of the instrument string, including the instruments located inside containment.

SR 4.4.3.1.d
This SR provides a routine check of primary containment pressure and temperature for indirect evidence of RCS leakage.

3/4.4.3.2 OPERATIONAL LEAKAGE

The allowable leakage rates from the reactor coolant system have been based on the predicted and experimentally observed behavior of cracks in pipes. The normally expected background leakage due to equipment design and the detection capability of the instrumentation for determining system leakage was also considered. The evidence obtained from experiments suggests that for leakage somewhat greater than that specified for UNIDENTIFIED LEAKAGE the probability is small that the imperfection or crack associated with such leakage would grow rapidly. However, in all cases, if the leakage rates exceed the values specified, the reactor will be shutdown to allow further investigation and corrective action. The limit of 2 gpm increase in UNIDENTIFIED LEAKAGE over a 24-hour period and the monitoring of drywell floor drain sump and drywell equipment drain tank flow rate at least once every eight (8) hours conforms with NRC staff positions specified in NRC Generic Letter 88-01, "NRC Position on IGSCC in BWR Austenitic Stainless Steel Piping," as revised by NRC Safety Evaluation dated March 6, 1990. The ACTION requirement for the 2 gpm increase in UNIDENTIFIED LEAKAGE limit ensures that such leakage is identified or a plant shutdown is initiated to allow further investigation and corrective action. Separating the sources of LEAKAGE (i.e., LEAKAGE from an identified source versus LEAKAGE from an unidentified source) is necessary for prompt identification of potentially adverse conditions, assessment of the safety significance, and corrective action. Once identified, reactor operation may continue dependent upon the impact on total leakage.

PRESSURE BOUNDARY LEAKAGE is prohibited as the leak itself could cause further reactor coolant pressure boundary deterioration, resulting in higher leakage. If PRESSURE BOUNDARY LEAKAGE exists, the affected component, pipe, or vessel must be isolated from the reactor coolant system by a closed manual valve, closed and de-activated automatic valve, blind flange, or check valve within 4 hours. While in this condition, structural integrity of the system should be considered because the structural integrity of the part of the system within the isolation boundary must be maintained under all licensing basis conditions, including consideration of the potential for further degradation of the isolated location. Normal leakage past the isolation device is acceptable as it will limit reactor coolant system leakage and is included in IDENTIFIED LEAKAGE or UNIDENTIFIED LEAKAGE. This ACTION is necessary to prevent further deterioration of the reactor coolant pressure boundary. If the ACTION cannot be completed in the required time, then the reactor will be shutdown to allow further investigation and corrective action.

The function of Reactor Coolant System Pressure Isolation Valves (PIVs) is to separate the high pressure Reactor Coolant System from an attached low pressure system. The ACTION requirements for pressure isolation valves are used in conjunction with the system specifications for which PIVs are listed in the Technical Requirements Manual and with primary containment isolation valve requirements to ensure that plant operation is appropriately limited.

The Surveillance Requirements for the RCS pressure isolation valves provide added assurance of valve integrity thereby reducing the probability of gross valve failure and consequent intersystem LOCA. Leakage from the RCS pressure isolation valves is not included in any other allowable operational leakage specified in Section 3.4.3.2.

3/4.4.4 (Deleted) INFORMATION FROM THIS SECTION RELOCATED TO THE TRM

3/4.4.4 (Deleted) INFORMATION FROM THIS SECTION RELOCATED TO THE TRM

3/4.4.5 SPECIFIC ACTIVITY

The limitations on the specific activity of the primary coolant ensure that the 2 hour thyroid and whole body doses resulting from a main steam line failure outside the containment during steady state operation will not exceed small fractions of the dose guidelines of 10 CFR Part 100. The values for the limits on specific activity represent interim limits based upon a parametric evaluation by the NRC of typical site locations. These values are conservative in that specific site parameters, such as SITE BOUNDARY location and meteorological conditions, were not considered in this evaluation.

The ACTION statement permitting POWER OPERATION to continue for limited time periods with the primary coolant's specific activity greater than 0.2 microcurie per gram DOSE EQUIVALENT I-131, but less than or equal to 4 microcuries per gram DOSE EQUIVALENT I-131, accommodates possible iodine spiking phenomenon which may occur following changes in the THERMAL POWER. This action is modified by a Note that permits the use of the provisions of Specification 3.0.4.c. This allowance permits entry into the applicable OPERATIONAL CONDITION (S) while relying on the ACTION requirements. Operation with specific activity levels exceeding 0.2 microcurie per gram DOSE EQUIVALENT I-131 but less than or equal to 4 microcuries per gram DOSE EQUIVALENT I-131 must be restricted since these activity levels increase the 2-hour thyroid dose at the SITE BOUNDARY following a postulated steam line rupture.

Closing the main steam line isolation valves prevents the release of activity to the environs should a steam line rupture occur outside containment. The surveillance requirements provide adequate assurance that excessive specific activity levels in the reactor coolant will be detected in sufficient time to take corrective action.

3/4.4.6 PRESSURE/TEMPERATURE LIMITS

All components in the reactor coolant system are designed to withstand the effects of cyclic loads due to system temperature and pressure changes. These cyclic loads are introduced by normal load transients, reactor trips, and startup and shutdown operations. The various categories of load cycles used for design purposes are provided in Section 3.9 of the FSAR. During startup and shutdown, the rates of temperature and pressure changes are limited so that the maximum specified heatup and cooldown rates are consistent with the design assumptions and satisfy the stress limits for cyclic operation.

INTENTIONALLY LEFT BLANK

PRESSURE/TEMPERATURE LIMITS (Continued)

The operating limit curves specified in the PTLR are derived from the fracture toughness requirements of 10 CFR 50 Appendix G and ASME Code Section XI, Appendix G. The curves are based on the RT_{NDT} and stress intensity factor information for the reactor vessel components. Fracture toughness limits and the basis for compliance are more fully discussed in FSAR Chapter 5, Paragraph 5.3.1.5, "Fracture Toughness."

The reactor vessel materials have been tested to determine their initial RT_{NDT}. The results of these tests are specified in the PTLR. Reactor operation and resultant fast neutron, E greater than 1 MeV, irradiation will cause an increase in the RT_{NDT}. Therefore, an adjusted reference temperature, based upon the fluence, nickel content and copper content of the material in question, can be predicted using the PTLR and the recommendations of Regulatory Guide 1.99, Revision 2, "Radiation Embrittlement of Reactor Vessel Materials." The pressure/temperature limit curves specified in the PTLR include an assumed shift in RT_{NDT} for the conditions at 57 EFPY.

The pressure-temperature limit lines specified in the PTLR for reactor criticality and for inservice leak and hydrostatic testing have been provided to assure compliance with the minimum temperature requirements of Appendix G to 10 CFR Part 50 for reactor criticality and for inservice leak and hydrostatic testing.

3/4.4.7 MAIN STEAM LINE ISOLATION VALVES

Double isolation valves are provided on each of the main steam lines to minimize the potential leakage paths from the containment in case of a line break. Only one valve in each line is required to maintain the integrity of the containment, however, single failure considerations require that two valves be OPERABLE. The surveillance requirements are based on the operating history of this type valve. The maximum closure time has been selected to contain fission products and to ensure the core is not uncovered following line breaks. The minimum closure time is consistent with the assumptions in the safety analyses to prevent pressure surges.

3/4.4.8 (DELETED)

3/4.4.9 RESIDUAL HEAT REMOVAL

The RHR system is required to remove decay heat and sensible heat in order to maintain the temperature of the reactor coolant. RHR shutdown cooling is comprised of four (4) subsystems which make two (2) loops. Each loop consists of two (2) motor driven pumps, a heat exchanger, and associated piping and valves. Both loops have a common suction from the same recirculation loop. Two (2) redundant, manually controlled shutdown cooling subsystems of the RHR System can provide the required decay heat removal capability. Each pump discharges the reactor coolant, after it has been cooled by circulation through the respective heat exchangers, to the reactor via the associated recirculation loop or to the reactor via the low pressure coolant injection pathway. The RHR heat exchangers transfer heat to the RHR Service Water System. The RHR shutdown cooling mode is manually controlled.

An OPERABLE RHR shutdown cooling subsystem consists of an RHR pump, a heat exchanger, valves, piping, instruments, and controls to ensure an OPERABLE flow path. In HOT SHUTDOWN condition, the requirement to maintain OPERABLE two (2) independent RHR shutdown cooling subsystems means that each subsystem considered OPERABLE must be associated with a different heat exhanger loop, i.e., the "A" RHR heat exchanger with the "A" RHR pump or the "C" RHR pump, and the "B" RHR heat exchanger with the "B" RHR pump or the "D" RHR pump are two (2) independent RHR shutdown cooling subsystems. Only one (1) of the two (2) RHR pumps associated with each RHR heat exchanger loop is

3/4.4.9 RESIDUAL HEAT REMOVAL (Continued)

required to be OPERABLE for that independent subsystem to be OPERABLE. During COLD SHUTDOWN and REFUELING conditions, however, the subsystems not only have a common suction source, but are allowed to have a common heat exchanger and common discharge piping. To meet the LCO of two (2) OPERABLE subsystems, both pumps in one (1) loop or one (1) pump in each of the two (2) loops must be OPERABLE. Since the piping and heat exchangers are passive components, that are assumed not to fail, they are allowed to be common to both subsystems. Additionally, each RHR shutdown cooling subsystem is considered OPERABLE if it can be manually aligned (remote or local) in the shutdown cooling mode for removal of decay heat. Operation (either continuous or intermittent) of one (1) subsystem can maintain and reduce the reactor coolant temperature as required. However, to ensure adequate core flow to allow for accurate average reactor coolant temperature monitoring, nearly continuous operation is required. Management of gas voids is important to RHR Shutdown Cooling System OPERABILITY.

Alternate decay heat removal methods are available to operators. These alternate methods of decay heat removal can be verified available either by calculation (which includes a review of component and system availability to verify that an alternate decay heat removal method is available) or by demonstration, and that a method of coolant mixing be operational. Decay heat removal capability by ambient losses can be considered in evaluating alternate decay heat removal capability.

RHR Shutdown Cooling System piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the RHR shutdown cooling subsystems and may also prevent water hammer, pump cavitation, and pumping of non-condensable gas into the reactor vessel. This surveillance verifies that the RHR Shutdown Cooling System piping is sufficiently filled with water prior to initially placing the system in operation during reactor shutdown. The RHR Shutdown Cooling System is OPERABLE when it is sufficiently filled with water to ensure that it can reliably perform its intended function.

The RHR Shutdown Cooling System is a manually initiated mode of the RHR System whose use is typically preceded by system piping flushes that disturb both the RHR pump suction and discharge piping. RHR Shutdown Cooling System is flushed and manually aligned for service using system operating procedures that ensure the RHR shutdown cooling suction and discharge flow paths are sufficiently filled with water. In the event that RHR Shutdown Cooling is required for emergency service, the system operating procedures that align and start the RHR System in shutdown cooling mode include the flexibility to eliminate piping flushes while maintaining minimum requirements to ensure that the suction and discharge flow paths are sufficiently filled with water. The RHR Shutdown Cooling System surveillance is met through the performance of the operating procedures that initially place the RHR shutdown cooling sub-system in service.

This surveillance requirement is modified by a Note allowing sufficient time (12 hours) to align the RHR System for Shutdown Cooling operation after reactor dome pressure is less than the RHR cut-in permissive set point.

INFORMATION CONTAINED ON THIS PAGE HAS BEEN DELETED

INFORMATION CONTAINED ON THIS PAGE HAS BEEN DELETED

3/4.5.1 ECCS - OPERATING

The core spray system (CSS), together with the LPCI mode of the RHR system, is provided to assure that the core is adequately cooled following a loss-of-coolant accident and provides adequate core cooling capacity for all break sizes up to and including the double-ended reactor recirculation line break, and for smaller breaks following depressurization by the ADS. Management of gas voids is important to ECCS injection/spray subsystem OPERABILITY.

The CSS is a primary source of emergency core cooling after the reactor vessel is depressurized and a source for flooding of the core in case of accidental draining.

The surveillance requirements provide adequate assurance that the CSS will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation through a test loop during reactor operation, a complete functional test requires reactor shutdown.

The low pressure coolant injection (LPCI) mode of the RHR system is provided to assure that the core is adequately cooled following a loss-of-coolant accident. Four subsystems, each with one pump, provide adequate core flooding for all break sizes up to and including the double-ended reactor recirculation line break, and for small breaks following depressurization by the ADS.

The surveillance requirements provide adequate assurance that the LPCI system will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation through a test loop during reactor operation, a complete functional test requires reactor shutdown.

The CCS pump flow of 3,175 gpm and the LPCI pump flow of 10,000 gpm are flow values at nominal grid frequency of 60 Hz. The 10 CFR 50.46 LOCA Analysis of Record (AOR) uses 80% of the prescribed TS SR flow values (2,500 and 8,000 respectively). The calculated TS SR flow rates at the reduced Emergency Diesel Generator minimum steady-state voltage of 4,160 V and 59.8 Hz, when off site power is not available, demonstrate that the ECCS flow rates used in the LOCA analysis are bounding and satisfy SRs 4.5.1.b.1 and 4.5.1.b.2.

The high pressure coolant injection (HPCI) system is provided to assure that the reactor core is adequately cooled to limit fuel clad temperature in the event of a small break in the reactor coolant system and loss of coolant which does not result in rapid depressurization of the reactor vessel. The HPCI system permits the reactor to be shut down while maintaining sufficient reactor vessel water level inventory until the vessel is depressurized. The HCPI system continues to operate until reactor vessel pressure is below the pressure at which CSS operation or LPCI mode of the RHR system operation maintains core cooling.

The capacity of the system is selected to provide the required core cooling. The HPCI pump is designed to deliver greater than or equal to 5600 gpm at reactor pressures between 1182 and 200 psig and is capable of delivering at least 5000 gpm between 1182 and 1205 psig. In the system's normal alignment, water from the condensate storage tank is used instead of injecting water from the suppression pool into the reactor, but no credit is taken in the safety analyses for the condensate storage tank water.

ECCS - OPERATING (Continued)

With the HPCI system inoperable, adequate core cooling is assured by the OPERABILITY of the redundant and diversified automatic depressurization system and both the CS and LPCI systems. In addition, the reactor core isolation cooling (RCIC) system, a system for which no credit is taken in the safety analysis, will automatically provide makeup at reactor operating pressures on a reactor low water level condition. The HPCI out-of-service period of 14 days is based on the demonstrated OPERABILITY of redundant and diversified low pressure core cooling systems and the RCIC system. The HPCI system, and one LPCI subsystem, and/or one CSS subsystem out-of-service period of 8 hours ensures that sufficient ECCS, comprised of a minimum of one CSS subsystem, three LPCI subsystems, and all of the ADS will be available to 1) provide for safe shutdown of the facility, and 2) mitigate and control accident conditions within the facility. Alternatively, the out-of-service times described above can be determined in accordance with the Risk Informed Completion Time Program. A Note prohibits the application of Specification 3.0.4.b to an inoperable HPCI subsystem. There is an increased risk associated with entering an OPERATIONAL CONDITION or other specified condition in the Applicability with an inoperable HPCI subsystem and the provisions of Specification 3.0.4.b, which allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, should not be applied in this circumstance.

The surveillance requirements provide adequate assurance that the HPCI system will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation through a test loop during reactor operation, a complete functional test with reactor vessel injection requires reactor shutdown.

During plant startup, when HPCI surveillance tests are being performed, the HPCI System is required to be tested within 12 hours after reactor pressure is adequate to perform each surveillance test. For the low reactor pressure surveillance requirement, the intent is to verify HPCI System operability prior to increasing reactor pressure above 215 psig. If operability of the HPCI System is not demonstrated within the 12-hour period, reactor steam dome pressure must be reduced to less than 200 psig within the following 72 hours. For the high reactor pressure surveillance test, the intent is to verify HPCI System operability as soon as possible once plant conditions support the testing. Power ascension can continue during the testing; however, if HPCI is found inoperable or the 12-hour period has elapsed power ascension must be stopped, and reactor steam dome pressure must be reduced to less than 200 psig within the following 72 hours.

The ECCS injection/spray subsystem flow path piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the ECCS injection/spray subsystems and may also prevent a water hammer, pump cavitation, and pumping of noncondensible gas into the reactor vessel.

Selection of ECCS injection/spray subsystem locations susceptible to gas accumulation is based on a review of system design information, including piping and instrumentation drawings, isometric drawings, plan and elevation drawings, and calculations. The design review is supplemented by system walk downs to validate the system high points and to confirm the location and orientation of important components that can become sources of gas or could otherwise cause gas to be trapped or difficult to remove during system maintenance or restoration. Susceptible locations depend on plant and system configuration, such as stand-by versus operating conditions.

The ECCS injection/spray subsystem is OPERABLE when it is sufficiently filled with water. Acceptance criteria are established for the volume of accumulated gas at susceptible locations. If accumulated gas is discovered that exceeds the acceptance criteria for the susceptible location (or the volume of accumulated gas at one or more susceptible locations exceeds an acceptance criteria for gas volume at the suction or discharge of a pump), the Surveillance is not met. Accumulated gas should be eliminated or brought within the acceptance criteria limits. ECCS injection/spray

ECCS - OPERATING (Continued)

subsystem locations susceptible to gas accumulation are monitored and, if gas is found, the gas volume is compared to the acceptance criteria for the location. Susceptible locations in the same system flow path which are subject to the same gas intrusion mechanisms may be verified by monitoring a representative subset of susceptible locations. Monitoring may not be practical for locations that are inaccessible due to radiological or environmental conditions, the plant configuration, or personnel safety. For these locations alternative methods (e.g., operating parameters, remote monitoring) may be used to monitor the susceptible location. Monitoring is not required for susceptible locations where the maximum potential accumulated gas void volume has been evaluated and determined to not challenge system OPERABILITY. The accuracy of the method used for monitoring the susceptible locations and trending of the results should be sufficient to assure system OPERABILITY during the Surveillance interval.

Surveillance 4.5.1.a.1.b is modified by a Note which exempts system vent flow paths opened under administrative control. The administrative control should be proceduralized and include stationing a dedicated individual at the system vent flow path who is in continuous communication with the operators in the control room. This individual will have a method to rapidly close the system vent flow path if directed.

Upon failure of the HPCI system to function properly after a small break loss-of-coolant accident, the automatic depressurization system (ADS) automatically causes selected safety/relief valves to open, depressurizing the reactor so that flow from the low pressure core cooling systems can enter the core in time to limit fuel cladding temperature to less than 2200°F. ADS is conservatively required to be OPERABLE whenever reactor vessel pressure exceeds 100 psig. This pressure is substantially below that for which the low pressure core cooling systems can provide adequate core cooling for events requiring ADS.

SR 4.5.1.c.1 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

ADS automatically controls five selected safety-relief valves. The safety analysis assumes all five are operable. The allowed out-of-service time for one valve for up to fourteen days is determined in a similar manner to other ECCS subsystem out-of-service time allowances. Alternatively, the allowed out-of-service time can be determined in accordance with the Risk Informed Completion Time Program.

Verification that ADS accumulator gas supply header pressure is ≥90 psig ensures adequate gas pressure for reliable ADS operation. The accumulator on each ADS valve provides pneumatic pressure for valve actuation. The design pneumatic supply pressure requirements for the accumulator are such that, following a failure of the pneumatic supply to the accumulator at least two valve actuations can occur with the drywell at 70% of design pressure. The ECCS safety analysis assumes only one actuation to achieve the depressurization required for operation of the low pressure ECCS. This minimum required pressure of ≥90 psig is provided by the PCIG supply.

3/4.5.2 - REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC)

Background:

The RPV contains penetrations below the top of the active fuel (TAF) that have the potential to drain the reactor coolant inventory to below the TAF. If the water level should drop below the TAF, the ability to remove decay heat is reduced, which could lead to elevated cladding temperatures and clad perforation. Safety Limit 2.1.4 requires the RPV water level to be above the top of the active irradiated fuel at all times to prevent such elevated cladding temperatures.

Applicable Safety Analysis:

With the unit in OPERATIONAL CONDITION 4 or 5, RPV water inventory control is not required to mitigate any events or accidents evaluated in the safety analyses. RPV water inventory control is required in OPERATIONAL CONDITIONS 4 and 5 to protect Safety Limit 2.1.4 and the fuel cladding barrier to prevent the release of radioactive material to the environment should an unexpected draining event occur.

A double-ended guillotine break of the Reactor Coolant System (RCS) is not considered in OPERATIONAL CONDITIONS 4 and 5 due to the reduced RCS pressure, reduced piping stresses, and ductile piping systems. Instead, an event is considered in which an initiating event allows draining of the RPV water inventory through a single penetration flow path with the highest flow rate, or the sum of the drain rates through multiple penetration flow paths susceptible to a common mode failure (an event that creates a drain path through multiple vessel penetrations located below top of active fuel, such as loss of normal power, or a single human error). It is assumed, based on engineering judgement, that while in OPERATIONAL CONDITIONS 4 and 5, one low pressure ECCS injection/spray subsystem can maintain adequate reactor vessel water level.

As discussed in References 1, 2, 3, 4, and 5, operating experience has shown RPV water inventory to be significant to public health and safety. Therefore, RPV Water Inventory Control satisfies Criterion 4 of 10 CFR 50.36(c)(2)(ii).

Limiting Condition for Operation:

The RPV water level must be controlled in OPERATIONAL CONDITIONS 4 and 5 to ensure that if an unexpected draining event should occur, the reactor coolant water level remains above the top of the active irradiated fuel as required by Safety Limit 2.1.4.

The Limiting Condition for Operation (LCO) requires the DRAIN TIME of RPV water inventory to the TAF to be $\geq$ 36 hours. A DRAIN TIME of 36 hours is considered reasonable to identify and initiate action to mitigate unexpected draining of reactor coolant. An event that could cause loss of RPV water inventory and result in the RPV water level reaching the TAF in greater than 36 hours does not represent a significant challenge to Safety Limit 2.1.4 and can be managed as part of normal plant operation.

One low pressure ECCS injection/spray subsystem is required to be OPERABLE and capable of being manually aligned and started from the control room to provide defense-in-depth should an unexpected draining event occur. OPERABILITY of the ECCS injection/spray subsystem includes any necessary valves, instrumentation, or controls needed to manually align and start the subsystem from the control room. A low pressure ECCS injection/spray subsystem consists of either one Core Spray System (CSS) subsystem or one Low Pressure Coolant Injection (LPCI) subsystem. Each CSS subsystem consists of two motor driven pumps, piping, and valves to transfer water from the suppression pool or condensate storage tank (CST) to the RPV. Each LPCI subsystem consists of one motor driven pump, piping, and valves to transfer water from the suppression pool to the RPV.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The LCO is modified by a note which allows a required LPCI subsystem to be considered OPERABLE during alignment and operation for decay heat removal if capable of being manually realigned (remote or local) to the LPCI mode and is not otherwise inoperable. Alignment and operation for decay heat removal includes when the required RHR pump is not operating or when the system is realigned from or to the RHR shutdown cooling mode. This allowance is necessary since the RHR System may be required to operate in the shutdown cooling mode to remove decay heat and sensible heat from the reactor. Because of the restrictions on DRAIN TIME, sufficient time will be available following an unexpected draining event to manually align and initiate LPCI subsystem operation to maintain RPV water inventory prior to the RPV water level reaching the TAF.

Applicability:

RPV water inventory control is required in OPERATIONAL CONDITIONS 4 and 5. Requirements on water inventory control are contained in LCO 3.3.3.A, REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC) INSTRUMENTATION, and LCO 3.5.2, REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC). RPV water inventory control is required to protect Safety Limit 2.1.4 which is applicable whenever irradiated fuel is in the reactor vessel.

Actions:

Action a. - If none of the required low pressure ECCS injection/spray subsystems are OPERABLE, one subsystem must be restored to OPERABLE status within 4 hours. In this condition, the LCO controls on DRAIN TIME minimize the possibility that an unexpected draining event could necessitate the use of the ECCS injection/spray subsystem; however, the defense-in-depth provided by the ECCS injection/spray subsystem is lost. The 4-hour allowed outage time for restoring the required low pressure ECCS injection/spray subsystem to OPERABLE status is based on engineering judgment that considers the LCO controls on DRAIN TIME and the low probability of an unexpected draining event that would result in loss of RPV water inventory.

If the inoperable ECCS injection/spray subsystem is not restored to OPERABLE status within 4 hours, action must be initiated immediately to establish a method of water injection capable of operating without offsite electrical power. The method of water injection includes the necessary instrumentation and controls, water sources, and pumps and valves needed to add water to the RPV or refueling cavity should an unexpected draining event occur. The method of water injection may be manually initiated and may consist of one or more systems or subsystems, and must be able to access water inventory capable of maintaining the RPV water level above the TAF for $\geq$ 36 hours. If recirculation of injected water would occur, it may be credited in determining the necessary water volume.

Action b. - Deleted

Action c. - With the DRAIN TIME less than 36 hours but greater than or equal to 8 hours, compensatory measures should be taken to ensure the ability to implement mitigating actions should an unexpected draining event occur. Should a draining event lower the reactor coolant level to below the TAF, there is potential for damage to the reactor fuel cladding and release of radioactive material. Additional actions are taken to ensure that radioactive material will be contained, diluted, and processed prior to being released to the environment.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The secondary containment provides a controlled volume in which fission products can be contained, diluted, and processed prior to release to the environment. Verification of the capability to establish SECONDARY CONTAINMENT INTEGRITY in less than the DRAIN TIME is required. The required verification confirms actions to establish SECONDARY CONTAINMENT INTEGRITY are preplanned and necessary materials are available. SECONDARY CONTAINMENT INTEGRITY is considered established when one Standby Gas Treatment (SGT) subsystem is capable of maintaining a negative pressure in the secondary containment with respect to the environment. Verification that SECONDARY CONTAINMENT INTEGRITY can be established must be performed within 4 hours. The required verification is an administrative activity and does not require manipulation or testing of equipment.

Secondary containment penetration flow paths form a part of SECONDARY CONTAINMENT INTEGRITY. Verification of the capability to isolate each secondary containment penetration flow path in less than the DRAIN TIME is required. The required verification confirms actions to isolate secondary containment penetration flow paths are preplanned and necessary materials are available. Power operated valves are not required to receive automatic isolation signals if they can be closed manually within the required time. Verification that secondary containment penetration flow paths can be isolated must be performed within 4 hours. The required verification is an administrative activity and does not require manipulation or testing of equipment.

One SGT subsystem is capable of maintaining the secondary containment at a negative pressure with respect to the environment and filter gaseous releases. Verification of the capability to place one SGT subsystem in operation in less than the DRAIN TIME is required. The required verification confirms actions to place a SGT subsystem in operation are preplanned and necessary materials are available. Verification that a SGT subsystem can be placed in operation must be performed within 4 hours. The required verification is an administrative activity and does not require manipulation or testing of equipment.

Action d. - With the DRAIN TIME less than 8 hours, mitigating actions are implemented in case an unexpected draining event should occur. Note that if the DRAIN TIME is less than 1 hour, the required Action e. to restore DRAIN TIME to 36 hours or greater is also applicable.

Immediate action to establish an additional method of water injection augmenting the ECCS injection/spray subsystem required by the LCO is required. The additional method of water injection includes the necessary instrumentation and controls, water sources, and pumps and valves needed to add water to the RPV or refueling cavity should an unexpected draining event occur. The note states that either the ECCS injection/spray subsystem or the additional method of water injection must be capable of operating without offsite electrical power. The additional method of water injection may be manually initiated and may consist of one or more systems or subsystems. The additional method of water injection must be able to access water inventory capable of being injected to maintain the RPV water level above the TAF for $\geq$ 36 hours. The additional method of water injection and the ECCS injection/spray subsystem may share all or part of the same water sources. If recirculation of injected water would occur, it may be credited in determining the required water volume.

Should a draining event lower the reactor coolant level to below the TAF, there is potential for damage to the reactor fuel cladding and release of radioactive material. Additional actions are taken to ensure that radioactive material will be contained, diluted, and processed prior to being released to the environment.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The secondary containment provides a control volume into which fission products can be contained, diluted, and processed prior to release to the environment. Actions to immediately establish SECONDARY CONTAINMENT INTEGRITY are required. With SECONDARY CONTAINMENT INTEGRITY established, one SGT subsystem is capable of maintaining a negative pressure in the secondary containment with respect to the environment.

The secondary containment penetrations form a part of SECONDARY CONTAINMENT INTEGRITY. Actions to immediately verify that each secondary containment penetration flow path is isolated or to verify that it can be automatically or manually isolated from the control room are required.

One SGT subsystem is capable of maintaining the secondary containment at a negative pressure with respect to the environment and filter gaseous releases. Actions to immediately verify that at least one SGT subsystem is capable of being placed in operation are required. The required verification is an administrative activity and does not require manipulation or testing of equipment.

Action e. - If the ACTIONs and associated allowed outage times are not met or if the DRAIN TIME is less than 1 hour, actions must be initiated immediately to restore the DRAIN TIME to ≥ 36 hours. In this condition, there may be insufficient time to respond to an unexpected draining event to prevent the RPV water inventory from reaching the TAF. Note that ACTIONs are also applicable when DRAIN TIME is less than 1 hour.

Surveillance Requirements:

Surveillance Requirement (SR) 4.5.2.1 verifies that the DRAIN TIME of RPV water inventory to the TAF is ≥ 36 hours. The period of 36 hours is considered reasonable to identify and initiate action to mitigate draining of reactor coolant. Loss of RPV water inventory that would result in the RPV water level reaching the TAF in greater than 36 hours does not represent a significant challenge to Safety Limit 2.1.4 and can be managed as part of normal plant operation.

The definition of DRAIN TIME states that realistic cross-sectional areas and drain rates are used in the calculation. A realistic drain rate may be determined using a single, step-wise, or integrated calculation considering the changing RPV water level during a draining event. For a control rod RPV penetration flow path with the control rod drive mechanism removed and not replaced with a blank flange, the realistic cross-sectional area is based on the control rod blade seated in the control rod guide tube. If the control rod blade will be raised from the penetration to adjust or verify seating of the blade, the exposed cross-sectional area of the RPV penetration flow path is used.

The definition of DRAIN TIME excludes from the calculation those penetration flow paths connected to an intact closed system, or isolated by manual or automatic valves that are closed and administratively controlled, blank flanges, or other devices that prevent flow of reactor coolant through the penetration flow paths. A blank flange or other bolted device must be connected with a sufficient number of bolts to prevent draining. Normal or expected leakage from closed systems or past isolation devices is permitted. Determination that a system is intact and closed or isolated must consider the status of branch lines.

The Residual Heat Removal (RHR) Shutdown Cooling System is only considered an intact closed system when misalignment issues (Reference 6) have been precluded by functional valve interlocks or by isolation devices, such that redirection of RPV water out of an RHR subsystem is precluded. Further, the RHR Shutdown Cooling System is only considered an intact closed system if its controls have not been transferred to Remote Shutdown, which disables the interlocks and isolation signals.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The exclusion of a single penetration flow path, or multiple penetration flow paths susceptible to a common mode failure, from the determination of DRAIN TIME should consider the effects of temporary alterations in support of maintenance (rigging, scaffolding, temporary shielding, piping plugs, freeze seals, etc.). If reasonable controls are implemented to prevent such temporary alterations from causing a draining event from a closed system or between the RPV and the isolation device, the effect of the temporary alterations on DRAIN TIME need not be considered. Reasonable controls include, but are not limited to, controls consistent with the guidance in NUMARC 93-01, "Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," Revision 4, NUMARC 91-06, "Guidelines for Industry Actions to Assess Shutdown Management," or commitments to NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants."

TS 4.0.1 requires SRs to be met between performances. Therefore, any changes in plant conditions that would change the DRAIN TIME requires that a new DRAIN TIME be determined.

SRs 4.5.2.2 and 4.5.2.3 - The minimum water level of 16 feet required for the suppression pool is periodically verified to ensure that the suppression pool will provide adequate net positive suction head (NPSH) for the CSS subsystem or LPCI subsystem pumps, recirculation volume, and vortex prevention. With the suppression pool water level less than the required limit, the required ECCS injection/spray subsystem is inoperable unless aligned to an OPERABLE CST.

The required CSS subsystem is OPERABLE if it can take suction from the CST, and the CST water level is sufficient to provide the required NPSH for the CSS pumps. Therefore, a verification that either the suppression pool water level is greater than or equal to 16 feet 0 inches or that a CSS subsystem is aligned to take suction from the CST and the CST contains greater than or equal to 135,000 available gallons of water, equivalent to a level of 29 feet 0 inches, ensures that the CSS subsystem can supply the required makeup water to the RPV.

SR 4.5.2.4 - The flow path piping has the potential to develop voids and pockets of entrained air. Maintaining the pump discharge lines of the required ECCS injection/spray subsystems full of water ensures that the ECCS subsystem will perform properly. This may also prevent a water hammer following an ECCS actuation. One acceptable method of ensuring that the lines are full is to vent at the high points.

SR 4.5.2.5 - DELETED

SR 4.5.2.6 - Verifying that the required ECCS injection/spray subsystem can be manually aligned, and the pump started and operate for at least 10 minutes demonstrates that the subsystem is available to mitigate a draining event. This surveillance requirement is modified by two footnotes. The first states that testing the ECCS injection/spray subsystem may be done through the test return line to avoid overfilling the refueling cavity. The second states that credit for meeting the surveillance requirement may be taken for normal system operation that satisfies the surveillance requirement, such as using the RHR mode of LPCI for greater than or equal to 10 minutes. The minimum operating time of 10 minutes was based on engineering judgement.

SR 4.5.2.7 and 4.5.2.8 exclude automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SRs do not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the applicable SR has been met within its required Frequency.

SR 4.5.2.7 - Verifying that each valve credited for automatically isolating a penetration flow path actuates to the isolation position on an actual or simulated RPV water level isolation signal is required to prevent RPV water inventory from dropping below the TAF should an unexpected draining event occur.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

SR 4.5.2.8 - This surveillance verifies that a required CSS subsystem or LPCI subsystem can be manually aligned and started from the control room, including any necessary valve alignment, instrumentation, or controls, to transfer water from the suppression pool or CST to the RPV.

The Surveillance Frequencies in the above SRs are controlled under the Surveillance Frequency Controlled Program.

3/4.5.3 SUPPRESSION CHAMBER

The suppression chamber is required to be OPERABLE as part of the ECCS to ensure that a sufficient supply of water is available to the HPCI, CS and LPCI systems in the event of a LOCA. This limit on suppression chamber minimum water volume ensures that sufficient water is available to permit recirculation cooling flow to the core. The OPERABILITY of the suppression chamber in OPERATIONAL CONDITION 1, 2, or 3 is also required by Specification 3.6.2.1.

BASES

3/4.6.1 PRIMARY CONTAINMENT

3/4.6.1.1 PRIMARY CONTAINMENT INTEGRITY

PRIMARY CONTAINMENT INTEGRITY ensures that the release of radioactive materials from the containment atmosphere will be restricted to those leakage paths and associated leak rates assumed in the safety analyses. This restriction, in conjunction with the leakage rate limitation, will limit the SITE BOUNDARY radiation doses to within the limits of 10 CFR Part 100 during accident conditions.

3/4.6.1.2 PRIMARY CONTAINMENT LEAKAGE

The limitations on primary containment leakage rates ensure that the total containment leakage volume will not exceed the value calculated in the safety analyses at the design basis LOCA maximum peak containment pressure of 44 psig, Pa. As an added conservatism, the measured overall integrated leakage rate (Type A Test) is further limited to less than or equal to 0.75 La during performance of the periodic tests to account for possible degradation of the containment leakage barriers between leakage tests.

Operating experience with the main steam line isolation valves has indicated that degradation has occasionally occurred in the leak tightness of the valves; therefore the special requirement for testing these valves.

The surveillance testing for measuring leakage rates is consistent with the Primary Containment Leakage Rate Testing Program.

Limerick has an approved license amendment to implement 10 CFR 50.69, “Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors”, and may voluntarily comply with the treatment requirements of 10 CFR 50.69 as an alternative to compliance with the Type B and Type C leakage testing requirements of 10 CFR 50, Appendix J for Risk-Informed Safety Classification (RISC) RISC-3 or RISC-4 penetrations and valves meeting the following criteria:

A. Containment penetrations that are either 1-inch nominal size or less, or continuously pressurized.
B. Containment isolation valves that meet one or more of the following criteria.
   1. The valve is required to be open under accident conditions to prevent or mitigate core damage events;
   2. The valve is normally closed and in a physically closed, water-filled system;
   3. The valve is in a physically closed system whose piping pressure rating exceeds the containment design pressure rating and is not connected to the reactor coolant pressure boundary; or
   4. The valve is 1-inch nominal size or less.

RISC-3 penetrations and valves that meet the criteria above may be removed from the scope of the Primary Containment Leakage Rate Testing Program, as implemented by Technical Specifications 3.6.1, 4.6.1 and 6.8.4.g. Alternative Treatment will be implemented in accordance with the requirements of 10 CFR 50.69(d).

3/4.6.1.3 PRIMARY CONTAINMENT AIR LOCK

The limitations on closure and leak rate for the primary containment air lock are required to meet the restrictions on PRIMARY CONTAINMENT INTEGRITY and the Primary Containment Leakage Rate Testing Program. Only one closed door in the air lock is required to maintain the integrity of the containment.

3/4.6.1.4 MSIV LEAKAGE ALTERNATE DRAIN PATHWAY

Calculated doses resulting from the maximum leakage allowances for the main steamline isolation valves in the postulated LOCA situations will not exceed the criteria of 10 CFR Part 100 guidelines, provided the main steam line system from the isolation valves up to and including the turbine condenser remains intact. Operating experience has indicated that degradation has occasionally occurred in the leak tightness of the MSIVs such that the specified leakage requirements have not always been continuously maintained. The requirement for the MSIV Leakage Alternate Drain Pathway serves to reduce the offsite dose.

3/4.6.1.5 PRIMARY CONTAINMENT STRUCTURAL INTEGRITY

This limitation ensures that the structural integrity of the containment will be maintained comparable to the original design standards for the life of the unit. Structural integrity is required to ensure that the containment will withstand the maximum calculated pressure in the event of a LOCA. A visual inspection in accordance with the Primary Containment Leakage Rate Testing Program is sufficient to demonstrate this capability.

3/4.6.1.6 DRYWELL AND SUPPRESSION CHAMBER INTERNAL PRESSURE

The limitations on drywell and suppression chamber internal pressure ensure that the calculated containment peak pressure does not exceed the design pressure of 55 psig during LOCA conditions or that the external pressure differential does not exceed the design maximum external pressure differential of 5.0 psid. The limit of - 1.0 to + 2.0 psig for initial containment pressure will limit the total pressure to ≤ 44 psig which is less than the design pressure and is consistent with the safety analysis.

3/4.6.1.7 DRYWELL AVERAGE AIR TEMPERATURE

The limitation on drywell average air temperature ensures that the containment peak air temperature does not exceed the design temperature of 340°F during steam line break conditions and is consistent with the safety analysis.

3/4.6.1.8 DRYWELL AND SUPPRESSION CHAMBER PURGE SYSTEM

The drywell and suppression chamber purge supply and exhaust isolation valves are required to be closed during plant operation except as required for inerting, deinerting, pressure control, ALARA or air quality considerations for personnel entry, or Surveillances that require the valves to be open. Limiting the use of the drywell and suppression chamber purge system to specific criteria is imposed to protect the integrity of the SGTS filters. Analysis indicates that should a LOCA occur while this pathway is being utilized, the associated pressure surge through the (18 or 24") purge lines will adversely affect the integrity of SGTS. This condition is not imposed on the 1 and 2 inch valves used for pressure control since a surge through these lines does not threaten the operability of SGTS.

Surveillance requirement 4.6.1.8 ensures that the primary containment purge valves are closed as required or, if open, open for an allowable reason. If a purge valve is open in violation of this SR, the valve is considered inoperable. The SR is modified by a Note stating that primary containment purge valves are only required to be closed in OPERATIONAL CONDITIONS 1, 2 and 3. The SR is also modified by a Note stating that the SR is not required to be met when the purge valves are open for the stated reasons. The Note states that these valves may be opened for inerting, deinerting, pressure control, ALARA or air quality considerations for personnel entry, or Surveillances that require the valves to be open. The 18 or 24 inch purge valves are capable of closing in the environment following a LOCA. Therefore, these valves are allowed to be open for limited periods of time.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.6.2 DEPRESSURIZATION SYSTEMS

The specifications of this section ensure that the primary containment pressure will not exceed the design pressure of 55 psig during primary system blowdown from full operating pressure. Management of gas voids is important to Suppression Pool Cooling/Spray Subsystem OPERABILITY.

The suppression chamber water provides the heat sink for the reactor coolant system energy release following a postulated rupture of the system. The suppression chamber water volume must absorb the associated decay and structural sensible heat released during reactor coolant system blowdown from rated conditions. Since all of the gases in the drywell are purged into the suppression chamber air space during a loss-of-coolant accident, the pressure of the suppression chamber air space must not exceed 55 psig. The design volume of the suppression chamber, water and air, was obtained by considering that the total volume of reactor coolant is discharged to the suppression chamber and that the drywell volume is purged to the suppression chamber.

Using the minimum or maximum water volumes given in this specification, suppression pool pressure during the design basis accident is below the design pressure. Maximum water volume of 134,600 ft^3 results in a downcomer submergence of 12'3" and the minimum volume of 122,120 ft^3 results in a submergence approximately 2'3" less. The majority of the Bodega tests were run with a submerged length of 4 feet and with complete condensation. Thus, with respect to the downcomer submergence, this specification is adequate. The maximum temperature at the end of the blowdown tested during the Humboldt Bay and Bodega Bay tests was 170°F and this is conservatively taken to be the limit for complete condensation of the reactor coolant, although condensation would occur for temperature above 170°F.

Should it be necessary to make the suppression chamber inoperable, this shall only be done as specified in Specification 3.5.3.

Under full power operating conditions, blowdown through safety/relief valves assuming an initial suppression chamber water temperature of 95°F results in a bulk water temperature of approximately 140°F immediately following blowdown which is below the 190°F bulk temperature limit used for complete condensation via T-quencher devices. At this temperature and atmospheric pressure, the available NPSH exceeds that required by both the RHR and core spray pumps, thus there is no dependency on containment overpressure during the accident injection phase. If both RHR loops are used for containment cooling, there is no dependency on containment overpressure for post-LOCA operations.

3/4.6.2 DEPRESSURIZATION SYSTEMS (Continued)

RHR Suppression Pool Cooling/Spray subsystem piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the RHR suppression pool subsystems and may also prevent water hammer and pump cavitation.

Selection of RHR Suppression Pool Cooling/Spray subsystem locations susceptible to gas accumulation is based on a review of system design information, including piping and instrumentation drawings, isometric drawings, plan and elevation drawings, and calculations. The design review is supplemented by system walk downs to validate the system high points and to confirm the location and orientation of important components that can become sources of gas or could otherwise cause gas to be trapped or difficult to remove during system maintenance or restoration. Susceptible locations depend on plant and system configuration, such as stand-by versus operating conditions.

The RHR Suppression Pool Cooling/Spray subsystem is OPERABLE when it is sufficiently filled with water. Acceptance criteria are established for the volume of accumulated gas at susceptible locations. If accumulated gas is discovered that exceeds the acceptance criteria for the susceptible location (or the volume of accumulated gas at one or more susceptible locations exceeds an acceptance criteria for gas volume at the suction or discharge of a pump), the Surveillance is not met. Accumulated gas should be eliminated or brought within the acceptance criteria limits.

RHR Suppression Pool Cooling/Spray subsystem locations susceptible to gas accumulation are monitored and, if gas is found, the gas volume is compared to the acceptance criteria for the location. Susceptible locations in the same system flow path which are subject to the same gas intrusion mechanisms may be verified by monitoring a representative subset of susceptible locations. Monitoring may not be practical for locations that are inaccessible due to radiological or environmental conditions, the plant configuration, or personnel safety. For these locations alternative methods (e.g., operating parameters, remote monitoring) may be used to monitor the susceptible location. Monitoring is not required for susceptible locations where the maximum potential accumulated gas void volume has been evaluated and determined to not challenge system OPERABILITY. The accuracy of the method used for monitoring the susceptible locations and trending of the results should be sufficient to assure system OPERABILITY during the Surveillance interval.

One of the surveillance requirements for the suppression pool cooling (SPC) mode of the RHR system is to demonstrate that each RHR pump develops a flow rate $\geq$10,000 gpm while operating in the SPC mode with flow through the heat exchanger and its associated closed bypass valve, ensuring that pump performance has not degraded during the cycle and that the flow path is operable. This test confirms one point on the pump design curve and is indicative of overall performance. Such inservice inspections confirm component operability, trend performance and detect incipient failures by indicating abnormal performance. The RHR heat exchanger bypass valve is used for adjusting flow through the heat exchanger and is not designed to be a tight shut-off valve. With the bypass valve closed, a portion of the total flow still travels through the bypass, which

3/4.6.2 DEPRESSURIZATION SYSTEMS (Continued)

can affect overall heat transfer. However, no heat transfer performance requirement of the heat exchanger is intended by the current Technical Specification surveillance requirement. This is confirmed by the lack of any flow requirement for the RHRSW system in Technical Specifications Section 3/4.7.1. Verifying an RHR flowrate through the heat exchanger does not demonstrate heat removal capability in the absence of a requirement for RHRSW flow. LGS does perform heat transfer testing of the RHR heat exchangers as part of its response to Generic Letter 89-13, which verified the commitment to meet the requirements of GDC 46.

Experimental data indicate that excessive steam condensing loads can be avoided if the peak local temperature of the suppression pool is maintained below 200°F during any period of relief valve operation for T-quencher devices. Specifications have been placed on the envelope of reactor operating conditions so that the reactor can be depressurized in a timely manner to avoid the regime of potentially high suppression chamber loadings.

Because of the large volume and thermal capacity of the suppression pool, the volume and temperature normally changes very slowly and monitoring these parameters daily is sufficient to establish any temperature trends. By requiring the suppression pool temperature to be frequently recorded during periods of significant heat addition, the temperature trends will be closely followed so that appropriate action can be taken.

In addition to the limits on temperature of the suppression chamber pool water, operating procedures define the action to be taken in the event a safety-relief valve inadvertently opens or sticks open. As a minimum this action shall include: (1) use of all available means to close the valve, (2) initiate suppression pool water cooling, (3) initiate reactor shutdown, and (4) if other safety-relief valves are used to depressurize the reactor, their discharge shall be separated from that of the stuck-open safety/relief valve to assure mixing and uniformity of energy insertion to the pool.

During a LOCA, potential leak paths between the drywell and suppression chamber airspace could result in excessive containment pressures, since the steam flow into the airspace would bypass the heat sink capabilities of the chamber. Potential sources of bypass leakage are the suppression chamber-to-drywell vacuum breakers (VBs), penetrations in the diaphragm floor, and cracks in the diaphragm floor and/or liner plate and downcomers located in the suppression chamber airspace. The containment pressure response to the postulated bypass leakage can be mitigated by manually actuating the suppression chamber sprays. An analysis was performed for a design bypass leakage area of $A/\sqrt{k}$ equal to 0.0500 ft^2 to verify that the operator has sufficient time to initiate the sprays prior to exceeding the containment design pressure of 55 psig. The limit of 10% of the design value of 0.0500 ft^2 ensures that the design basis for the steam bypass analysis is met.

THIS PAGE INTENTIONALLY LEFT BLANK

DEPRESSURIZATION SYSTEMS (Continued)

The drywell-to-suppression chamber bypass test at a differential pressure of at least 4.0 psi verifies the overall bypass leakage area for simulated LOCA conditions is less than the specified limit. For those outages where the drywell-to-suppression chamber bypass leakage test in not conducted, the VB leakage test verifies that the VB leakage area is less than the bypass limit, with a 76% margin to the bypass limit to accommodate the remaining potential leakage area through the passive structural components. Previous drywell-to-suppression chamber bypass test data indicates that the bypass leakage through the passive structural components will be much less than the 76% margin. The VB leakage limit, combined with the negligible passive structural leakage area, ensures that the drywell-to-suppression chamber bypass leakage limit is met for those outages for which the drywell-to-suppression chamber bypass test is not scheduled.

3/4.6.3 PRIMARY CONTAINMENT ISOLATION VALVES

The OPERABILITY of the primary containment isolation valves ensures that the containment atmosphere will be isolated from the outside environment in the event of a release of radioactive material to the containment atmosphere or pressurization of the containment and is consistent with the requirements of GDC 54 through 57 of Appendix A of 10 CFR Part 50. Containment isolation within the time limits specified for those isolation valves designed to close automatically ensures that the release of radioactive material to the environment will be consistent with the assumptions used in the analyses for a LOCA.

The scram discharge volume vent and drain valves serve a dual function, one of which is primary containment isolation. Since the other safety functions of the scram discharge volume vent and drain valves would not be available if the normal PCIV actions were taken, actions are provided to direct the user to the scram discharge volume vent and drain operability requirements contained in Specification 3.1.3.1. However, since the scram discharge volume vent and drain valves are PCIVs, the Surveillance Requirements of Specification 4.6.3 still apply to these valves.

The opening of a containment isolation valve that was locked or sealed closed to satisfy Technical Specification 3.6.3 Action statements, may be reopened on an intermittent basis under administrative controls. These controls consist of stationing a dedicated individual at the controls of the valve, who is in continuous communication with the control room. In this way, the penetration can be rapidly isolated when a need for primary containment isolation is indicated.

Primary containment isolation valves governed by this Technical Specification are identified in Table 3.6.3-1 of the TRM.

This Surveillance Requirement requires a demonstration that a representative sample of reactor instrument line excess flow check valves (EFCVs) is OPERABLE by verifying that the valve actuates to the isolation position on a simulated instrument line break signal. The representative sample consists of an approximately equal number of EFCVs, such that each EFCV is tested in accordance with the Surveillance Frequency Control Program. In addition, the EFCVs in the sample are representative of the various plant configurations, models, sizes, and operating environments. This ensures that any potentially common problem with a specific type or application of EFCV is detected at the earliest possible time. This Surveillance Requirement provides assurance that the instrumentation line EFCVs will perform so that predicted radiological consequences will not be exceeded during a postulated instrument line break event. Furthermore, any EFCV failures will be evaluated to determine if additional testing in the test interval is warranted to ensure overall reliability is maintained. Operating experience has demonstrated that these components are highly reliable and that failures to isolate are very infrequent. Therefore, testing of a representative sample was concluded to be acceptable from a reliability standpoint. For some EFCVs, this Surveillance can be performed with the reactor at power.

3/4.6.4 VACUUM RELIEF

Vacuum relief valves are provided to equalize the pressure between the suppression chamber and drywell. This system will maintain the structural integrity of the primary containment under conditions of large differential pressures.

The vacuum breakers between the suppression chamber and the drywell must not be inoperable in the open position since this would allow bypassing of the suppression pool in case of an accident. Two pairs of valves are required to protect containment structural integrity. There are four pairs of valves (three to provide minimum redundancy) so that operation may continue for up to 72 hours or in accordance with the Risk Informed Completion Time Program with no more than two pairs of vacuum breakers inoperable in the closed position.

Each vacuum breaker valve's position indication system is of great enough sensitivity to ensure that the maximum steam bypass leakage coefficient of

$$\frac{A}{\sqrt{k}} = 0.05 \text{ ft}^2$$

for the vacuum relief system (assuming one valve fully open) will not be exceeded.

3/4.6.5 SECONDARY CONTAINMENT

Secondary containment is designed to minimize any ground level release of radioactive material which may result from an accident. The Reactor Enclosure and associated structures provide secondary containment during normal operation when the drywell is sealed and in service. At other times the drywell may be open and, when required, secondary containment integrity is specified.

Establishing and maintaining a vacuum in the reactor enclosure secondary containment with the standby gas treatment system in accordance with the Surveillance Frequency Control Program, along with the surveillance of the doors, hatches, dampers and valves, is adequate to ensure that there are no violations of the integrity of the secondary containment.

The OPERABILITY of the reactor enclosure recirculation system and the standby gas treatment systems ensures that sufficient iodine removal capability will be available in the event of a LOCA. The reduction in containment iodine inventory reduces the resulting SITE BOUNDARY and Control Room radiation doses associated with containment leakage. The operation of these systems and resultant iodine removal capacity are consistent with the assumptions used in the LOCA analysis. Provisions have been made to continuously purge the filter plenums with instrument air when the filters are not in use to prevent buildup of moisture on the adsorbers and the HEPA filters.

As a result of the Alternative Source Term (AST) project, secondary containment integrity of the refueling area is not required during certain conditions when handling irradiated fuel or during CORE ALTERATIONS and alignment of the Standby Gas Treatment System to the refueling area is not required. The control room dose analysis for the Fuel Handling Accident (FHA) is based on unfiltered releases from the South Stack and therefore, does not require the Standby Gas Treatment System to be aligned to the refueling area.

However, when handling RECENTLY IRRADIATED FUEL, secondary containment integrity of the refueling area is required and alignment of the Standby Gas Treatment System to the refueling area is required. The AST fuel handling analysis does not include an accident involving RECENTLY IRRADIATED FUEL or an accident involving draining the reactor vessel.

The Standby Gas Treatment System is required to be OPERABLE when handling irradiated fuel, handling RECENTLY IRRADIATED FUEL and during CORE ALTERATIONS. Fuel Handling Accident releases from the North Stack must be filtered through the Standby Gas Treatment System to maintain control room doses within regulatory limits. The OPERABILITY of the Standby Gas Treatment System assures that releases, if made through the North Stack, are filtered prior to release.

SECONDARY CONTAINMENT (Continued)

Surveillances 4.6.5.1.1.a and 4.6.5.1.2.a are each modified by a footnote (*) which states the surveillance is not required to be met for up to 4 hours if an analysis demonstrates that one standby gas treatment subsystem remains capable of establishing the required secondary containment vacuum. Use of the footnote is expected to be infrequent but may be necessitated by situations in which secondary containment vacuum may be less than the required containment vacuum, such as, but not limited to, wind gusts or failure or change of operating normal ventilation subsystems. These conditions do not indicate any change in the leak tightness of the secondary containment boundary. The analysis should consider the actual conditions (equipment configuration, temperature, atmospheric pressure, wind conditions, measured secondary containment vacuum, etc.) to determine whether, if an accident requiring secondary containment to be OPERABLE were to occur, one train of standby gas treatment could establish the assumed secondary containment vacuum within the time assumed in the accident analysis. If so, the surveillance may be considered met for a period up to 4 hours. The 4-hour limit is based on the expected short duration of the situations when the footnote would be applied.

Surveillances 4.6.5.1.1.b.2 and 4.6.5.1.2.b.2 require verifying that one secondary containment personnel access door in each access opening is closed which provides adequate assurance that exfiltration from the secondary containment will not occur. An access opening contains at least one inner and one outer door. The intent is to not breach the secondary containment, which is achieved by maintaining the inner or outer personnel access door closed. Surveillances 4.6.5.1.1.b.2 and 4.6.5.1.2.b.2 provide an allowance for brief, inadvertent, simultaneous openings of redundant secondary containment personnel access doors for normal entry and exit conditions.

SR 4.6.5.3.d.2 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

Although the safety analyses assumes that the reactor enclosure secondary containment draw down time will take 930 seconds, these surveillance requirements specify a draw down time of 916 seconds. This 14 second difference is due to the diesel generator starting and sequence loading delays which is not part of this surveillance requirement.

The reactor enclosure secondary containment draw down time analyses assumes a starting point of 0.25 inch of vacuum water gauge and worst case SGTS dirty filter flow rate of 2800 cfm. The surveillance requirements satisfy this assumption by starting the drawdown from ambient conditions and connecting the adjacent reactor enclosure and refueling area to the SGTS to split the exhaust flow between the three zones and verifying a minimum flow rate of 2800 cfm from the test zone. This simulates the worst case flow alignment and verifies adequate flow is available to drawdown the test zone within the required time. The Technical Specification Surveillance Requirement 4.6.5.3.b.3 is intended to be a multi-zone air balance verification without isolating any test zone.

SECONDARY CONTAINMENT (Continued)

The SGTS fans are sized for three zones and therefore, when aligned to a single zone or two zones, will have excess capacity to more quickly drawdown the affected zones. There is no maximum flow limit to individual zones or pairs of zones and the air balance and drawdown time are verified when all three zones are connected to the SGTS.

The three zone air balance verification and drawdown test will be done after any major system alteration, which is any modification which will have an effect on the SGTS flowrate such that the ability of the SGTS to drawdown the reactor enclosure to greater than or equal to 0.25 inch of vacuum water gage in less than or equal to 916 seconds could be affected.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.6.5 SECONDARY CONTAINMENT (Continued)

The field tests for bypass leakage across the SGTS charcoal adsorber and HEPA filter banks are performed at a flow rate of 5764 ± 10% cfm. The laboratory analysis performed on the SGTS carbon samples will be tested at a velocity of 66 fpm based on the system residence time.

The SGTS filter train pressure drop is a function of air flow rate and filter conditions. Surveillance testing is performed using either the SGTS or drywell purge fans to provide operating convenience.

Each reactor enclosure secondary containment zone and refueling area secondary containment zone is tested independently to verify the design leak tightness. A design leak tightness of 2500 cfm or less for each reactor enclosure and 764 cfm or less for the refueling area at a 0.25 inch of vacuum water gage will ensure that containment integrity is maintained at an acceptable level if all zones are connected to the SGTS at the same time.

The Reactor Enclosure Secondary Containment Automatic Isolation Valves and Refueling Area Secondary Containment Automatic Isolation Valves can be found in the UFSAR.

SR 4.6.5.4.d.2 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

The post-LOCA offsite dose analysis assumes a reactor enclosure secondary containment post-draw down leakage rate of 2500 cfm and certain post-accident X/Q values. While the post-accident X/Q values represent a statistical interpretation of historical meteorological data, the highest ground level wind speed which can be associated with these values is 7 mph (Pasquill-Gifford stability Class G for a ground level release). Therefore, the surveillance requirement assures that the reactor enclosure secondary containment is verified under meteorological conditions consistent with the assumptions utilized in the design basis analysis. Reactor Enclosure Secondary Containment leakage tests that are successfully performed at wind speeds in excess of 7 mph would also satisfy the leak rate surveillance requirements, since it shows compliance with more conservative test conditions.

3/4.6.6 PRIMARY CONTAINMENT ATMOSPHERE CONTROL

The primary containment atmospheric mixing system is provided to ensure adequate mixing of the containment atmosphere to prevent localized accumulations of hydrogen and oxygen from exceeding the lower flammability limit during post-LOCA conditions.

All nuclear reactors must be designed to withstand events that generate hydrogen either due to the zirconium metal water reaction in the core or due to radiolysis. The primary method to control hydrogen is to inert the primary containment. With the primary containment inert, that is, oxygen concentration <4.0 volume percent (v/o), a combustible mixture cannot be present in the primary containment for any hydrogen concentration. The capability to inert the primary containment and maintain oxygen <4.0 v/o works together with Drywell Hydrogen Mixing System to provide redundant and diverse methods to mitigate events that produce hydrogen.

3/4.6.6 PRIMARY CONTAINMENT ATMOSPHERE CONTROL (Continued)

If oxygen concentration is ≥ 4.0 v/o at any time while operating in OPERATIONAL CONDITION 1 or 2, oxygen concentration must be restored to < 4.0 v/o within 72 hours. The 72 hour Completion Time is allowed when oxygen concentration is ≥ 4.0 v/o because of the low probability and long duration of an event that would generate significant amounts of hydrogen occurring during this period.

The provision of Specification 3.0.4.c is applicable. This allowance permits entry into the applicable OPERATIONAL CONDITION(S) while relying on the Actions. This allowance is acceptable because inerting the primary containment prevents containment access without an appropriate breathing apparatus. Therefore, the primary containment is inerted as late as possible in the plant startup, after entering OPERATIONAL CONDITIONS 1 and 2, and deinerted as soon as possible in the plant shutdown. It is acceptable to intentionally enter the Action prior to a shutdown in order to begin deinerting the primary containment prior to exiting the Applicability.

If oxygen concentration cannot be restored to within the limit within the required Completion Time, the plant must be brought to a OPERATIONAL CONDITION in which the LCO does not apply. To achieve this status, power must be reduced to HOT SHUTDOWN within 12 hours. The 12 hour Completion Time is reasonable, based on operating experience, to reduce reactor power from full power conditions in an orderly manner and without challenging plant systems.

3/4.7.1 SERVICE WATER SYSTEMS - COMMON SYSTEMS

The OPERABILITY of the service water systems ensures that sufficient cooling capacity is available for continued operation of safety-related equipment during normal and accident conditions. The redundant cooling capacity of these systems, assuming a single failure, is consistent with the assumptions used in the accident conditions within acceptable limits.

The RHRSW and ESW systems are common to Units 1 and 2 and consist of two independent subsystems each with two pumps. One pump per subsystem (loop) is powered from a Unit 1 safeguard bus and the other pump is powered from a Unit 2 safeguard bus. In order to ensure adequate onsite power sources to the systems during a loss of offsite power event, the inoperability of these supplies are restricted in system ACTION statements.

RHRSW is a manually operated system used for core and containment heat removal. Each of two RHRSW subsystems has one heat exchanger per unit. Each RHRSW pump provides adequate cooling for one RHR heat exchanger. By limiting operation with less than three OPERABLE RHRSW pumps with OPERABLE Diesel Generators, each unit is ensured adequate heat removal capability for the design scenario of LOCA/LOOP on one unit and simultaneous safe shutdown of the other unit.

Each ESW pump provides adequate flow to the cooling loads in its associated loop. With only two divisions of power required for LOCA mitigation of one unit and one division of power required for safe shutdown of the other unit, one ESW pump provides sufficient capacity to fulfill design requirements. ESW pumps are automatically started upon start of the associated Diesel Generators. Therefore, the allowable out of service times for OPERABLE ESW pumps and their associated Diesel Generators is limited to ensure adequate cooling during a loss of offsite power event. Alternatively, the allowable out-of-service times can be determined in accordance with the Risk Informed Completion Time Program.

SR 4.7.1.2.b.1 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

3/4.7.2.1 CONTROL ROOM EMERGENCY FRESH AIR SUPPLY SYSTEM - COMMON SYSTEM

The OPERABILITY of the control room emergency fresh air supply system ensures that the control room will remain habitable for occupants during and following an uncontrolled release of radioactivity, hazardous chemicals, or smoke. Constant purge of the system at 1 cfm is sufficient to reduce the buildup of moisture on the adsorbers and HEPA filters. The OPERABILITY of this system in conjunction with control room design provisions is based on limiting the radiation exposure to personnel occupying the control room to 5 rem or less Total Effective Dose Equivalent. This limitation is consistent with the requirements of 10 CFR Part 50.67, Accident Source Term.

Each CREFAS subsystem is considered OPERABLE when the individual components necessary to limit Control Room Envelope occupant exposure are OPERABLE. A subsystem is considered OPERABLE when its associated:

a. CREFAS fan is OPERABLE, and

b. HEPA filter and charcoal adsorbers are capable of performing their filtration function, and

c. Heater, ductwork, dampers, controls, and power are OPERABLE, and air circulation to the occupied areas can be maintained. Air circulation is a support system function provided by one control room AC supply fan and one control room AC return air fan, and

d. CRE boundary is OPERABLE.

Since the Control Room Emergency Fresh Air Supply System is not credited for filtration in OPERATIONAL CONDITIONS 4 and 5, applicability to 4 and 5 is only required to support the Chlorine and Toxic Gas design basis isolation requirements.

The Control Room Envelope (CRE) is the area within the confines of the CRE boundary that contains the spaces that control room occupants inhabit to control the unit during normal and accident conditions. This area encompasses the control room, and other noncritical areas including adjacent support offices, toilet and utility rooms. The CRE is protected during normal operation, natural events, and accident conditions. The CRE boundary is the combination of walls, floor, ceiling, ducting, valves, doors, penetrations and equipment that physically form the CRE. The OPERABILITY of the CRE boundary must be maintained to ensure that the inleakage of unfiltered air into the CRE will not exceed the inleakage assumed in the licensing basis analysis of design basis accident (DBA) consequences to CRE occupants. The CRE and its boundary are defined in the Control Room Envelope Habitability Program.

In addition, The CREFAS System provides protection from smoke and hazardous chemicals to the CRE occupants. The analysis of hazardous chemical releases demonstrates that the toxicity limits are not exceeded in the CRE following a hazardous chemical release (Ref. 1). The evaluation of a smoke challenge demonstrates that it will not result in the inability of the CRE occupants to control the reactor either from the control room or from the remote shutdown panels (Ref. 2).

In order for the CREFAS subsystems to be considered OPERABLE, the CRE boundary must be maintained such that the CRE occupant dose from a large radioactive release does not exceed the calculated dose in the licensing basis consequence analyses for DBAs, and that CRE occupants are protected from hazardous chemicals and smoke.

The LCO is modified by a Note allowing the CRE boundary to be opened intermittently under administrative controls. This Note only applies to openings in the CRE boundary that can be rapidly restored to the design condition, such as doors, hatches, floor plugs, and access panels. For entry and exit through doors, the administrative control of the opening is performed by the person(s) entering or exiting the area. For other openings, these controls should be proceduralized and consist of stationing a dedicated individual at the opening who is in continuous communication with the operators in the CRE. This individual will have a method to rapidly close the opening and to restore the CRE boundary to a condition equivalent to the design condition when a need for CRE isolation is indicated.

3/4.7.2.1 CONTROL ROOM EMERGENCY FRESH AIR SUPPLY SYSTEM - COMMON SYSTEM
(Continued)

If the unfiltered inleakage of potentially contaminated air past the CRE boundary and into the CRE can result in CRE occupant radiological dose greater than the calculated dose of the licensing basis analyses of DBA consequences (allowed to be up to 5 rem TEDE), or inadequate protection of CRE occupants from hazardous chemicals or smoke, the CRE boundary is inoperable. Actions must be taken to restore an OPERABLE CRE boundary within 90 days.

During the period that the CRE boundary is considered inoperable, action must be initiated immediately to implement mitigating actions to lessen the effect on CRE occupants from the potential hazards of a radiological or chemical event or a challenge from smoke. Actions must be taken within 24 hours to verify that in the event of a DBA, the mitigating actions will ensure that CRE occupant radiological exposures will not exceed the calculated dose of the licensing basis analyses of DBA consequences, and that CRE occupants are protected from hazardous chemicals and smoke. These mitigating actions (i.e., actions that are taken to offset the consequences of the inoperable CRE boundary) should be preplanned for implementation upon entry into the condition, regardless of whether entry is intentional or unintentional. The 24 hour Completion Time is reasonable based on the low probability of a DBA occurring during this time period, and the use of mitigating actions. The 90 day Completion Time is reasonable based on the determination that the mitigating actions will ensure protection of CRE occupants within analyzed limits while limiting the probability that CRE occupants will have to implement protective measures that may adversely affect their ability to control the reactor and maintain it in a safe shutdown condition in the event of a DBA. In addition, the 90 day Completion Time is a reasonable time to diagnose, plan and possibly repair, and test most problems with the CRE boundary.

SR 4.7.2.2 verifies the OPERABILITY of the CRE boundary by testing for unfiltered air inleakage past the CRE boundary and into the CRE. The details of the testing are specified in the Control Room Envelope Habitability Program.

The CRE is considered habitable when the radiological dose to CRE occupants calculated in the licensing basis analyses of DBA consequences is no more than 5 rem Total Effective Dose Equivalent and the CRE occupants are protected from hazardous chemicals and smoke. SR 4.7.2.2 verifies that the unfiltered air inleakage into the CRE is no greater than the flow rate assumed in the licensing basis analyses of DBA consequences. When unfiltered air inleakage is greater than the assumed flow rate, Required Action 3.7.2.a.2 must be entered. Required Action 3.7.2.a.2.c allows time to restore the CRE boundary to OPERABLE status provided mitigating actions can ensure that the CRE remains within the licensing basis habitability limits for the occupants following an accident. Compensatory measures are discussed in Regulatory Guide 1.196, Section C.2.7.3, (Ref. 3) which endorses, with exceptions, NEI 99-03, Section 8.4 and Appendix F (Ref. 4). These compensatory measures may also be used as mitigating actions as required by Required Action 3.7.2.a.2.b. Temporary analytical methods may also be used as compensatory measures to restore OPERABILITY (Ref. 5). Options for restoring the CRE boundary to OPERABLE status include changing the licensing basis DBA consequence analysis, repairing the CRE boundary, or a combination of these actions. Depending upon the nature of the problem and the corrective action, a full scope inleakage test may not be necessary to establish that the CRE boundary has been restored to OPERABLE status.

3/4.7.2.2 CONTROL ROOM AIR CONDITIONING (AC) SYSTEM COMMON SYSTEM

Each MCR AC subsystem is considered operable when the individual components necessary to maintain the control room temperature are functional. Each subsystem includes a supply fan, a return air fan, associated ductwork, dampers, centrifugal water chiller, a chilled water circulating pump, MCR cooling coil, controls, power, piping, and valves. One control room supply fan and one control room return air fan and their associated ductwork, dampers and controls are also required for air circulation to support the CREFAS subsystem function by providing a flow path to and from the control room whenever CREFAS is operating.

If both chillers or subsystems become inoperative and main control room temperature remains less than 90°F WBGT, 72-hours is permitted to restore one chiller/subsystem provided control room temperature is monitored once per 4 hours to ensure that temperature is being maintained low enough that occupants and equipment in the control room are not adversely affected. This repair time duration is reasonable considering that the control room temperature is being maintained within allowable limits and the low probability of an event occurring requiring control room isolation.

The main control room purge mode of operation, and any other viable supplemental cooling options (portable cooling, fans, opening doors, etc.) can be utilized if both chillers or subsystems are inoperative. A concurrent design basis event is not postulated while in the complete loss of cooling LCO to support supplemental cooling, as required, in order to maintain main control room temperature less than 90°F WBGT. This is based upon the low probability of a concurrent event occurring while in the 72-hour LCO that requires MCR isolation.

Temporary DWCW to CECW crosstie jumpers can also be utilized as a viable supplemental cooling option, but it requires a HELB door between the Turbine Enclosure and Control Enclosure to be breached (blocked open) while only in the 72-hour complete loss of cooling LCO. It is permitted to breach the subject HELB door for supplemental cooling jumper use although it impacts several multi-train TS systems and creates a loss of function situation which is not permitted under TS 3.0.9 if a HELB occurred. CREFAS SGT, and EDGs (required for DBA accident mitigation) all constitute loss of function situations.

The safety related SSCs protected by the breached HELB door to solely facilitate utilizing the CECW to DWCW crosstie cooling jumpers are not required to be declared inoperable while in the complete loss of CECW cooling 72-hour LCO.

The justification for this request was (1) the low probability of HELB occurring while in the LCO and (2) the ability to realistic detect a turbine enclosure high energy line leak far prior to a break occurring. The caveat for breaching the HELB door for this supplemental cooling provision is to confirm that a main steam line or feedwater high energy line leak is nonexistent. With this basis, safety related equipment in Control Enclosure room 619 would not be exposed to any HELB environmental conditions that could compromise equipment functionality while only in the 72-hour complete loss of cooling dual unit LCO. Notwithstanding the above justification, if a postulated HELB occurred with the HELB door breached, while in the LCO, the ability to mitigate the consequences of a HELB are still maintained and plant safe shutdown can be achieved by using a preexisting fire safe shutdown strategy.

A list of impacted Tech. Spec. SSCs protected by the breached HELB door are provided below:

- Unit 1 and 2 SGT TS 3.6.5.3, 3.0.3 dual unit shutdown
- Unit 1 and 2 CREFAS TS 3.7.2.1, 3.0.3 dual unit shutdown
- Unit 1 RERS TS 3.6.5.4, 12-hour shutdown
- Unit 1 EDG Power TS 3.8.1.1 (3 inoperable EDGs), 2-hour action
- Unit 2 2B RERS, TS 3.6.5.4. 7 day LCO
- Unit 2 EDG Power TS 3.8.1.1 (2 inoperable EDGs), 72-hour LCO

3/4.7.2.2 CONTROL ROOM AIR CONDITIONING (AC) SYSTEM - COMMON SYSTEM (Continued)

The MCR AC periodic surveillance requirement verifies that the system is capable of removing the control room design basis heat loads.

When handling RECENTLY IRRADIATED FUEL, a fuel handling accident is postulated and therefore it is appropriate to suspend movement of RECENTLY IRRADIATED FUEL.

3/4.7.3 REACTOR CORE ISOLATION COOLING SYSTEM

The reactor core isolation cooling (RCIC) system is provided to assure adequate core cooling in the event of reactor isolation from its primary heat sink and the loss of feedwater flow to the reactor vessel without requiring actuation of any of the emergency core cooling system equipment. The RCIC system is conservatively required to be OPERABLE whenever reactor pressure ex-ceeds 150 psig. This pressure is substantially below that for which low pressure core cooling systems can provide adequate core cooling. Management of gas voids is important to RCIC System OPERABILITY.

The RCIC system specifications are applicable during OPERATIONAL CONDITIONS 1, 2, and 3 when reactor vessel pressure exceeds 150 psig because RCIC is the primary non-ECCS source of emergency core cooling when the reactor is pressurized.

With the RCIC system inoperable, adequate core cooling is assured by the OPERABILITY of the HPCI system and justifies the specified 14 day out-of-service period. Alternatively, out-of-service time can be determined in accordance with the Risk Informed Completion Time Program. A Note prohibits the application of Specification 3.0.4.b to an inoperable RCIC system. There is an increased risk associated with entering an OPERATIONAL CONDITION or other specified condition in the Applicability with an inoperable RCIC subsystem and the provisions of Specification 3.0.4.b, which allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, should not be applied in this circumstance.

The surveillance requirements provide adequate assurance that RCIC will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation during reactor operation, a complete functional test requires reactor shutdown.

During plant startup, when RCIC surveillance tests are being performed, the RCIC System is required to be tested within 12 hours after reactor pressure is adequate to perform each surveillance test. For the low reactor pressure surveillance requirement, the intent is to verify RCIC System operability prior to increasing reactor pressure above 165 psig. If operability of the RCIC System is not demonstrated within the 12-hour period, reactor steam dome pressure must be reduced to less than 150 psig within the following 72 hours. For the high reactor pressure surveillance test, the intent is to verify RCIC System operability as soon as possible once plant conditions support the testing. Power ascension can continue during the testing; however, if RCIC is found inoperable or the 12-hour period has elapsed power ascension must be stopped, and reactor steam dome pressure must be reduced to less than 150 psig within the following 72 hours.

3/4.7.3 REACTOR CORE ISOLATION COOLING SYSTEM (Continued)

The RCIC System flow path piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the required RCIC System and may also prevent water hammer, pump cavitation, and pumping of noncondensible gas into the reactor vessel.

Selection of RCIC System locations susceptible to gas accumulation is based on a review of system design information, including piping and instrumentation drawings, isometric drawings, plan and elevation drawings, and calculations. The design review is supplemented by system walk downs to validate the system high points and to confirm the location and orientation of important components that can become sources of gas or could otherwise cause gas to be trapped or difficult to remove during system maintenance or restoration. Susceptible locations depend on plant and system configuration, such as stand-by versus operating conditions.

The RCIC System is OPERABLE when it is sufficiently filled with water. Acceptance criteria are established for the volume of accumulated gas at susceptible locations. If accumulated gas is discovered that exceeds the acceptance criteria for the susceptible location (or the volume of accumulated gas at one or more susceptible locations exceeds an acceptance criteria for gas volume at the suction or discharge of a pump), the Surveillance is not met. Accumulated gas should be eliminated or brought within the acceptance criteria limits.

RCIC System locations susceptible to gas accumulation are monitored and, if gas is found, the gas volume is compared to the acceptance criteria for the location. Susceptible locations in the same system flow path which are subject to the same gas intrusion mechanisms may be verified by monitoring a representative subset of susceptible locations. Monitoring may not be practical for locations that are inaccessible due to radiological or environmental conditions, the plant configuration, or personnel safety. For these locations alternative methods (e.g., operating parameters, remote monitoring) may be used to monitor the susceptible location. Monitoring is not required for susceptible locations where the maximum potential accumulated gas void volume has been evaluated and determined to not challenge system OPERABILITY. The accuracy of the method used for monitoring the susceptible locations and trending of the results should be sufficient to assure system OPERABILITY during the Surveillance interval.

Surveillance 4.7.3.a.2 is modified by a Note which exempts system vent flow paths opened under administrative control. The administrative control should be proceduralized and include stationing a dedicated individual at the system vent flow path who is in continuous communication with the operators in the control room. This individual will have a method to rapidly close the system vent flow path if directed.

SR 4.7.3.c.1 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.7.4 DELETED

3/4.7.5 SEALED SOURCE CONTAMINATION

The limitations on removable contamination for sources requiring leak testing, including alpha emitters, is based on 10 CFR 70.39(c) limits for plutonium. This limitation will ensure that leakage from byproduct, source, and special nuclear material sources will not exceed allowable intake values. Sealed sources are classified into three groups according to their use, with surveillance requirements commensurate with the probability of damage to a source in that group. Those sources which are frequently handled are required to be tested more often than those which are not. Sealed sources which are continuously enclosed within a shielded mechanism, i.e,, sealed sources within radiation monitoring devices, are considered to be stored and need not be tested unless they are removed from the shielded mechanism.

3/4 7.6 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4.7.7 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4 7.8 MAIN TURBINE BYPASS SYSTEM

The required OPERABILITY of the main turbine bypass system is consistent with the assumptions of the feedwater controller failure analysis in the cycle specific transient analysis.

The main turbine bypass system is required to be OPERABLE to limit peak pressure in the main steam lines and to maintain reactor pressure within acceptable limits during events that cause rapid pressurization such that the Safety Limit MCPR is not exceeded. With the main turbine bypass system inoperable, continued operation is based on the cycle specific transient analysis which has been performed for the feedwater controller failure, maximum demand with bypass failure.

3/4 7.9 TURBINE ENCLOSURE MAIN STEAM LINE TUNNEL TEMPERATURE

Should a temperature greater than the limit be detected, operators will determine if there is a leak from the Main Steam Line pressure boundary. Evidence of a Main Steam Line leak includes, but is not limited to:

- An unexpected sudden rise in tunnel temperature,
- An unexpected increase in radiation monitor readings,
- An unexpected rise in TE sump levels,
- An unexpected decrease in plant electrical output, or
- Visual and sound indications.

If a Main Steam Line pressure boundary leak is detected, a plant shutdown is required. Pressure boundary leakage includes ASME SSC(s). Leakage past gaskets, packing, and seals is not pressure boundary leakage.

3/4.8.1, 3/4.8.2, and 3/4.8.3 A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS

The OPERABILITY of the A.C. and D.C. power sources and associated distribution systems during operation ensures that sufficient power will be available to supply the safety-related equipment required for (1) the safe shutdown of the facility and (2) the mitigation and control of accident conditions within the facility. The minimum specified independent and redundant A.C. and D.C. power sources and distribution systems satisfy the requirements of General Design Criterion 17 of Appendix A to 10 CFR Part 50.

An offsite power source consists of all breakers, transformers, switches, interrupting devices, cabling, and controls required to transmit power from the offsite transmission network to the onsite Class 1E emergency bus or buses. The determination of the OPERABILITY of an offsite source of power is dependent upon grid and plant factors that, when taken together, describe the design basis calculation requirements for voltage regulation. The combination of these factors ensures that the offsite source(s), which provide power to the plant emergency buses, will be fully capable of supporting the equipment required to achieve and maintain safe shutdown during postulated accidents and transients.

The plant factors consist of the status of the Startup Transformer (#10 and #20) load tap changers (LTCs), the status of the Safeguard Transformer (#101 and #201) load tap changers (LTCs), and the alignment of emergency buses on the Safeguard Buses (101-Bus and 201-Bus). For an offsite source to be considered operable, both of its respective LTCs (#10 AND #101 for the source to the 101-Bus, #20 AND #201 for the source to the 201-Bus) must be in service, and in automatic. For the third offsite source (from 66 kV System) to be considered operable, the connected Safeguard Transformer (#101 or #201) LTC must be in service and in automatic. There is a dependency between the alignment of the emergency buses and the allowable post contingency voltage drop percentage.

The grid factors consist of actual grid voltage levels (real time) and the post trip contingency voltage drop percentage value.

The minimum offsite source voltage levels are established by the voltage regulation calculation. The transmission system operator (TSO) will notify LGS when an agreed upon limit is approached.

The post trip contingency percentage voltage drop is a calculated value determined by the TSO that would occur as a result of the tripping of one of the Limerick generators. The TSO will notify LGS when an agreed upon limit is exceeded. The voltage regulation calculation establishes the acceptable percentage voltage drop based upon plant configuration; the acceptable value is dependent upon plant configuration.

Due to the 20 Source being derived from the tertiary of the 4A and 4B transformer, its operability is influenced by both the 230 kV system and the 500 kV system. The 10 Source operability is only influenced by the 230 kV system.

3/4.8.1, 3/4.8.2, and 3/4.8.3 A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS

The anticipated post trip contingency voltage drop for the 66 kV Source (Transformer 80) is calculated to be less than the 230 kV and 500 kV systems. This is attributed to the electrical distance between the output of the Limerick generators and the input to the 80 transformer. Additionally, the Unit Auxiliary Buses do not transfer to the 80 transformer; this provides margin to the calculated post trip contingency voltage drop limit.

There are various means of hardening the 10 and 20 Sources to obtain additional margin to the post trip contingency voltage drop limits. These means include, but are not limited to, source alignment of the 4 kV buses, preventing transfer of 13 kV buses, limiting transfer of selected 13 kV loads, and operation with 13 kV buses on the offsite sources. The specific post trip contingency voltage drop percentage limits for these alignments are identified in the voltage regulation calculation, and controlled via plant procedures. There are also additional restrictions that can be applied to these limits in the event that an LTC is taken to manual, or if the bus alignment is outside the Two Source rule set.

LGS unit post trip contingency voltage drop percentage calculations are performed by the PJM Energy Management System (EMS). The PJM EMS consists of a primary and backup system. LGS will be notified if the real time contingency analysis capability of PJM is lost. Upon receipt of this notification, LGS is to request PJM to provide an assessment of the current condition of the grid based on the tools that PJM has available. The determination of the operability of the offsite sources would consider the assessment provided by PJM and whether the current condition of the grid is bounded by the grid studies previously performed for LGS.

Based on specific design analysis, variations to any of these parameters can be determined, usually at the sacrifice of another parameter, based on plant conditions. Specifics regarding these variations must be controlled by plant procedures or by operability determinations, backed by specific design calculations.

The ACTION requirements specified for the levels of degradation of the power sources provide restriction upon continued facility operation commensurate with the level of degradation. The OPERABILITY of the power sources are consistent with the initial condition assumptions of the safety analyses and are based upon maintaining at least two of the onsite A.C. and the corresponding D.C. power sources and associated distribution systems OPERABLE during accident conditions coincident with an assumed loss-of-offsite power and single failure of the other onsite A.C. or D.C. source. At least two onsite A.C. and their corresponding D.C. power sources and distribution systems providing power for at least two ECCS divisions (1 Core Spray loop, 1 LPCI pump and 1 RHR pump in suppression pool cooling) are required for design basis accident mitigation as discussed in UFSAR Table 6.3-3.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

Onsite A.C. operability requirements for common systems such as RHRSW and ESW are addressed in the appropriate system specification action statements.

A.C. Sources

As required by Specification 3.8.1.1, Action e, when one or more diesel generators are inoperable, there is an additional ACTION requirement to verify that all required systems, subsystems, trains, components, and devices, that depend on the remaining OPERABLE diesel generators as a source of emergency power, are also OPERABLE. The LPCI mode of the RHR system is considered a four train system, of which only two trains are required. The verification for LPCI is not required until two diesel generators are inoperable. This requirement is intended to provide assurance that a loss-of-offsite power event will not result in a complete loss of safety function of critical systems during the period when one or more of the diesel generators is inoperable. The term verify as used in this context means to administratively check by examining logs or other information to determine if certain components are out-of-service for maintenance or other reasons. It does not mean to perform the surveillance requirements needed to demonstrate the OPERABILITY of the component.

Specification 3.8.1.1, Action j, prohibits the application of Specification 3.0.4.b to an inoperable diesel generator. There is an increased risk associated with entering an OPERATIONAL CONDITION or other specified condition in the Applicability with an inoperable diesel generator subsystem and the provisions of Specification 3.0.4.b, which allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, should not be applied in this circumstance.

If it can be determined that the cause of the inoperable EDG does not exist on the remaining operable EDG(s), based on a common-mode evaluation, then the EDG start test (SR 4.8.1.1.2.a.4) does not have to be performed. If it cannot otherwise be determined that the cause of the initial inoperable EDG does not exist on the remaining EDG(s), then satisfactory performance of the start test suffices to provide assurance of continued operability of the remaining EDG(s). If the cause of the initial inoperability exists on the remaining operable EDG(s), the EDG(s) shall be declared inoperable upon discovery and the appropriate action statement for multiple inoperable EDGs shall be entered. In the event the inoperable EDG is restored to operable status prior to completing the EDG start test (SR 4.8.1.1.2.a.4) or common-mode failure evaluation as required in Specification 3.8.1.1, the plant corrective action program shall continue to evaluate the common-mode failure possibility. However, this continued evaluation is not subject to the time constraint imposed by the action statement. The provisions contained in the inoperable EDG action requirements that avoid unnecessary EDG testing are based on Generic Letter 93-05, “Line-Item Technical Specifications Improvement to Reduce Surveillance Requirements for Testing During Power Operation,” dated September 27, 1993.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

The time, voltage, and frequency acceptance criteria specified for the EDG single largest post-accident load rejection test (SR 4.8.1.1.2.e.2) are derived from Regulatory Guide 1.9, Rev. 2, December 1979, recommendations. The test is acceptable if the EDG speed does not exceed the nominal (synchronous) speed plus 75% of the difference between nominal speed and the overspeed trip setpoint, or 115% of nominal, whichever is lower. This computes to be 66.5 Hz for the LGS EDGs. The RHR pump motor represents the single largest post-accident load. The 1.8 seconds specified is equal to 60% of the 3-second load sequence interval associated with sequencing the next load following the RHR pumps in response to an undervoltage on the electrical bus concurrent with a LOCA. This provides assurance that EDG frequency does not exceed predetermined limits and that frequency stability is sufficient to support proper load sequencing following a rejection of the largest single load.

D.C. Sources

With one division with one or two battery chargers inoperable (e.g., the voltage limit of 4.8.2.1.a.2 is not maintained), the ACTIONS provide a tiered response that focuses on returning the battery to the fully charged state and restoring a fully qualified charger to OPERABLE status in a reasonable time period. Action a.1 requires that the battery terminal voltage be restored to greater than or equal to the minimum established float voltage within 2 hours. This time provides for returning the inoperable charger to OPERABLE status or providing an alternate means of restoring battery terminal voltage to greater than or equal to the minimum established float voltage. Restoring the battery terminal voltage to greater than or equal to the minimum established float voltage provides good assurance that, within 18 hours, the battery will be restored to its fully charged condition (Action a.2) from any discharge that might have occurred due to the charger inoperability.

A discharged battery having terminal voltage of at least the minimum established float voltage indicates that the battery is on the exponential charging current portion (the second part) of its recharge cycle. The time to return a battery to its fully charged state under this condition is simply a function of the amount of the previous discharge and the recharge characteristic of the battery. Thus there is good assurance of fully recharging the battery within 18 hours, avoiding a premature shutdown with its own attendant risk.

If established battery terminal float voltage cannot be restored to greater than or equal to the minimum established float voltage within 2 hours, and the charger is not operating in the current-limiting mode, a faulty charger is indicated. A faulty charger that is incapable of maintaining established battery terminal float voltage does not provide assurance that it can revert to and operate properly in the current limit mode that is necessary during the recovery period following a battery discharge event that the DC system is designed for.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

If the charger is operating in the current limit mode after 2 hours that is an indication that the battery is partially discharged and its capacity margins will be reduced. The time to return the battery to its fully charged condition in this case is a function of the battery charger capacity, the amount of loads on the associated DC system, the amount of the previous discharge, and the recharge characteristic of the battery. The charge time can be extensive, and there is not adequate assurance that it can be recharged within 18 hours (Action a.2).

Action a.2 requires that the battery float current be verified for Divisions 1 and 2 as $\leq$ 2 amps, and for Divisions 3 and 4 as $\leq$ 1 amp. This indicates that, if the battery had been discharged as the result of the inoperable battery charger, it has now been fully recharged. If at the expiration of the initial 18 hour period the battery float current is not within limits this indicates there may be additional battery problems.

Action a.3 limits the restoration time for the inoperable battery charger to 7 days or in accordance with the Risk Informed Completion Time Program. This action is applicable if an alternate means of restoring battery terminal voltage to greater than or equal to the minimum established float voltage has been used (e.g., balance of plant non-Class 1E battery charger). The 7 days reflects a reasonable time to effect restoration of the qualified battery charger to OPERABLE status. Alternatively, the allowable out-of-service time can be determined in accordance with the Risk Informed Completion Time Program.

With one or more cells in one or more batteries in one division < 2.07 V, the battery cell is degraded. Per Action b.1, within 2 hours, verification of the required battery charger OPERABILITY is made by monitoring the battery terminal voltage (4.8.2.1.a.2) and of the overall battery state of charge by monitoring the battery float charge current (4.8.2.1.a.1). This assures that there is still sufficient battery capacity to perform the intended function. Therefore, with one or more cells in one or more batteries < 2.07 V, continued operation is permitted for a limited period up to 24 hours.

Division 1 or 2 with float current > 2 amps, or Division 3 or 4 with float current > 1 amp, indicates that a partial discharge of the battery capacity has occurred. This may be due to a temporary loss of a battery charger or possibly due to one or more battery cells in a low voltage condition reflecting some loss of capacity. Per Action b.2, within 2 hours verification of the required battery charger OPERABILITY is made by monitoring the battery terminal voltage.

Since Actions b.1 and b.2 only specify "perform," a failure of 4.8.2.1.a.1 or 4.8.2.1.a.2 acceptance criteria does not result in this Action not being met. However, if one of the Surveillance Requirements is failed the appropriate Action(s), depending on the cause of the failures, is also entered.

If the Action b.2 condition is due to one or more cells in a low voltage condition but still greater than 2.07 V and float voltage is found to be satisfactory, this is not indication of a substantially discharged battery and 18 hours is a reasonable time prior to declaring the battery inoperable.

With one or more batteries in one division with one or more cells electrolyte level above the top of the plates, but below the minimum established design limits (i.e., greater than minimum level indication mark), the battery still retains sufficient capacity to perform the intended function. Per Action b.3, within 31 days the minimum established design limits for electrolyte level must be re-established.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

With electrolyte level below the top of the plates there is a potential for dryout and plate degradation. Action b.3 addresses this potential (as well as provisions in Specification 6.8.4.h, "Battery Monitoring and Maintenance Program"). Within 8 hours level is required to be restored to above the top of the plates. The Action requirement to verify that there is no leakage by visual inspection and the Specification 6.8.4.h item to initiate action to equalize and test in accordance with manufacturer's recommendation are taken from Annex D of IEEE Standard 450-1995. They are performed following the restoration of the electrolyte level to above the top of the plates. Based on the results of the manufacturer's recommended testing the battery may have to be declared inoperable and the affected cell(s) replaced.

Per Action b.4, with one or more batteries in one division with pilot cell temperature less than the minimum established design limits, 12 hours is allowed to restore the temperature to within limits. A low electrolyte temperature limits the current and power available. Since the battery is sized with margin, while battery capacity is degraded, sufficient capacity exists to perform the intended function and the affected battery is not required to be considered inoperable solely as a result of the pilot cell temperature not met.

Per Action b.5, with one or more batteries in more than one division with battery parameters not within limits there is not sufficient assurance that battery capacity has not been affected to the degree that the batteries can still perform their required function, given that multiple divisions are involved. With multiple divisions involved, this potential could result in a total loss of function on multiple systems that rely upon the batteries. The longer restoration times specified for battery parameters on one division not within limits are therefore not appropriate, and the parameters must be restored to within limits on all but one division within 2 hours.

When any battery parameter is outside the allowances of Actions b.1, b.2, b.3, b.4, or b.5, sufficient capacity to supply the maximum expected load requirement is not ensured and a 2 hour restoration time is appropriate. Additionally, discovering one or more batteries in one division with one or more battery cells float voltage less than 2.07 V and float current greater than limits indicates that the battery capacity may not be sufficient to perform the intended functions. The battery must therefore be restored within 2 hours.

When any batteries and/or battery chargers in two divisions of the required D.C. electrical sources are inoperable, or when two or more of the required A.C. and/or D.C. distribution system divisions are not energized resulting in a loss of function, the unit must be brought to an OPERATIONAL CONDITION in which the LCO does not apply. To achieve this status, the plant must be brought to at least HOT SHUTDOWN within 12 hours and to COLD SHUTDOWN within 36 hours. The allowed times are reasonable, based on operating experience, to reach the required plant conditions from full power conditions in an orderly manner and without challenging plant systems.

The OPERABILITY of the minimum specified A.C. and D.C. power sources and associated distribution systems during shutdown and refueling ensures that (1) the facility can be maintained in the shutdown or refueling condition for extended time periods and (2) sufficient instrumentation and control capability is available for monitoring and maintaining the unit status.

The surveillance requirements for demonstrating the OPERABILITY of the diesel generators are in accordance with the recommendations of Regulatory Guide 1.9,

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

"Selection of Diesel Generator Set Capacity for Standby Power Supplies," March 10, 1971, Regulatory Guide 1.137 "Fuel-Oil Systems for Standby Diesel Generators," Revision 1, October 1979 and Regulatory Guide 1.108, "Periodic Testing of Diesel Generator Units Used as Onsite Electric Power Systems at Nuclear Power Plants," Revision 1, August 1977 except for paragraphs C.2.a(3), C.2.b, C.2.c(1), C.2.c(2), C.2.d(3) and C.2.d(4), and the periodic testing will be performed in accordance with the Surveillance Frequency Control Program. The exceptions to Regulatory Guide 1.108 allow for gradual loading of diesel generators during testing and decreased surveillance test frequencies (in response to Generic Letter 84-15). The single largest post-accident load on each diesel generator is the RHR pump.

The Surveillance Requirement for removal of accumulated water from the fuel oil storage tanks is for preventive maintenance. The presence of water does not necessarily represent failure of the Surveillance Requirement, provided the accumulated water is removed during performance of the Surveillance. Accumulated water in the fuel oil storage tanks constitutes a collection of water at a level that can be consistently and reliably measured. The minimum level at which accumulated water can be consistently and reliably measured in the fuel oil storage tank sump is 0.25 inches. Microbiological fouling is a major cause of fuel oil degradation. There are numerous bacteria that can grow in fuel oil and cause fouling, but all must have a water environment in order to survive. Removal of accumulated water from the fuel storage tanks once every (31) days eliminates the necessary environment for bacterial survival. This is the most effective means of controlling microbiological fouling. In addition, it eliminates the potential for water entrainment in the fuel oil during DG operation. Water may come from any of several sources, including condensation, ground water, rain water, contaminated fuel oil, and from breakdown of the fuel oil by bacteria. Frequent checking for and removal of accumulated water minimizes fouling and provides data regarding the watertight integrity of the fuel oil system. The Surveillance Frequencies are established by Regulatory Guide 1.137.

The surveillance requirements for demonstrating the OPERABILITY of the units batteries are in accordance with the recommendations of IEEE Standard 450-1995, "IEEE Recommended Practice for Maintenance, Testing, and Replacement of Vented Lead-Acid Batteries for Stationary Applications."

Verifying battery float current while on float charge (4.8.2.1.a.1) is used to determine the state of charge of the battery. Float charge is the condition in which the charger is supplying the continuous charge required to overcome the internal losses of a battery and maintain the battery in a charged state. The float current requirements are based on the float current indicative of a charged battery. Use of float current to determine the state of charge of the battery is consistent with IEEE Standard 450-1995.

This Surveillance Requirement (4.8.2.1.a.1) states the float current requirement is not required to be met when battery terminal voltage is less than the minimum established float voltage of 4.8.2.1.a.2. When this float voltage is not maintained, the Actions of 3.8.2.1 Action a., provides the necessary and appropriate verifications of the battery condition. Furthermore, the float current limits are established based on the float voltage range and is not directly applicable when this voltage is not maintained.

THIS PAGE INTENTIONALLY LEFT BLANK

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

Verifying, per 4.8.2.1.a.2, battery terminal voltage while on float charge for the batteries helps to ensure the effectiveness of the battery chargers, which support the ability of the batteries to perform their intended function. Float charge is the condition in which the charger is supplying the continuous charge required to overcome the internal losses of a battery and maintain the battery in a fully charged state while supplying the continuous steady state loads of the associated DC subsystem. On float charge, battery cells will receive adequate current to optimally charge the battery. The voltage requirements are based on the minimum float voltage established by the battery manufacturer (2.20 Vpc, average, or 132 V at the battery terminals). This voltage maintains the battery plates in a condition that supports maintaining the grid life (expected to be approximately 20 years).

Surveillance Requirements 4.8.2.1.b.1 and 4.8.2.1.c require verification that the cell float voltages are equal to or greater than 2.07 V.

The limit specified in 4.8.2.1.b.2 for electrolyte level ensures that the plates suffer no physical damage and maintains adequate electron transfer capability.

Surveillance Requirement 4.8.2.1.b.3 verifies that the pilot cell temperature is greater than or equal to the minimum established design limit (i.e., 60 degrees Fahrenheit). Pilot cell electrolyte temperature is maintained above this temperature to assure the battery can provide the required current and voltage to meet the design requirements. Temperatures lower than assumed in battery sizing calculations act to inhibit or reduce battery capacity.

Surveillance Requirement 4.8.2.1.d.1 verifies the design capacity of the battery chargers. According to Regulatory Guide 1.32, the battery charger supply is recommended to be based on the largest combined demands of the various steady state loads and the charging capacity to restore the battery from the design minimum charge state to the fully charged state, irrespective of the status of the unit during these demand occurrences. The minimum required amperes and duration ensures that these requirements can be satisfied.

Surveillance Requirement 4.8.2.1.d.1 requires that each battery charger be capable of supplying the amps listed for the specified charger at the minimum established float voltage for 4 hours. The ampere requirements are based on the output rating of the chargers. The voltage requirements are based on the charger voltage level after a response to a loss of AC power. This time period is sufficient for the charger temperature to have stabilized and to have been maintained for at least 2 hours.

A battery service test, per 4.8.2.1.d.2, is a special test of the battery's capability, as found, to satisfy the design requirements (battery duty cycle) of the DC electrical power system. The discharge rate and test length corresponds to the design duty cycle requirements as specified in the UFSAR.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

A battery performance discharge test (4.8.2.1.e and f) is a test of constant current capacity of a battery, normally done in the as found condition, after having been in service, to detect any change in the capacity determined by the acceptance test. The test is intended to determine overall battery degradation due to age and usage. Degradation (as used in 4.8.2.1.f) is indicated when the battery capacity drops more than 10% from its capacity on the previous performance test, or is below 90% of the manufacturer's rating.

Either the battery performance discharge test or the modified performance discharge test is acceptable for satisfying 4.8.2.1.e and 4.8.2.1.f; however, only the modified performance discharge test may be used to satisfy the battery service test requirements of 4.8.2.1.d.2.

3/4.8.4 ELECTRICAL EQUIPMENT PROTECTIVE DEVICES

The RPS Electric Power Monitoring System is provided to isolate the RPS bus from the RPS/UPS inverter or an alternate power supply in the event of overvoltage, undervoltage, or underfrequency. This system protects the loads connected to the RPS bus from unacceptable voltage and frequency conditions. The essential equipment powered from the RPS buses includes the RPS logic, scram solenoids, and valve isolation logic.

The Allowable Values are derived from equipment design limits, corrected for calibration and instrument errors. The trip setpoints are then determined, accounting for the remaining instrument errors (e.g., drift). The trip setpoints derived in this manner provide adequate protection and include allowances for instrumentation uncertainties, calibration tolerances, and instrument drift.

The Allowable Values for the instrument settings are based on the RPS providing power within the design ratings of the associated RPS components (e.g., RPS logic, scram solenoids). The most limiting voltage requirement and associated line losses determine the settings of the electric power monitoring instrument channels.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.9.1 REACTOR MODE SWITCH

Locking the OPERABLE reactor mode switch in the Refuel position, as specified, ensures that the restrictions on control rod withdrawal and refueling platform movement during the refueling operations are properly activated. These conditions reinforce the refueling procedures and reduce the probability of inadvertent criticality, damage to reactor internals or fuel assemblies, and exposure of personnel to excessive radioactivity.

The effect of these requirements is to lock the Reactor Mode Switch in the Refuel position during refueling operations, which is defined at Limerick by our refueling procedures and only occurs during OPCON 5. Additionally, in OPCON 3 and 4 when the one rod out interlock is required to be OPERABLE to withdraw a single control rod with the Mode Switch in the Refuel Position.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

3/4.9.2 INSTRUMENTATION

The OPERABILITY of at least two source range monitors ensures that redundant monitoring capability is available to detect changes in the reactivity condition of the core. The minimum count rate is not required when sixteen or fewer fuel assemblies are in the core. During a typical core reloading, two, three or four irradiated fuel assemblies will be loaded adjacent to each SRM to produce greater than the minimum required count rate. Loading sequences are selected to provide for a continuous multiplying medium to be established between the required operable SRMs and the location of the core alteration. This enhances the ability of the SRMs to respond to the loading of each fuel assembly. During a core un-loading, the last fuel to be removed is that fuel adjacent to the SRMs.

3/4.9.3 CONTROL ROD POSITION

The requirement that all control rods be inserted during other CORE ALTERATIONS ensures that fuel will not be loaded into a cell without a control rod.

3/4.9.4 DECAY TIME

The minimum requirement for reactor subcriticality prior to fuel movement ensures that sufficient time has elapsed to allow the radioactive decay of the short lived fission products. This decay time is consistent with the assumptions used in the accident analyses.

3/4.9.5 COMMUNICATIONS

The requirement for communications capability ensures that refueling station personnel can be promptly informed of significant changes in the facility status or core reactivity condition during movement of fuel within the reactor pressure vessel.

3/4.9.6 REFUELING PLATFORM

The OPERABILITY requirements ensure that (1) the refueling platform will be used for handling control rods and fuel assemblies within the reactor pressure vessel, (2) each hoist has sufficient load capacity for handling fuel assemblies and control rods, (3) the core internals and pressure vessel are protected from excessive lifting force in the event they are inadvertently engaged during lifting operations, and (4) inadvertent criticality will not occur due to fuel being loaded into a unrodded cell.

Inadvertent criticality is prevented by the refueling interlocks that block unacceptable operations (e.g., loading fuel into a cell with a control rod withdrawn or withdrawal of a rod from the core while the grapple is over the core and loaded with fuel). The hoist loaded values identified in Sections 4.9.6.1b and 4.9.6.1c support the refueling interlock logic by ensuring that the hoist fuel loaded switches function with a load lighter than the weight of a single fuel assembly in water. Load values represent fuel (load) on the grapple. The values of 485 +/- 50 pounds and 550 + 0, - 115 pounds are both less than the weight of a single fuel assembly in water attached to the grapple. These load values ensure that as soon as a fuel assembly is grappled and lifted, the refueling interlocks (control rod block and bridge motion interlock) are enforced as required. The hoist load weighing system is compensated for mast weight to ensure that lifting of components other than fuel assemblies (e.g., blade guides) do not cause inadvertent control rod blocks or bridge motion stops.

3/4.9.7 CRANE TRAVEL - SPENT FUEL STORAGE POOL

The restriction on movement of loads in excess of the nominal weight of a fuel assembly and associated lifting device over other fuel assemblies in the storage pool ensures that in the event this load is dropped 1) the activity release will be limited to that contained in a single fuel assembly, and 2) any possible distortion of fuel in the storage racks will not result in a critical array. This assumption is consistent with the activity release assumed in the safety analyses.

3/4.9.8 and 3/4.9.9 WATER LEVEL - REACTOR VESSEL and WATER LEVEL - SPENT FUEL STORAGE POOL

The restrictions on minimum water level ensure that sufficient water depth is available to remove 99% of the assumed 10% iodine gap activity released from the rupture of an irradiated fuel assembly. This minimum water depth is consistent with the assumptions of the accident analysis.

3/4.9.10 CONTROL ROD REMOVAL

These specifications ensure that maintenance or repair of control rods or control rod drives will be performed under conditions that limit the probability of inadvertent criticality. The requirements for simultaneous removal of more than one control rod are more stringent since the SHUTDOWN MARGIN specification provides for the core to remain subcritical with only one control rod fully withdrawn.

3/4.9.11 RESIDUAL HEAT REMOVAL AND COOLANT CIRCULATION

Irradiated fuel in the shutdown reactor core generates heat during the decay of fission products and increases the temperature of the reactor coolant. This decay heat must be removed by the RHR system to maintain adequate reactor coolant temperature.

RHR shutdown cooling is comprised of four (4) subsystems which make two (2) loops. Each loop consists of two (2) motor driven pumps, a heat exchanger, and associated piping and valves. Both loops have a common suction from the same recirculation loop. Two (2) redundant, manually controlled shutdown cooling subsystems of the RHR system provide decay heat removal. Each pump discharges the reactor coolant, after circulation through the respective heat exchanger, to the reactor via the associated recirculation loop. The RHR heat exchangers transfer heat to the RHR Service Water System.

An OPERABLE RHR shutdown cooling subsystem consists of one (1) OPERABLE RHR pump, one (1) heat exchanger, and the associated piping and valves. The requirement for having one (1) RHR shutdown cooling subsystem OPERABLE ensures that 1) sufficient cooling capacity is available to remove decay heat and maintain the water in the reactor pressure vessel below 140°F, and 2) sufficient coolant circulation would be available through the reactor core to assure accurate temperature indication. Management of gas voids is important to RHR Shutdown Cooling Subsystem OPERABILITY.

The requirement to have two (2) RHR shutdown cooling subsystems OPERABLE when there is less than 22 feet of water above the reactor vessel flange ensures that a single failure of the operating loop will not result in a complete loss of residual heat removal capability. With the reactor vessel head removed and 22 feet of water above the reactor vessel flange, a large heat sink is available for core cooling. Thus, in the event of a failure of the operating RHR subsystem, adequate time is provided to initiate alternate methods capable of decay heat removal or emergency procedures to cool the core.

To meet the LCO of the two (2) subsystems OPERABLE when there is less than 22 feet of water above the reactor vessel flange, both pumps in one (1) loop or one (1) pump in each of the two (2) loops must be OPERABLE. The two (2) subsystems have a common suction source and are allowed to have a common heat exchanger and common discharge piping. Additionally, each shutdown cooling subsystem can provide the required decay heat removal capability; however, ensuring operability of the other shutdown cooling subsystem provides redundancy.

The required cooling capacity of an alternate method of decay heat removal should be ensured by verifying its capability to maintain or reduce reactor coolant temperature either by calculation (which includes a review of component and system availability to verify that an alternate decay heat removal method is available) or by demonstration. Decay heat removal capability by ambient losses can be considered in evaluating alternate decay heat removal capability.

3/4.9.11 RESIDUAL HEAT REMOVAL AND COOLANT CIRCULATION (Continued)

RHR Shutdown Cooling System piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the RHR shutdown cooling subsystems and may also prevent water hammer, pump cavitation, and pumping of non-condensible gas into the reactor vessel. This surveillance verifies that the RHR Shutdown Cooling System piping is sufficiently filled with water prior to placing the system in operation when in OPCON 5. The RHR Shutdown Cooling System is OPERABLE when it is sufficiently filled with water to ensure that it can reliably perform its intended function.

The RHR Shutdown Cooling System is a manually initiated mode of the RHR System that is aligned for service using system operating procedures that ensure the RHR shutdown cooling suction and discharge flow paths are sufficiently filled with water. An RHR Shutdown Cooling sub-system that is already in operation at the time of entry into the APPLICABILITY is OPERABLE. For an idle RHR Shutdown Cooling subsystem, the surveillance is met through the performance of the operating procedures that place the RHR Shutdown Cooling subsystem in service.

With the required decay heat removal subsystem(s) inoperable and the required alternate method(s) of decay heat removal not available in accordance with Action "a", additional actions are required to minimize any potential fission product release to the environment. This includes ensuring Refueling Floor Secondary Containment is OPERABLE; one (1) Standby Gas Treatment subsystem is OPERABLE; and Secondary Containment isolation capability (i.e., one (1) Secondary Containment isolation valve and associated instrumentation are OPERABLE or other acceptable administrative controls to assure isolation capability) in each associated penetration not isolated that is assumed to be isolated to mitigate radioactive releases. This may be performed as an administrative check, by examining logs or other information to determine whether the components are out of service for maintenance or other reasons. It is not necessary to perform the Surveillances needed to demonstrate the OPERABILITY of the components. If, however, any required component is inoperable, then it must be restored to OPERABLE status. In this case, the surveillance may need to be performed to restore the component to OPERABLE status. Actions must continue until all required components are OPERABLE.

If no RHR subsystem is in operation, an alternate method of coolant circulation is required to be established within one (1) hour. The Completion Time is modified such that one (1) hour is applicable separately for each occurrence involving a loss of coolant circulation.

3.4.10.1 PRIMARY CONTAINMENT INTEGRITY

The requirement for PRIMARY CONTAINMENT INTEGRITY is not applicable during the period when open vessel tests are being performed during the low power PHYSICS TESTS.

3/4.10.2 ROD WORTH MINIMIZER

In order to perform the tests required in the technical specifications it is necessary to bypass the sequence restraints on control rod movement. The additional surveillance requirements ensure that the specifications on heat generation rates and shutdown margin requirements are not exceeded during the period when these tests are being performed and that individual rod worths do not exceed the values assumed in the safety analysis.

3/4.10.3 SHUTDOWN MARGIN DEMONSTRATIONS

Performance of shutdown margin demonstrations with the vessel head removed requires additional restrictions in order to ensure that criticality does not occur. These additional restrictions are specified in this LCO.

3/4.10.4 RECIRCULATION LOOPS

This special test exception permits reactor criticality under no flow conditions and is required to perform certain startup and PHYSICS TESTS while at low THERMAL POWER levels.

3/4.10.5 OXYGEN CONCENTRATION

Relief from the oxygen concentration specifications is necessary in order to provide access to the primary containment during the initial startup and testing phase of operation. Without this access the startup and test program could be restricted and delayed.

3/4.10.6 TRAINING STARTUPS

This special test exception permits training startups to be performed with the reactor vessel depressurized at low THERMAL POWER and temperature while controlling RCS temperature with one RHR subsystem aligned in the shutdown cooling mode in order to minimize contaminated water discharge to the radioactive waste disposal system.

3/4.10.7 RESERVED - CURRENTLY NOT USED

3/4.10.8 INSERVICE LEAK AND HYDROSTATIC TESTING

This special test exception permits certain reactor coolant pressure tests to be performed in OPERATIONAL CONDITION 4 when the metallurgical characteristics of the reactor pressure vessel (RPV) or plant temperature control capabilities during these tests require the pressure testing at temperatures greater than 200°F (normally corresponding to OPERATIONAL CONDITION 3). The additionally imposed OPERATIONAL CONDITION 3 requirements for SECONDARY CONTAINMENT INTEGRITY provide conservatism in response to an operational event.

Invoking the requirement for Refueling Area Secondary Containment Integrity along with the requirement for Reactor Enclosure Secondary Containment Integrity applies the requirements for Reactor Enclosure Secondary Containment Integrity to an extended area encompassing Zones 1 and 3. Core alterations and fuel handling are prohibited in this secondary containment configuration. Drawdown and inleakage testing performed for the combined zone system alignment shall be considered adequate to demonstrate integrity of the combined zones.

Inservice hydrostatic testing and inservice leak pressure tests required by Section XI of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code are performed prior to the reactor going critical after a refueling outage. The minimum temperatures (at the required pressures) allowed for these tests are determined from the RPV pressure and temperature (P/T) limits required by LCO 3.4.6, Reactor Coolant System Pressure/Temperature Limits. These limits are conservatively based on the fracture toughness of the reactor vessel, taking into account anticipated vessel neutron fluence. With increased reactor fluence over time, the minimum allowable vessel temperature increases at a given pressure.

3/4.11.1.4 LIQUID HOLDUP TANKS

The tanks listed in this specification include all those outdoor radwaste tanks that are not surrounded by liners, dikes, or walls capable of holding the tank contents and that do not have tank overflows and surrounding area drains connected to the liquid radwaste treatment system.

Restricting the quantity of radioactive material contained in the specified tanks provides assurance that in the event of an uncontrolled release of the tanks' contents, the resulting concentrations would be less than 10 times the limits of 10 CFR Part 20, Appendix B, Table 2, Column 2, at the nearest potable water supply and the nearest surface water supply in an UNRESTRICTED AREA.

3/4.11.2.1 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM.

3/4.11.2.5 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4.11.2.6 MAIN CONDENSER

Restricting the gross radioactivity rate of noble gases from the main condenser provides reasonable assurance that the total body exposure to an individual at the exclusion area boundary will not exceed a small fraction of the limits of 10 CFR Part 100 in the event this effluent is inadvertently discharged directly to the environment without treatment. This specification implements the requirements of General Design Criteria 60 and 64 of Appendix A to 10 CFR Part 50.

BASES

FOR

SECTION 2.0

SAFETY LIMITS

AND

LIMITING SAFETY SYSTEM SETTINGS

NOTE

The BASES contained in succeeding pages summarize the reasons for the Specifications in Section 2.0, but in accordance with 10 CFR 50.36 are not part of these Technical Specifications.

2.0 INTRODUCTION

The fuel cladding, reactor pressure vessel and primary system piping are the principle barriers to the release of radioactive materials to the environs. Safety Limits are established to protect the integrity of these barriers during normal plant operations and anticipated transients. The Tech Spec Safety Limit is set generically on a fuel product Minimum Critical Power Ratio (MCPR) correlation basis as the MCPR which corresponds to a 95% probability at a 95% confidence level that transition boiling will not occur, referred to as SLMCPR(95/95). The fuel cladding integrity Safety Limit is set such that no significant fuel damage is calculated to occur if the limit is not violated. Because fuel damage is not directly observable, a step-back approach is used to establish a Safety Limit such that the MCPR is not less than the limit specified in Specification 2.1.2 MCPR greater than the specified limit represents a conservative margin relative to the conditions required to maintain fuel cladding integrity. The fuel cladding is one of the physical barriers which separate the radioactive materials from the environs. The integrity of this cladding barrier is related to its relative freedom from perforations or cracking. Although some corrosion or use related cracking may occur during the life of the cladding, fission product migration from this source is incrementally cumulative and continuously measurable. Fuel cladding perforations, however, can result from thermal stresses which occur from reactor operation significantly above design conditions and the Limiting Safety System Settings. While fission product migration from cladding perforation is just as measurable as that from use related cracking, the thermally caused cladding perforations signal a threshold beyond which still greater thermal stresses may cause gross rather than incremental cladding deterioration. Therefore, the fuel cladding Safety Limit is defined with a margin to the conditions which would produce onset of transition boiling, MCPR of 1.0. These conditions represent a significant departure from the condition intended by design for planned operation. This is accomplished by having a Safety Limit Minimum Critical Power Ratio (SLMCPR) design basis, referred to as SLMCPR(95/95), which corresponds to a 95% probability at a 95% confidences level (the 95/95 MCPR criterion) that transition boiling will not occur.

2.1.1 THERMAL POWER, Low Pressure or Low Flow

GNF critical power correlation for GNF3 is applicable for all critical power calculations at pressures ≥ 700 psia and core flows ≥ 10% of rated flow (Ref. 3). For operation at low pressures or low flows, another basis is used. This is done by establishing a limiting condition on core THERMAL POWER with the following basis. Since the pressure drop in the bypass region is essentially all elevation head, the core pressure drop at low power and flows will always be greater than 4.5 psi. Analyses show that with a bundle flow of 28×10^3 lb/hr, bundle pressure drop is nearly independent of bundle power and has a value of 3.5 psi. Thus, the bundle flow with a 4.5 psi driving head will be greater than 28×10^3 lb/hr. Full scale ATLAS test data taken at pressures from 14.7 psia to 800 psia indicate that the fuel assembly critical power at this flow is approximately 3.35 MWt. With the design peaking factors, this corresponds to a THERMAL POWER of more than 50% of RATED THERMAL POWER. Thus, a THERMAL POWER limit of 25% of RATED THERMAL POWER for reactor pressure below 700 psia is conservative.

2.1.2 THERMAL POWER, High Pressure and High Flow

The fuel cladding integrity Safety Limit is set such that no fuel damage is calculated to occur if the limit is not violated. Since the parameters which result in fuel damage are not directly observable during reactor operation, the thermal and hydraulic conditions resulting in a departure from nucleate boiling have been used to mark the beginning of the region where fuel damage could occur. Although it is recognized that a departure from nucleate boiling would not necessarily result in damage to BWR fuel rods, the critical power at which boiling transition is calculated to occur has been adopted as a convenient limit. The Technical Specification Safety Limit value is dependent on the fuel product line and the corresponding MCPR correlation, which is cycle independent. The value is based on the Critical Power Ratio (CPR) data statistics and a 95% probability with 95% confidence that rods are not susceptible to boiling transition, referred to as MCPR(95/95).

The Safety Limit is based on GNF3 fuel. For cores with a single fuel product line, the SLMCPR(95/95) is the MCPR(95/95) for the fuel type. For cores loaded with a mix of applicable fuel types, the SLMCPR(95/95) is based on the largest (i.e., most limiting) of the MCPR values for the fuel product lines that are fresh or once-burnt at the start of the cycle.

INTENTIONALLY LEFT BLANK

2.1.3 REACTOR COOLANT SYSTEM PRESSURE

The Safety Limit for the reactor coolant system pressure has been selected such that it is at a pressure below which it can be shown that the integrity of the system is not endangered. The reactor pressure vessel is designed to Section III of the ASME Boiler and Pressure Vessel Code 1968 Edition, including Addenda through Summer 1969, which permits a maximum pressure transient of 110%, 1375 psig, of design pressure 1250 psig. The Safety Limit of 1325 psig, as measured by the reactor vessel steam dome pressure indicator, is equivalent to 1375 psig at the lowest elevation of the reactor coolant system. The reactor coolant system is designed to the ASME Boiler and Pressure Vessel Code, 1977 Edition, including Addenda through Summer 1977 for the reactor recirculation piping, which permits a maximum pressure transient of 110%, 1375 psig of design pressure, 1250 psig for suction piping and 1500 psig for discharge piping. The pressure Safety Limit is selected to be the lowest transient overpressure allowed by the ASME Boiler and Pressure Vessel Code Section III, Class I.

2.1.4 REACTOR VESSEL WATER LEVEL

With fuel in the reactor vessel during periods when the reactor is shutdown, consideration must be given to water level requirements due to the effect of decay heat. If the water level should drop below the top of the active irradiated fuel during this period, the ability to remove decay heat is reduced. This reduction in cooling capability could lead to elevated cladding temperatures and clad perforation in the event that the water level became less than two-thirds of the core height. The Safety Limit has been established at the top of the active irradiated fuel to provide a point which can be monitored and also provide adequate margin for effective action.

2.2.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS

The Reactor Protection System instrumentation setpoints specified in Table 2.2.1-1 are the values at which the reactor trips are set for each para-meter. The Trip Setpoints have been selected to ensure that the reactor core and reactor coolant system are prevented from exceeding their Safety Limits during normal operation and design basis anticipated operational occurrences and to assist in mitigating the consequences of accidents. Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is equal to or less than the drift allowance assumed for each trip in the safety analyses.

1. Intermediate Range Monitor, Neutron Flux - High

The IRM system consists of 8 chambers, 4 in each of the reactor trip systems. The IRM is a 5 decade 10 range instrument. The trip setpoint of 120 divisions of scale is active in each of the 10 ranges. Thus as the IRM is ranged up to accommodate the increase in power level, the trip setpoint is also ranged up. The IRM instruments provide for overlap with both the APRM and SRM systems.

The most significant source of reactivity changes during the power increase is due to control rod withdrawal. In order to ensure that the IRM provides the required protection, a range of rod withdrawal accidents have been analyzed. The results of these analyses are in Section 15.4 of the FSAR. The most severe case involves an initial condition in which THERMAL POWER is at approximately 1% of RATED THERMAL POWER. Additional conservatism was taken in this analysis by assuming the IRM channel closest to the control rod being withdrawn is bypassed. The results of this analysis show that the reactor is shutdown and peak power is limited to 21% of RATED THERMAL POWER with the peak fuel enthalpy well below the fuel failure threshold of 170 cal/gm. Based on this analysis, the IRM provides protection against local control rod errors and continuous withdrawal of control rods in sequence and provides backup protection for the APRM.

2. Average Power Range Monitor

The APRM system is divided into four APRM channels and four 2-Out-Of-4 Voter channels. The four voter channels are divided into two groups of two each, with each group of two providing inputs to one RPS trip system. All four voters will trip (full scram) when any two unbypassed APRM channels exceed their trip setpoints.

APRM trip Functions 2.a, 2.b, 2.c, and 2.d are voted independently from OPRM Upscale Function 2.f. Therefore, any Function 2.a, 2.b, 2.c, or 2.d trip from any two unbypassed APRM channels will result in a full trip in each of the four voter channels. Similarly, a Function 2.f trip from any two unbypassed APRM channels will result in a full trip from each of the four voter channels.

For operation at low pressure and low flow during STARTUP, the APRM Neutron Flux-Upscale (Setdown) scram setting of 15% of RATED THERMAL POWER provides adequate hermal margin between the setpoint and the Safety Limits. The margin accommodates the anticipated maneuvers associated with power plant startup. Effects of increasing pressure at zero or low void content are minor and cold water from sources available during startup is not much colder than that already in the system. Tempera-ture coefficients are small and control rod patterns are constrained by the RWM. Of all the possible sources of reactivity input, uniform control rod withdrawal is the most probable cause of significant power increase.

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

Average Power Range Monitor (Continued)

Because the flux distribution associated with uniform rod withdrawals does not involve high local peaks and because several rods must be moved to change power by a significant amount, the rate of power rise is very slow. Generally the heat flux is in near equilibrium with the fission rate. In an assumed uniform rod withdrawal approach to the trip level, the rate of power rise is not more than 5% of RATED THERMAL POWER per minute and the APRM system would be more than adequate to assure shutdown before the power could exceed the Safety Limit. The 15% Neutron Flux - Upscale (Setdown) trip remains active until the mode switch is placed in the Run position.

The APRM trip system is calibrated using heat balance data taken during steady state conditions. Fission chambers provide the basic input to the system and therefore the monitors respond directly and quickly to changes due to transient operation for the case of the Neutron Flux - Upscale setpoint; i.e., for a power increase, the THERMAL POWER of the fuel will be less than that indicated by the neutron flux due to the time constants of the heat transfer associated with the fuel. For the Simulated Thermal Power - Upscale setpoint, a time constant of 6 ± 0.6 seconds is introduced into the flow-biased APRM in order to simulate the fuel thermal transient characteristics. A more conservative maximum value is used for the flow-biased setpoint as shown in Table 2.2.1-1.

A reduced Trip Setpoint and Allowable Value is provided for the Simulated Thermal Power - Upscale Function, applicable when the plant is operating in Single Loop Operation (SLO) per LCO 3.4.1.1. In SLO, the drive flow values (W) used in the Trip Setpoint and Allowable Value equations is reduced by 7.6%. The 7.6% value is established to conservatively bound the inaccuracy created in the core flow/drive flow correlation due to back flow in the jet pumps associated with the inactive recirculation loop. The Trip Setpoint and Allowable Value thus maintain thermal margins essentially unchanged from those for two-loop operation. The Trip Setpoint and Allowable Value equations for single loop operation are only valid for flows down to W = 7.6%. The Trip Setpoint and Allowable Value do not go below 61.5% and 62.0% RATED THERMAL POWER, respectively. This is acceptable because back flow in the inactive recirculation loop is only an issue with drive flows of approximately 40% or greater (Reference 1).

The APRM setpoints were selected to provide adequate margin for the Safety Limits and yet allow operating margin that reduces the possibility of unneces-sary shutdown.

The APRM channels also include an Oscillation Power Range Monitor (OPRM) Upscale Function. The OPRM Upscale Function provides compliance with GDC 10 and GDC 12, thereby providing protection from exceeding the fuel MCPR Safety Limit due to anticipated thermal-hydraulic power oscillations. The OPRM Upscale Function receives input signals from the local power range monitors (LPRMs) within the reactor core, which are combined into “cells” for evaluation by the OPRM algorithms.

References 2, 3 and 4 describe three algorithms for detecting thermal-hydraulic instability related neutron flux oscillations: the period based detection algorithm, the amplitude based algorithm, and the growth rate algorithm. All three are implemented in the OPRM Upscale Function, but the safety analysis takes credit only for the period based detection algorithm. The remaining algorithms provide defense in depth and additional protection against unanticipated oscillations. OPRM Upscale Function OPERABILITY for Technical Specification purposes is based only on the period based detection algorithm.

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

Average Power Range Monitor (Continued)

The OPRM Upscale trip output shall be automatically enabled (not bypassed) when APRM Simulated Thermal Power is ≥ 29.5% and recirculation drive flow is < 60% as indicated by APRM measured recirculation drive flow. (NOTE: 60% recirculation drive flow is the recirculation drive flow that corresponds to 60% of rated core flow. Refer to TS Bases 3/4.3.1 for further discussion concerning the recirculation drive flow/core flow relationship.) This is the operating region where actual thermal-hydraulic instability and related neutron flux oscillations may occur. See Reference 5 for additional discussion of OPRM Upscale trip enable region limits. These setpoints, which are sometimes referred to as the "auto-bypass" setpoints, establish the boundaries of the OPRM Upscale rip enabled region. The APRM Simulated Thermal Power auto-enable setpoint has 1% deadband while the drive flow setpoint has a 2% deadband. The deadband for these setpoints is established so that it increases the enabled region.

An OPRM Upscale trip is issued from an APRM channel when the period based detection algorithm in that channel detects oscillatory changes in the neutron flux, indicated by the combined signals of the LPRM detectors in a cell, with period confirmations and relative cell amplitude exceeding specified setpoints. One or more cells in a channel exceeding the trip conditions will result in a channel trip. An OPRM Upscale trip is also issued from the channel if either the growth rate or amplitude based algorithms detect oscillatory changes in the neutron flux for one or more cells in that channel.

There are four "sets" of OPRM related setpoints or adjustment parameters: a) OPRM trip auto-enable setpoints for APRM Simulated Thermal Power (29.5%) and recirculation drive flow (60%); b) period based detection algorithm (PBDA) confirmation count and amplitude setpoints; c) period based detection algorithm tuning parameters; and d) growth rate algorithm (GRA) and amplitude based algorithm (ABA) setpoints.

The first set, the OPRM auto-enable region setpoints, are treated as nominal setpoints with no additional margins added as discussed in Reference 5. The settings, 29.5% APRM Simulated Thermal Power and 60% recirculation drive flow, are defined (limit values) in a note to Table 2.2.1-1. The second set, the OPRM PBDA trip setpoints, are established in accordance with methodologies defined in Reference 4, and are documented in the COLR. There are no allowable values for these setpoints. The third set, the OPRM PBDA "tuning" parameters, are established or adjusted in accordance with and controlled by station procedures. The fourth set, the GRA and ABA setpoints, in accordance with References 2 and 3, are established as nominal values only, and controlled by station procedures.

3. Reactor Vessel Steam Dome Pressure-High

High pressure in the nuclear system could cause a rupture to the nuclear system process barrier resulting in the release of fission products. A pressure increase while operating will also tend to increase the power of the reactor by compressing voids thus adding reactivity. The trip will quickly reduce the neutron flux, counteracting the pressure increase. The trip setting is slightly higher than the operating pressure to permit normal operation without spurious trips. The setting provides for a wide margin to the maximum allowable design pressure and takes into account the location of the pressure measurement compared to the highest pressure that occurs in the system during a transient. This trip setpoint is effective at low power/flow conditions when the turbine stop valve and control fast closure trips are bypassed. For a turbine trip or load rejection under these conditions, the transient analysis indicated an adequate margin to the thermal hydraulic limit.

INTENTIONALLY LEFT BLANK

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

4. Reactor Vessel Water Level-Low

The reactor vessel water level trip setpoint has been used in transient analyses dealing with coolant inventory decrease. The scram setting was chosen far enough below the normal operating level to avoid spurious trips but high enough above the fuel to assure that there is adequate protection for the fuel and pressure limits.

5. Main Steam Line Isolation Valve-Closure

The main steam line isolation valve closure trip was provided to limit the amount of fission product release for certain postulated events. The MSIVs are closed automatically from measured parameters such as high steam flow, low reactor water level, high steam tunnel temperature, and low steam line pressure. The MSIVs closure scram anticipates the pressure and flux transients which could follow MSIV closure and thereby protects reactor vessel pressure and fuel thermal/hydraulic Safety Limits.

6. DELETED

7. Drywell Pressure-High

High pressure in the drywell could indicate a break in the primary pressure boundary systems or a loss of drywell cooling. The reactor is tripped in order to minimize the possibility of fuel damage and reduce the amount of energy being added to the coolant and to the primary containment. The trip setting was selected as low as possible without causing spurious trips.

REACTOR PROTECTION SYSTEM INSTRUMENTATION SETPOINTS (Continued)

8. Scram Discharge Volume Water Level-High

The scram discharge volume receives the water displaced by the motion of the control rod drive pistons during a reactor scram. Should this volume fill up to a point where there is insufficient volume to accept the displaced water at pressures below 65 psig, control rod insertion would be hindered. The reactor is therefore tripped when the water level has reached a point high enough to indicate that it is indeed filling up, but the volume is still great enough to accommodate the water from the movement of the rods at pressures below 65 psig when they are tripped. The trip setpoint for each scram discharge volume is equivalent to a contained volume of 25.58 gallons of water.

9. Turbine Stop Valve-Closure

The turbine stop valve closure trip anticipates the pressure, neutron flux, and heat flux increases that would result from closure of the stop valves. With a trip setting of 5% of valve closure from full open, the resultant increase in heat flux is such that adequate thermal margins are maintained during the worst design basis transient.

10. Turbine Control Valve Fast Closure, Trip Oil Pressure-Low

The turbine control valve fast closure trip anticipates the pressure, neutron flux, and heat flux increase that could result from fast closure of the turbine control valves due to load rejection with or without coincident failure of the turbine bypass valves. The Reactor Protection System initiates a trip when fast closure of the control valves is initiated by the fast acting solenoid valves and in less than 30 milliseconds after the start of control valve fast closure. This is achieved by the action of the fast acting solenoid valves in rapidly reducing hydraulic trip oil pressure at the main turbine control valve actuator disc dump valves. This loss of pressure is sensed by pressure switches whose contacts form the one-out-of-two-twice logic input to the Reactor Protection System. This trip setting, a faster closure time, and a different valve characteristic from that of the turbine stop valve, combine to produce transients which are very similar to that for the stop valve. Relevant transient analyses are discussed in Section 15.2.2 of the Final Safety Analysis Report.

11. Reactor Mode Switch Shutdown Position

The reactor mode switch Shutdown position is a redundant channel to the automatic protective instrumentation channels and provides additional manual reactor trip capability.

12. Manual Scram

The Manual Scram is a redundant channel to the automatic protective instrumentation channels and provides manual reactor trip capability.

BASES FOR

SECTIONS 3.0 AND 4.0

LIMITING CONDITIONS FOR OPERATION

AND

SURVEILLANCE REQUIREMENTS

INTENTIONALLY LEFT BLANK

NOTE

The BASES contained in succeeding pages summarize the reasons for the Specifications in Sections 3.0 and 4.0, but in accordance with 10 CFR 50.36 are not part of these Technical Specifications.

THIS PAGE INTENTIONALLY LEFT BLANK

Specifications 3.0.1 through 3.0.9 establish the general requirements applicable to Limiting Conditions for Operation. These requirements are based on the requirements for Limiting Conditions for Operation stated in the Code of Federal Regulations, 10 CFR 50.36(c)(2):

> "Limiting Conditions for operation are the lowest functional capability or performance levels of equipment required for safe operation of the facility. When a limiting condition for operation of a nuclear reactor is not met, the licensee shall shut down the reactor or follow any remedial action permitted by the technical specification until the condition can be met."

Specification 3.0.1 establishes the Applicability statement within each individual specification as the requirement for when (i.e., in which OPERATIONAL CONDITIONS or other specified conditions) conformance to the Limiting Conditions for Operation is required for safe operation of the facility. The ACTION requirements establish those remedial measures that must be taken within specified time limits when the requirements of a Limiting Condition for Operation are not met. The ACTIONS for not meeting a single LCO adequately manage any increase in plant risk, provided any unusual external conditions (e.g., severe weather, offsite power instability) are considered. In addition, the increased risk associated with simultaneous removal of multiple structures, systems, trains or components from service is assessed and managed in accordance with 10 CFR 50.65(a)(4).

There are two basic types of ACTION requirements. The first specifies the remedial measures that permit continued operation of the facility which is not further restricted by the time limits of the ACTION requirements. In this case, conformance to the ACTION requirements provides an acceptable level of safety for unlimited continued operation as long as the ACTION requirements continue to be met. The second type of ACTION requirement specifies a time limit in which conformance to the conditions of the Limiting Condition for Operation must be met. This time limit is the allowable outage time to restore an inoperable system or component to OPERABLE status or for restoring parameters within specified limits. If these actions are not completed within the allowable outage time limits, a shutdown is required to place the facility in an OPERATIONAL CONDITION or other specified condition in which the specification no longer applies.

The specified time limits of the ACTION requirements are applicable from the point of time it is identified that a Limiting Condition for Operation is not met. The time limits of the ACTION requirements are also applicable when a system or component is removed from service for surveillance testing or investigation of operational problems. Individual specifications may include a specified time limit for the completion of a Surveillance Requirement when equipment is removed from service. In this case, the allowable outage time limits of the ACTION requirements are applicable when this limit expires if the surveillance has not been completed. When a shutdown is required to comply with ACTION requirements, the plant may have entered an OPERATIONAL CONDITION in which a new specification becomes applicable. In this case, the time limits of the ACTION requirements would apply from the point in time that the new specification becomes applicable if the requirements of the Limiting Condition for Operation are not met.

Specification 3.0.2 establishes that noncompliance with a specification exists when the requirements of the Limiting Condition for Operation are not met and the associated ACTION requirements have not been implemented within the specified time interval, unless otherwise specified. The purpose of this specification is to clarify that (1) implementation of the ACTION requirements within the specified time interval constitutes compliance with a specification and (2) completion of the remedial measures of the ACTION requirements is not required when compliance with a Limiting Condition of Operation is restored within the time interval specified in the associated ACTION requirements.

Specification 3.0.3 establishes the shutdown ACTION requirements that must be implemented when a Limiting Condition for Operation is not met and the condition is not specifically addressed by the associated ACTION requirements or the required ACTION is not met. The purpose of this specification is to delineate the time limits for placing the unit in a safe shutdown CONDITION when plant operation cannot be maintained within the limits defined by the Limiting Conditions for Operation and its ACTION requirements. Planned entry into LCO 3.0.3 should be avoided. If it is not practicable to avoid planned entry into LCO 3.0.3, plant risk should be assessed and managed in accordance with 10 CFR 50.65(a)(4), and the planned entry into LCO 3.0.3 should have less effect on plant safety than other practicable alternatives.

Upon entering LCO 3.0.3, a risk assessment addressing inoperable systems and components must be completed and appropriate risk management actions must be implemented within 6 hours. The risk assessment must consider all inoperable equipment regardless of whether the equipment is included in the normal 10 CFR 50.65(a)(4) risk assessment scope. The risk assessments will be conducted using the procedures and guidance endorsed by Regulatory Guide 1.160, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." Regulatory Guide 1.160 endorses the guidance in Section 11 of NUMARC 93-01, “Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants.” All relevant elements of the risk assessment description in Section 11 will be included. These documents address general guidance for conduct of the risk assessment, quantitative and qualitative guidelines for establishing risk management actions, and example risk management actions. These include actions to plan and conduct other activities in a manner that controls overall risk, increased risk awareness by shift and management personnel, actions to reduce the duration of the condition, actions to minimize the magnitude of risk increases (establishment of backup success paths or compensatory measures). A formal cause or apparent cause evaluation is not required because of the limited time available, but the likely cause of the conditions that resulted in LCO 3.0.3 entry are considered. If the extent of condition is unknown, the risk assessment will consider the possibility of common cause failure either numerically or through risk management actions.

Continuing operation for a limited time is acceptable if the risk assessment determines that for the current plant configuration, the Incremental Core Damage Probability (ICDP) is less than 1E-5, and the Incremental Large Early Release Probability (ILERP) is less than 1E-6. Non-quantifiable factors will also be assessed. In addition, the configuration-specific Core Damage Frequency (CDF) and Large Early Release Frequency (LERF) will be evaluated to identify high-risk situations. A configuration-specific CDF in excess of 1E-3/year or LERF in excess of 1E-4/year does not support continuing operation. The impact on plant risk is evaluated from the baseline, zero-maintenance, condition.

Whenever practicable, a quantitative value for risk will be determined. If determination of a quantitative value for risk is not practicable, a qualitative assessment of risk may be used with appropriate consideration of the plant conditions and uncertainties to determine whether continued operation for a limited time is acceptable.

If during the 24-hour period the plant configuration changes such that plant risk may be increased, the risk must be reassessed. If the configuration no longer supports continuing plant operation, action must be initiated to shut down the unit in accordance with the LCO 3.0.3 requirements.

Appropriate risk management actions are implemented in accordance with the Maintenance Rule procedures that are appropriate for the current plant condition and the inoperable equipment. Risk management actions are used to address non-quantifiable factors, increase risk awareness, and reduce the risk magnitude and duration.

If the risk assessment determines that continuing operation is acceptable, that the appropriate risk management actions are implemented, and that entry into LCO 3.0.3 was unplanned, action to shut down the unit must be initiated within 24 hours of entry into LCO 3.0.3. It is not necessary for the planned restoration of compliance with the LCO or ACTIONS to be within 24 hours as other actions are available, such as regulatory relief or an orderly shutdown. The 24-hour provision may not be used if the LCO 3.0.3 entry is planned, such as intentionally removing a train from service when the redundant train is inoperable. However, it may be used for emergent conditions that occur in parallel with other planned or unplanned inoperabilities.

The determination that continuing operation is acceptable will be documented in sufficient detail to allow a knowledgeable individual to understand the basis for the determination.

If the risk assessment determines that continuing operation is not acceptable, if the risk assessment was not completed, the appropriate risk management actions were not implemented, or if entry into LCO 3.0.3 was planned, action to shut down the unit must be initiated following the 6 hour time period provided to perform the risk assessment and implement risk management actions.

All times for completing actions and entering OPERATIONAL CONDITIONS are determined from entry into LCO 3.0.3.

The time limits specified to enter lower CONDITIONS of operation permit the shutdown to proceed in a controlled and orderly manner that is well within the specified maximum cooldown rate and within the cooldown capabilities of the facility assuming only the minimum required equipment is OPERABLE. This reduces thermal stresses on components of the primary coolant system and the potential for a plant upset that could challenge safety systems under conditions for which this specification applies.

If remedial measures permitting limited continued operation of the facility under the provisions of the ACTION requirements are completed, the shutdown may be terminated. The time limits of the ACTION requirements are applicable from the point in time there was a failure to meet a Limiting Condition for Operation. Therefore, the shutdown may be terminated if the ACTION requirements have been met, the ACTION is no longer applicable, or time limits of the ACTION requirements have not expired, thus providing an allowance for the completion of the required actions.

The time limits of Specification 3.0.3 allow 36 hours for the plant to be in COLD SHUTDOWN after a shutdown is initiated during POWER operation. If the plant is in a lower CONDITION of operation when a shutdown is initiated, the time limit for entering the next lower CONDITION of operation applies. However, if a lower CONDITION of operation is entered in less time than allowed, the total allowable time to enter COLD SHUTDOWN, or other OPERATIONAL CONDITION, is not reduced. For example, if HOT SHUTDOWN is entered 10 hours after a shutdown is initiated, the time allowed to enter COLD SHUTDOWN is the next 26 hours because the total time to enter COLD SHUTDOWN is not reduced from the allowable limit of 36 hours after a shutdown is initiated. Therefore, if remedial measures are completed that would permit a return to POWER operation, a penalty is not incurred by having to enter a lower CONDITION of operation in less than the total time allowed.

The same principle applies with regard to the allowable outage time limits of the ACTION requirements, if compliance with the ACTION requirements for one specification results in entry into an OPERATIONAL CONDITION or condition of operation for another specification in which the requirements of the Limiting Condition for Operation are not met. If the new specification becomes applicable in less time than specified, the difference may be added to the allowable outage time limits of the second specification. However, the allowable outage time of ACTION requirements for a higher CONDITION of operation may not be used to extend the allowable outage time that is applicable when a Limiting Condition for Operation is not met in a lower CONDITION of operation.

The shutdown requirements of Specification 3.0.3 do not apply in CONDITIONS 4 and 5, because the ACTION requirements of individual specifications define the remedial measures to be taken.

Specification 3.0.4 establishes limitations on changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability when a Limiting Condition for Operation is not met. It allows placing the unit in an OPERATIONAL CONDITION or other specified condition stated in that Applicability (e.g., the Applicability desired to be entered) when unit conditions are such that the requirements of the Limiting Condition for Operation would not be met, in accordance with either Specification 3.0.4.a, Specification 3.0.4.b, or Specification 3.0.4.c.

Specification 3.0.4.a allows entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met when the associated ACTION requirements to be entered following entry into the OPERATIONAL CONDITION or other specified condition in the Applicability will permit continued operation within the MODE or other specified condition for an unlimited period of time. Compliance with ACTIONS requirements that permit continued operation of the unit for an unlimited period of time in an OPERATIONAL CONDITION or other specified condition provides an acceptable level of safety for continued operation. This is without regard to the status of the unit before or after the OPERATIONAL CONDITION change. Therefore, in such cases, entry into an OPERATIONAL CONDITION or other specified condition in the Applicability may be made and the Required Actions followed after entry into the Applicability.

For example, LCO 3.0.4.a may be used when the Required Action to be entered states that an inoperable instrument channel must be placed in the trip condition within the Completion Time. Transition into a MODE or other specified condition in the Applicability may be made in accordance with LCO 3.0.4 and the channel is subsequently placed in the tripped condition within the Completion Time, which begins when the Applicability is entered. If the instrument channel cannot be placed in the tripped condition and the subsequent default ACTION ("Required Action and associated Completion Time not met") allows the OPERABLE train to be placed in operation, use of LCO 3.0.4.a is acceptable because the subsequent ACTIONS to be entered following entry into the MODE include ACTIONS (place the OPERABLE train in operation) that permit safe plant operation for an unlimited period of time in the MODE or other specified condition to be entered.

Specification 3.0.4.b allows entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, consideration of the results, determination of the acceptability of entering the OPERATIONAL CONDITION or other specified condition in the Applicability, and establishment of risk management actions, if appropriate.

The risk assessment may use quantitative, qualitative, or blended approaches, and the risk assessment will be conducted using the plant program, procedures, and criteria in place to implement 10 CFR 50.65(a)(4), which requires that risk impacts of maintenance activities be assessed and managed. The risk assessment, for the purposes of Specification 3.0.4.b, must take into account all inoperable Technical Specification equipment regardless of whether the equipment is included in the normal 10 CFR 50.65(a)(4) risk assessment scope. The risk assessments will be conducted using the procedures and guidance endorsed by Regulatory Guide 1.182, "Assessing and Managing Risk Before Maintenance Activities at Nuclear Power Plants." Regulatory Guide 1.182 endorses the guidance in Section 11 of NUMARC 93-01, "Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." These documents address general guidance for conduct of the risk assessment, quantitative and qualitative guidelines for establishing risk management actions, and example risk management actions. These include actions to plan and conduct other activities in a manner that controls overall risk, increased risk awareness by shift and management personnel, actions to reduce the duration of the condition, actions to minimize the magnitude of risk increases (establishment of backup success paths or compensatory measures), and determination that the proposed OPERATIONAL CONDITION change is acceptable. Consideration should also be given to the probability of completing restoration such that the requirements of the Limiting Condition for Operation would be met prior to the expiration of the ACTION requirement's specified time interval that would require exiting the Applicability.

Specification 3.0.4.b may be used with single, or multiple systems and components unavailable. NUMARC 93-01 provides guidance relative to consideration of simultaneous unavailability of multiple systems and components.

The results of the risk assessment shall be considered in determining the acceptability of entering the OPERATIONAL CONDITION or other specified condition in the Applicability, and any corresponding risk management actions. The Specification 3.0.4.b risk assessments do not have to be documented.

The Technical Specifications allow continued operation with equipment unavailable in OPERATIONAL CONDITION 1 for the duration of the specified time interval. Since this is allowable, and since in general the risk impact in that particular OPERATIONAL CONDITION bounds the risk of transitioning into and through the applicable OPERATIONAL CONDITIONS or other specified conditions in the Applicability of the Limiting Condition for Operation, the use of the Specification 3.0.4.b allowance should be generally acceptable, as long as the risk is assessed and managed as stated above. However, there is a small subset of systems and components that have been determined to be more important to risk and use of the Specification 3.0.4.b allowance is prohibited. The Limiting Condition for Operations governing these system and components contain Notes prohibiting the use of Specification 3.0.4.b by stating that Specification 3.0.4.b is not applicable.

Specification 3.0.4.c allows entry into a OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met based on a Note in the Specification which states Specification 3.0.4.c is applicable. These specific allowances permit entry into OPERATIONAL CONDITIONS or other specified conditions in the Applicability when the associated ACTION requirements to be entered do not provide for continued operation for an unlimited period of time and a risk assessment has not been performed. This allowance may apply to all the ACTION requirements or to a specific ACTION requirement of a Specification. The risk assessments

performed to justify the use of Specification 3.0.4.b usually only consider systems and components. For this reason, Specification 3.0.4.c is typically applied to Specifications which describe values and parameters (e.g., Reactor Coolant Specific Activity), and may be applied to other Specifications based on NRC plant-specific approval.

The provisions of this Specification should not be interpreted as endorsing the failure to exercise the good practice of restoring systems or components to OPERABLE status before entering an associated OPERATIONAL CONDITION or other specified condition in the Applicability.

The provisions of Specification 3.0.4 shall not prevent changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability that are required to comply with ACTION requirements. In addition, the provisions of Specification 3.0.4 shall not prevent changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability that result from any unit shutdown. In this

THIS PAGE INTENTIONALLY LEFT BLANK

context, a unit shutdown is defined as a change in OPERATIONAL CONDITION or other specified condition in the Applicability associated with transitioning from OPERATIONAL CONDITION 1 to OPERATIONAL CONDITION 2, OPERATIONAL CONDITION 2 to OPERATIONAL CONDITION 3, and OPERATIONAL CONDITION 3 to OPERATIONAL CONDITION 4.

Upon entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met, Specification 3.0.1 and Specification 3.0.2 require entry into the applicable Conditions and ACTION requirements until the Condition is resolved, until the Limiting Condition for Operation is met, or until the unit is not within the Applicability of the Technical Specification.

Surveillances do not have to be performed on the associated inoperable equipment (or on variables outside the specified limits), as permitted by Specification 4.0.1. Therefore, utilizing Specification 3.0.4 is not a violation of Specification 4.0.1 or Specification 4.0.4 for any Surveillances that have not been performed on inoperable equipment. However, SRs must be met to ensure OPERABILITY prior to declaring the associated equipment OPERABLE (or variable within limits) and restoring compliance with the affected Limiting Condition for Operation.

Specification 3.0.5 establishes the allowance for restoring equipment to service under administrative controls when it has been removed from service or declared inoperable to comply with ACTIONs. The sole purpose of this Specification is to provide an exception to Specifications 3.0.1 and 3.0.2 (e.g., to not comply with the applicable ACTION(s)) to allow the performance of required testing to demonstrate:

a. The OPERABILITY of the equipment being returned to service, or

b. The OPERABILITY of other equipment.

The administrative controls ensure the time the equipment is returned to service in conflict with the requirements of the ACTIONs is limited to the time necessary to perform the required testing to demonstrate OPERABILITY. This Specification does not provide time to perform any other preventive or corrective maintenance. LCO 3.0.5 should not be used in lieu of other practicable alternatives that comply with Required Actions and that do not require changing the MODE or other specified conditions in the Applicability in order to demonstrate equipment is OPERABLE. LCO 3.0.5 is not intended to be used repeatedly.

An example of demonstrating equipment is OPERABLE with the Required Actions not met is opening a manual valve that was closed to comply with Required Actions to isolate a flowpath with excessive Reactor Coolant System (RCS) Pressure Isolation Valve (PIV) leakage in order to perform testing to demonstrate that RCS PIV leakage is now within limit.

Examples of demonstrating equipment OPERABILITY include instances in which it is necessary to take an inoperable channel or trip system out of a tripped condition that was directed by a Required Action, if there is no Required Action Note for this purpose. An example of verifying OPERABILITY of equipment removed from service is taking a tripped channel out of the tripped condition to permit the logic to function and indicate the appropriate response during performance of required testing on the inoperable channel.

Examples of demonstrating the OPERABILITY of other equipment are taking an inoperable channel or trip system out of the tripped condition to 1) prevent the trip function from occurring during the performance of required testing on another channel in the other trip system, or 2) to permit the logic to function and indicate the appropriate response during the performance of required testing on another channel in the same trip system.

The administrative controls in LCO 3.0.5 apply in all cases to systems or components in Chapter 3 of the Technical Specifications, as long as the testing could not be conducted while complying with the Required Actions. This includes the realignment or repositioning of redundant or alternate equipment or trains previously manipulated to comply with ACTIONS, as well as equipment removed from service or declared inoperable to comply with ACTIONS.

THIS PAGE INTENTIONALLY LEFT BLANK

Specification 3.0.6 establishes an exception to Specifications 3.0.1 and 3.0.2 for supported systems that have a support system Limiting Condition for Operation specified in the Technical Specifications (TS). The exception to Specification 3.0.1 is provided because Specification 3.0.1 would require that the ACTIONs of the associated inoperable supported system Limiting Condition for Operation be entered solely due to the inoperability of the support system. This exception is justified because the actions that are required to ensure the plant is maintained in a safe condition are specified in the support system Limiting Condition for Operation's ACTIONs. These ACTIONs may include entering the supported system's ACTIONs or may specify other ACTIONs. The exception to Specification 3.0.2 is provided because Specification 3.0.2 would consider not entering into the ACTIONs for the supported system within the specified time intervals as a TS noncompliance.

When a support system is inoperable and there is a Limiting Condition for Operation specified for it in the TS, the supported system(s) are required to be declared inoperable if determined to be inoperable as a result of the support system inoperability. However, it is not necessary to enter into the supported systems' ACTIONs unless directed to do so by the support system's ACTIONs. The potential confusion and inconsistency of requirements related to the entry into multiple support and supported systems' Limiting Condition for Operations' ACTIONs are eliminated by providing all the actions that are necessary to ensure the plant is maintained in a safe condition in the support system's ACTIONs.

However, there are instances where a support system's ACTION may either direct a supported system to be declared inoperable or direct entry into ACTIONS for the supported system. This may occur immediately or after some specified delay to perform some other ACTION. Regardless of whether it is immediate or after some delay, when a support system's ACTION directs a supported system to be declared inoperable or directs entry into ACTIONs for a supported system, the applicable ACTIONs shall be entered in accordance with Specification 3.0.1.

Specification 6.17, "Safety Function Determination Program (SFDP)," ensures loss of safety function is detected and appropriate actions are taken. Upon entry into Specification 3.0.6, an evaluation shall be made to determine if loss of safety function exists. Additionally, other limitations, remedial actions, or compensatory actions may be identified as a result of the support system inoperability and corresponding exception to entering supported system ACTIONs. The SFDP implements the requirements of Specification 3.0.6.

The following examples use Figure B 3.0-1 to illustrate loss of safety function conditions that may result when a TS support system is inoperable. In this figure, the fifteen systems that comprise Train A are independent and redundant to the fifteen systems that comprise Train B. To correctly use the figure to illustrate the SFDP provisions for a cross train check, the figure establishes a relationship between support and supported systems as follows: the figure shows System 1 as a support system for System 2 and System 3; System 2 as a support system for System 4 and System 5; and System 4 as a support system for System 8 and System 9. Specifically, a loss of safety function may exist when a support system is inoperable and:

a. A system redundant to system(s) supported by the inoperable support system is also inoperable (EXAMPLE B 3.0.6-1),

b. A system redundant to system(s) in turn supported by the inoperable supported system is also inoperable (EXAMPLE B 3.0.6-2), or

c. A system redundant to support system(s) for the supported systems (a) and (b) above is also inoperable (EXAMPLE B 3.0.6-3).

For the following examples, refer to Figure B 3.0-1.

EXAMPLE B 3.0.6-1
If System 2 of Train A is inoperable and System 5 of Train B is inoperable, a loss of safety function exists in Systems 5, 10, and 11.

EXAMPLE B 3.0.6-2

If System 2 of Train A is inoperable, and System 11 of Train B is inoperable, a loss of safety function exists in System 11.

EXAMPLE B 3.0.6-3

If System 2 of Train A is inoperable, and System 1 of Train B is inoperable, a loss of safety function exists in Systems 2, 4, 5, 8, 9, 10 and 11.

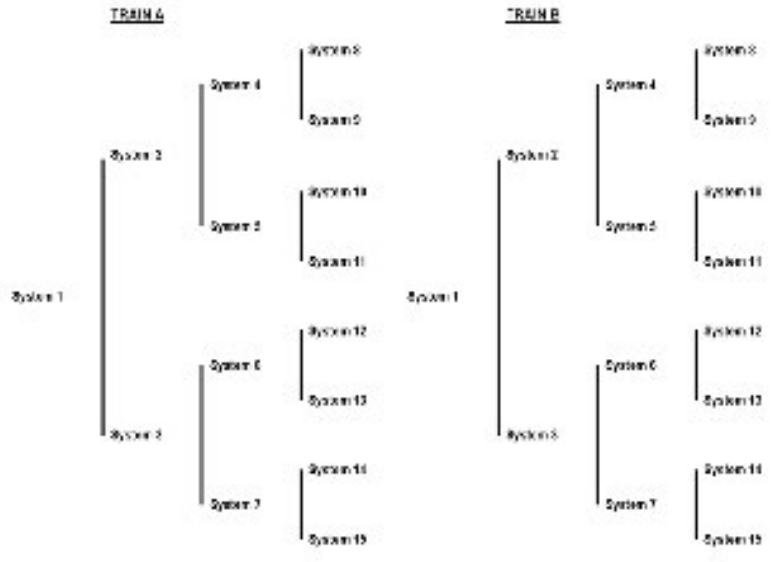

Figure B 3.0-1
Configuration of Trains and Systems

If an evaluation determines that a loss of safety function exists, the appropriate ACTIONs of the Limiting Condition for Operation in which the loss of safety function exists are required to be entered. This loss of safety function does not require the assumption of additional single failures or loss of offsite power. Since operations are being restricted in accordance with the ACTIONs of the support system, any resulting temporary loss of redundancy or single failure protection is taken into account.

When loss of safety function is determined to exist, and the SFDP requires entry into the appropriate ACTIONs of the Limiting Condition for Operation in which the loss of safety function exists, consideration must be given to the specific type of function affected. Where a loss of function is solely due to a single Technical Specification support system (e.g., loss of automatic start due to inoperable instrumentation, or loss of pump suction source due to low tank level), the appropriate Limiting Condition for Operation is the Limiting Condition for Operation for the support system. The ACTIONs for a support system Limiting Condition for Operation adequately address the inoperabilities of that system without reliance on entering its supported system Limiting Condition for Operation. When the loss of function is the result of multiple support systems, the appropriate Limiting Condition for Operation is the Limiting Condition for Operation for the supported system.

Specification 3.0.7 - Not Used

Specification 3.0.8 establishes conditions under which systems are considered to remain capable of performing their intended safety function when associated snubbers are not capable of providing their associated support function(s). This Specification states that the supported system is not considered to be inoperable solely due to one or more snubbers not capable of performing their associated support function(s). This is appropriate because a limited length of time is allowed for maintenance, testing, or repair of one or more snubbers not capable of performing their associated support function(s) and appropriate compensatory measures are specified in the snubber requirements, which are located outside of the Technical Specifications (TS) under licensee control. The snubber requirements do not meet the criteria in 10 CFR 50.36(c)(2)(ii), and, as such, are appropriate for control by the licensee.

If the allowed time expires and the snubber(s) are unable to perform their associated support function(s), the affected supported system's Limiting Condition for Operation must be declared not met and the associated ACTION requirements shall be met in accordance with Specification 3.0.1.

Specification 3.0.8.a applies when one or more snubbers are not capable of providing their associated support function(s) to a single train or subsystem of a multiple train or subsystem supported system or to a single train or subsystem supported system. Specification 3.0.8.a allows 72 hours to restore the snubber(s) before declaring the supported system inoperable. The 72-hour Completion Time is reasonable based on the low probability of a seismic event concurrent with an event that would require operation of the supported system occurring while the snubber(s) are not capable of performing their associated support function and due to the availability of the redundant train of the supported system.

Specification 3.0.8.b applies when one or more snubbers are not capable of providing their associated support function(s) to more than one train or subsystem of a multiple train or subsystem supported system. Specification 3.0.8.b allows 12 hours to restore the snubber(s) before declaring the supported system inoperable. The 12-hour Completion Time is reasonable based on the low probability of a seismic event concurrent with an event that would require operation of the supported system occurring while the snubber(s) are not capable of performing their associated support function.

The following configuration restrictions shall be applied to the use of Specification 3.0.8:

(1) Specification 3.0.8.a can only be used if one of the following two means of heat removal is available:

a. At least one high pressure makeup path (e.g., using High Pressure Coolant Injection (HPCI) or Reactor Core Isolation Cooling (RCIC) or its equivalent) and heat removal capability (e.g., suppression pool cooling), including a minimum set of supporting equipment required for success, not associated with the inoperable snubber(s), or

b. At least one low pressure makeup path (e.g., Low Pressure Coolant Injection (LPCI) or Core Spray (CS)) and heat removal capability (e.g., suppression pool cooling or shutdown cooling), including a minimum set of supporting equipment required for success, not associated with the inoperable snubber(s).

(2) Specification 3.0.8.b can only be used following verification that at least one success path exists, using equipment not associated with the inoperable snubber(s), to provide makeup and core cooling needed to mitigate Loss of Offsite Power (LOOP) accident sequences (i.e., initiated by a seismically-induced LOOP event with concurrent loss of all safety system trains supported by the out-of-service snubbers).

Specification 3.0.8 only applies to the seismic function of snubbers; it does not apply to the non-seismic functions of snubbers. Therefore, each use of Specification 3.0.8 for seismic snubbers that also have non-seismic functions requires confirmation that at least one train (or subsystem) of systems supported by the inoperable snubbers would remain capable of performing their required safety or support functions for postulated design loads other than seismic loads. In addition, a record of the design function of the inoperable snubber (i.e., seismic vs. non-seismic), implementation and compliance with the configuration restrictions defined above, and the associated plant configuration shall be available on a recoverable basis for NRC inspection.

Specification 3.0.8 requires that risk be assessed and managed. Industry and NRC guidance on the implementation of 10 CFR 50.65(a)(4) (i.e., the Maintenance Rule) does not address seismic risk. However, use of Specification 3.0.8 should be considered with respect to other plant maintenance activities, and integrated into the existing Maintenance Rule process to the extent possible so that maintenance on any unaffected train or subsystem is properly controlled, and emergent issues are properly addressed. The risk assessment need not be quantified, but may be a qualitative awareness of the vulnerability of systems and components when one or more snubbers are not able to perform their associated support function.

Specification 3.0.9 establishes conditions under which systems described in the Technical Specifications are considered to remain OPERABLE when required barriers are not capable of providing their related support function(s).

Barriers are doors, walls, floor plugs, curbs, hatches, installed structures or components, or other devices, not explicitly described in Technical Specifications, that support the performance of the safety function of systems described in the Technical Specifications. This Limiting Condition for Operation states that the supported system is not considered to be inoperable

solely due to required barriers not capable of performing their related support function(s) under the described conditions. Limiting Condition for Operation 3.0.9 allows 30 days before declaring the supported system(s) inoperable and the Limiting Conditions for Operation associated with the supported system(s) not met. A maximum time is placed on each use of this allowance to ensure that as required barriers are found or are otherwise made unavailable, they are restored. However, the allowable duration may be less than the specified maximum time based on the risk assessment.

If the allowed time expires and the barriers are unable to perform their related support function(s), the supported system's Limiting Conditions for Operation must be declared not met and the Conditions and Required Actions entered in accordance with Limiting Condition for Operation 3.0.2.

This provision does not apply to barriers which support ventilation systems or to fire barriers. The Technical Specifications for ventilation systems provide specific Conditions for inoperable barriers. Fire barriers are addressed by other regulatory requirements and associated plant programs. This provision does not apply to barriers which are not required to support system OPERABILITY (see NRC Regulatory Issue Summary 2001-09, "Control of Hazard Barriers," dated April 2, 2001).

The provisions of Limiting Condition for Operation 3.0.9 are justified because of the low risk associated with required barriers not being capable of performing their related support function. This provision is based on consideration of the following initiating event categories:

- Loss of coolant accidents;
- High energy line breaks;
- Feedwater line breaks;
- Internal flooding;
- External flooding;
- Turbine missile ejection; and
- Tornado or high wind.

The risk impact of the barriers which cannot perform their related support function(s) must be addressed pursuant to the risk assessment and management provision of the Maintenance Rule, 10 CFR 50.65 (a)(4), and the associated implementation guidance, Regulatory Guide 1.160, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." Regulatory Guide 1.160 endorses the guidance in Section 11 of NUMARC 93-01, "Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." This guidance provides for the consideration of dynamic plant configuration issues, emergent conditions, and other aspects pertinent to plant operation with the barriers unable to perform their related support function(s). These considerations may result in risk management and other compensatory actions being required during the period that barriers are unable to perform their related support function(s).

Limiting Condition for Operation 3.0.9 may be applied to one or more trains or subsystems of a system supported by barriers that cannot provide their related support function(s), provided that risk is assessed and managed (including consideration of the effects on Large Early Release and from external events). If applied concurrently to more than one train or subsystem of a multiple train or subsystem supported system, the barriers supporting each of these trains or subsystems must provide their related support function(s) for different categories of initiating events. For example, Limiting Condition for Operation 3.0.9 may be applied for up to 30 days for more than one train of a multiple train supported system if the affected barrier for one train protects against internal flooding and the affected barrier for the other train protects against tornado missiles. In this example, the affected barrier may be the same physical barrier but serve different protection functions for each train.

The HPCI and RCIC systems are single train systems for injecting makeup water into the reactor during an accident or transient event. For the purposes of Limiting Condition for Operation 3.0.9, the HPCI system, the RCIC system, and the ADS are considered independent subsystems of a single system and Limiting Condition for Operation 3.0.9 can be used on these single train systems in a manner similar to multiple train or subsystem systems.

If during the time that Limiting Condition for Operation 3.0.9 is being used, the required OPERABLE train or subsystem becomes inoperable, it must be restored to OPERABLE status within 24 hours. Otherwise, the train(s) or subsystem(s) supported by barriers that cannot perform their related support function(s) must be declared inoperable and the associated Limiting Conditions for Operation declared not met. This 24 hour period provides time to respond to emergent conditions that would otherwise likely lead to entry into Limiting Condition for Operation 3.0.3 and a rapid plant shutdown, which is not justified given the low probability of an initiating event which would require the barrier(s) not capable of performing their related support function(s). During this 24 hour period, the plant risk associated with the existing conditions is assessed and managed in accordance with 10 CFR 50.65(a)(4).

BASES

Specification 4.0.1 through 4.0.5 establish the general requirements applicable to Surveillance Requirements. SR 4.0.2 and SR 4.0.3 apply in Section 6, Administrative Controls, only when invoked by a Section 6 Specification. These requirements are based on the Surveillance Requirements stated in the Code of Federal Regulations 10 CFR 50.36(c)(3):

"Surveillance requirements are requirements relating to test, calibration, or inspection to ensure that the necessary quality of systems and components is maintained, that facility operation will be within safety limits, and that the limiting conditions of operation will be met."

Specification 4.0.1 establishes the requirement that SRs must be met during the OPERATIONAL CONDITIONS or other specified conditions in the Applicability for which the requirements of the Limiting Condition for Operation apply, unless otherwise specified in the individual SRs. This Specification is to ensure that Surveillances are performed to verify the OPERABILITY of systems and components, and that variables are within specified limits. Failure to meet a Surveillance within the specified Surveillance time interval and allowed extension, in accordance with Specification 4.0.2, constitutes a failure to meet the Limiting Condition for Operation.

Systems and components are assumed to be OPERABLE when the associated SRs have been met. Nothing in this Specification, however, is to be construed as implying that systems or components are OPERABLE when:

a. The systems or components are known to be inoperable, although still meeting the SRs; or

b. The requirements of the Surveillance(s) are known to be not met between required Surveillance performances.

Surveillances do not have to be performed when the unit is in an OPERATIONAL CONDITION or other specified condition for which the requirements of the associated Limiting Condition for Operation are not applicable, unless otherwise specified. The SRs associated with a Special Test Exception Limiting Condition for Operation are only applicable when the Special Test Exception Limiting Condition for Operation is used as an allowable exception to the requirements of a Specification.

Unplanned events may satisfy the requirements (including applicable acceptance criteria) for a given SR. In this case, the unplanned event may be credited as fulfilling the performance of the SR. This allowance includes those SRs whose performance is normally precluded in a given OPERATIONAL CONDITION or other specified condition.

Surveillances, including Surveillances invoked by ACTION requirements, do not have to be performed on inoperable equipment because the ACTIONS define the remedial measures that apply. Surveillances have to be met and performed in accordance with Specification 4.0.2, prior to returning equipment to OPERABLE status.

Upon completion of maintenance, appropriate post maintenance testing is required to declare equipment OPERABLE. This includes ensuring applicable Surveillances are not failed and their most recent performance is in accordance with Specification 4.0.2. Post maintenance testing may not be possible in the current OPERATIONAL CONDITION or other specified conditions in the Applicability due to the necessary unit parameters not having been established. In these situations, the equipment may be considered OPERABLE provided testing has been satisfactorily completed to the extent possible and the equipment is not otherwise believed to be incapable of performing its function. This will allow operation to proceed to an OPERATIONAL CONDITION or other specified condition where other necessary post maintenance tests can be completed.

Some examples of this process are:

a. Control Rod Drive maintenance during refueling that requires scram testing at > 950 psi. However, if other appropriate testing is satisfactorily completed and the scram time testing of Specification 4.1.3.2 is satisfied, the control rod can be considered OPERABLE. This allows startup to proceed to reach 950 psi to perform other necessary testing.

b. High pressure coolant injection (HPCI) maintenance during shutdown that requires system functional tests at a specified pressure. Provided other appropriate testing is satisfactorily completed, startup can proceed with HPCI considered OPERABLE. This allows operation to reach the specified pressure to complete the necessary post maintenance testing.

Specification 4.0.2 establishes the limit for which the specified time interval for Surveillance Requirements may be extended. It permits an allowable extension of the normal surveillance interval to facilitate surveillance scheduling and consideration of plant operating conditions that may not be suitable for conducting the surveillance; e.g., transient conditions or other ongoing surveillance or maintenance activities. It also provides flexibility to accommodate the length of a fuel cycle for surveillances that are performed at each refueling outage and are specified with an 24-month surveillance interval. It is not intended that this provision be used repeatedly as a convenience to extend the surveillance intervals beyond that specified for surveillances that are not performed during refueling outages. Likewise, it is not the intent that REFUELING INTERVAL surveillances be performed during power operation unless it is consistent with safe plant operation. The limitation of Specification 4.0.2 is based on engineering judgment and the recognition that the most probable result of any particular surveillance being performed is the verification of conformance with the Surveillance Requirements. This provision is sufficient to ensure that the reliability ensured through surveillance activities is not significantly degraded beyond that obtained from the specified surveillance interval.

Specification 4.0.3 establishes the flexibility to defer declaring affected equipment inoperable or an affected variable outside the specified limits when a Surveillance has not been performed within the specified Surveillance time interval and allowed extension. A delay period of up to 24 hours or up to the limit of the specified Surveillance time interval, whichever is greater, applies from the point in time that it is discovered that the Surveillance has not been performed in accordance with Specification 4.0.2, and not at the time that the specified Surveillance time interval and allowed extension was not met.

When a Section 6.8, “Procedures and Programs,” specification states that the provisions of SR 4.0.3 are applicable, it permits the flexibility to defer declaring the testing requirement not met in accordance with SR 4.0.3 when the testing has not been completed within the testing interval (including the allowance of SR 4.0.2 if invoked by the Section 6.8 specification).

This delay period provides adequate time to perform Surveillances that have been missed. This delay period permits the performance of a Surveillance before complying with ACTION requirements or other remedial measures that might preclude performance of the Surveillance.

The basis for this delay period includes consideration of unit conditions, adequate planning, availability of personnel, the time required to perform the Surveillance, the safety significance of the delay in completing the required Surveillance, and the recognition that the most probable result of any particular Surveillance being performed is the verification of conformance with the requirements. When a Surveillance with a Surveillance time interval based not on time intervals, but upon specified unit conditions, operating situations, or requirements of regulations (e.g., prior to entering OPERATIONAL CONDITION 1 after each fuel loading, or in accordance with 10 CFR 50, Appendix J, as modified by approved exemptions, etc.) is discovered to have not been performed when specified, Specification 4.0.3 allows for the full delay period of up to the specified Surveillance time interval to perform the Surveillance. However, since there is not a time interval specified, the missed Surveillance should be performed at the first reasonable opportunity.

Specification 4.0.3 provides a time limit for, and allowances for the performance of, Surveillances that become applicable as a consequence of OPERATIONAL CONDITION changes imposed by ACTION requirements.

Specification 4.0.3 (Continued)

SR 4.0.3 is only applicable if there is a reasonable expectation the associated equipment is OPERABLE or that variables are within limits, and it is expected that the Surveillance will be met when performed. Many factors should be considered, such as the period of time since the Surveillance was last performed, or whether the Surveillance, or a portion thereof, has ever been performed, and any other indications, tests, or activities that might support the expectation that the Surveillance will be met when performed. An example of the use of SR 4.0.3 would be a relay contact that was not tested as required in accordance with a particular SR, but previous successful performances of the SR included the relay contact; the adjacent, physically connected relay contacts were tested during the SR performance; the subject relay contact has been tested by another SR; or historical operation of the subject relay contact has been successful. It is not sufficient to infer the behavior of the associated equipment from the performance of similar equipment. The rigor of determining whether there is a reasonable expectation a Surveillance will be met when performed should increase based on the length of time since the last performance of the Surveillance. If the Surveillance has been performed recently, a review of the Surveillance history and equipment performance may be sufficient to support a reasonable expectation that the Surveillance will be met when performed. For Surveillances that have not been performed for a long period or that have never been performed, a rigorous evaluation based on objective evidence should provide a high degree of confidence that the equipment is OPERABLE. The evaluation should be documented in sufficient detail to allow a knowledgeable individual to understand the basis for the determination.

Failure to comply with specified Surveillance time intervals and allowed extensions for SRs is expected to be an infrequent occurrence. Use of the delay period established by Specification 4.0.3 is a flexibility which is not intended to be used repeatedly to extend Surveillance intervals.

THIS PAGE INTENTIONALLY LEFT BLANK

While up to 24 hours or the limit of the specified Surveillance time interval is provided to perform the missed Surveillance, it is expected that the missed Surveillance will be performed at the first reasonable opportunity. The determination of the first reasonable opportunity should include consideration of the impact on plant risk (from delaying the Surveillance as well as any plant configuration changes required or shutting the plant down to perform the Surveillance) and impact on any analysis assumptions, in addition to unit conditions, planning, availability of personnel, and the time required to perform the Surveillance. This risk impact should be managed through the program in place to implement 10 CFR 50.65(a)(4) and its implementation guidance, NRC Regulatory Guide 1.182, 'Assessing and Managing Risk Before Maintenance Activities at Nuclear Power Plants.' This Regulatory Guide addresses consideration of temporary and aggregate risk impacts, determination of risk management action thresholds, and risk management action up to and including plant shutdown. The missed Surveillance should be treated as an emergent condition as discussed in the Regulatory Guide. The risk evaluation may use quantitative, qualitative, or blended methods. The degree of depth and rigor of the evaluation should be commensurate with the importance of the component. Missed Surveillances for important components should be analyzed quantitatively. If the results of the risk evaluation determine the risk increase is significant, this evaluation should be used to determine the safest course of action. All missed Surveillances will be placed in the Corrective Action Program.

If a Surveillance is not completed within the allowed delay period, then the equipment is considered inoperable or the variable is considered outside the specified limits and the ACTION requirements for the applicable Limiting Condition for Operation begin immediately upon expiration of the delay period. If a Surveillance is failed within the delay period or the variable is outside the specified limits, then the equipment is inoperable and the Completion Times of the Required Actions for the applicable LCO Conditions begin immediately upon the failure of the Surveillance.

Completion of the Surveillance within the delay period allowed by this Specification, or within the allowed times specified in the ACTION requirements, restores compliance with Specification 4.0.1.

Specification 4.0.4 establishes the requirement that all applicable SRs must be met before entry into an OPERATIONAL CONDITION or other specified condition in the Applicability.

This Specification ensures that system and component OPERABILITY requirements and variable limits are met before entry into OPERATIONAL CONDITIONS or other specified conditions in the Applicability for which these systems and components ensure safe operation of the unit. The provisions of this Specification should not be interpreted as endorsing the failure to exercise the good practice of restoring systems or components to OPERABLE status before entering an associated OPERATIONAL CONDITION or other specified condition in the Applicability.

A provision is included to allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability when a Limiting Condition for Operation is not met due to a Surveillance not being met in accordance with Specification 3.0.4.

However, in certain circumstances, failing to meet an SR will not result in Specification 4.0.4 restricting an OPERATIONAL CONDITION change or other specified

condition change. When a system, subsystem, division, component, device, or variable is inoperable or outside its specified limits, the associated SR(s) are not required to be performed, per Specification 4.0.1, which states that surveillances do not have to be performed on inoperable equipment. When equipment is inoperable, Specification 4.0.4 does not apply to the associated SR(s) since the requirement for the SR(s) to be performed is removed. Therefore, failing to perform the Surveillance(s) within the specified Surveillance time interval does not result in a Specification 4.0.4 restriction to changing OPERATIONAL CONDITIONS or other specified conditions of the Applicability. However, since the Limiting Condition for Operation is not met in this instance, Specification 3.0.4 will govern any restrictions that may (or may not) apply to OPERATIONAL CONDITION or other specified condition changes. Specification 4.0.4 does not restrict changing OPERATIONAL CONDITIONS or other specified conditions of the Applicability when a Surveillance has not been performed within the specified Surveillance time interval, provided the requirement to declare the Limiting Condition for Operation not met has been delayed in accordance with Specification 4.0.3.

The provisions of Specification 4.0.4 shall not prevent entry into OPERATIONAL CONDITIONS or other specified conditions in the Applicability that are required to comply with ACTION requirements. In addition, the provisions of Specification 4.0.4 shall not prevent changes in OPERATIONAL CONDITIONS or other specified conditions in the Applicability that result from any unit shutdown. In this context, a unit shutdown is defined as a change in OPERATIONAL CONDITION or other specified condition in the Applicability associated with transitioning from OPERATIONAL CONDITION 1 to OPERATIONAL CONDITION 2, OPERATIONAL CONDITION 2 to OPERATIONAL CONDITION 3, and OPERATIONAL CONDITION 3 to OPERATIONAL CONDITION 4.

Specification 4.0.5 establishes the requirement that inservice inspection of ASME Code Class 1, 2 and 3 components and inservice testing of ASME Code Class 1, 2 and 3 pumps and valves shall be performed in accordance with a periodically updated version of Section XI of the ASME Boiler and Pressure Vessel Code and Addenda, and the ASME Code for Operation and Maintenance of Nuclear Power Plants (ASME OM Code) and applicable Addenda as required by 10 CFR 50.55a. The provisions of SR 4.0.2 and SR 4.0.3 do not apply to the INSERVICE TESTING PROGRAM unless there is a specific SR referencing usage of the program.

Limerick Generating Station has received a license amendment to implement 10 CFR 50.69, “Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors,” and may voluntarily comply with the requirements of 10 CFR 50.69 as an alternative to compliance with the following requirements for structures, systems, and components (SSCs) that have a Risk-Informed Safety Class (RISC) of RISC-3:

(1) The INSERVICE TESTING PROGRAM requirements of 10 CFR 50.55a(f), and
(2) The inservice inspection, and repair and replacement (with the exception of fracture toughness), requirements for ASME Class 2 and Class 3 SSCs in 10 CFR 50.55a(g).

Therefore, SSCs that have been categorized as RISC-3 in accordance with 10 CFR 50.69 may be removed from the INSERVICE TESTING [IST] PROGRAM and the Inservice Inspection (ISI) Program in accordance with 10 CFR 50.69(b)(1)(v).

RISC-3 SSCs with technical specification surveillance requirements referencing Technical Specification 4.0.5, which have been removed from the IST/ISI programs, are subject to the alternative treatment requirements of 10 CFR 50.69(d)(2). The SSCs must continue to meet the acceptance criteria specified in associated technical specification surveillance requirements, as applicable; however, the surveillance frequency is determined as part of the alternative treatment.

BASES

3/4.1.1 SHUTDOWN MARGIN

A sufficient SHUTDOWN MARGIN ensures that (1) the reactor can be made subcritical from all operating conditions, (2) the reactivity transients associated with postulated accident conditions are controllable within acceptable limits, and (3) the reactor will be maintained sufficiently subcritical to preclude inadvertent criticality in the shutdown condition.

Since core reactivity values will vary through core life as a function of fuel depletion and poison burnup, the demonstration of SHUTDOWN MARGIN will be performed in the cold, xenon-free condition and shall show the core to be subcritical by at least R + 0.38% Δ k/k or R + 0.28% Δ k/k, as appropriate. The 0.38% Δ k/k includes uncertainties and calculation biases. The value of R in units of % Δ k/k is the difference between the calculated value of minimum shutdown margin during the operating cycle and the calculated shutdown margin at the time of the shutdown margin test at the beginning of cycle. The value of R must be positive or zero and must be determined for each fuel loading cycle.

Two different values are supplied in the Limiting Condition for Operation to provide for the different methods of demonstration of the SHUTDOWN MARGIN. The highest worth rod may be determined analytically or by test. The SHUTDOWN MARGIN is demonstrated by (an insequence) control rod withdrawal at the beginning of life fuel cycle conditions, and, if necessary, at any future time in the cycle if the first demonstration indicates that the required margin could be reduced as a function of exposure. Observation of subcriticality in this condition assures subcriticality with the most reactive control rod fully withdrawn.

This reactivity characteristic has been a basic assumption in the analysis of plant performance and can be best demonstrated at the time of fuel loading, but the margin must also be determined anytime a control rod is incapable of insertion.

3/4.1.2 REACTIVITY ANOMALIES

Since the SHUTDOWN MARGIN requirement for the reactor is small, a careful check on actual conditions to the predicted conditions is necessary, and the changes in reactivity can be inferred from these comparisons of core $k_{effective}$ (k_{eff}). Since the comparisons are easily done, frequent checks are not an imposition on normal operations. A 1% change is larger than is expected for normal operation so a change of this magnitude should be thoroughly evaluated. A change as large as 1% would not exceed the design conditions of the reactor and is on the safe side of the postulated transients.

3/4.1.3 CONTROL RODS

The specification of this section ensure that (1) the minimum SHUTDOWN MARGIN is maintained, (2) the control rod insertion times are consistent with those used in the accident analysis, and (3) the potential effects of the rod drop accident are limited. The ACTION statements permit variations from the basic requirements but at the same time impose more restrictive criteria for continued operation. A limitation on inoperable rods is set such that the resultant effect on total rod worth and scram shape will be kept to a minimum. The requirements for the various scram time measurements ensure that any indication of systematic problems with rod drives will be investigated on a timely basis.

Damage within the control rod drive mechanism could be a generic problem, therefore with a control rod immovable because of excessive friction or mechanical interference, operation of the reactor is limited to a time period which is reasonable to determine the cause of the inoperability and at the same time prevent operation with a large number of inoperable control rods.

Control rods that are inoperable for other reasons are permitted to be taken out of service provided that those in the nonfully-inserted position are consistent with the SHUTDOWN MARGIN requirements.

With two or more withdrawn control rods immovable, the reactor must be brought to HOT SHUTDOWN. The occurrence of more than one control rod immovable at a withdrawn position increases the probability that the reactor cannot be shut down if required. Insertion of all insertable control rods eliminates the possibility of an additional failure of a control rod to insert.

The number of control rods permitted to be inoperable could be more than the eight allowed by the specification, but the occurrence of eight inoperable rods could be indicative of a generic problem and the reactor must be shutdown for investigation and resolution of the problem.

The control rod system is designed to bring the reactor subcritical at a rate fast enough to prevent the MCPR from becoming less than the fuel cladding safety limit during the limiting power transient analyzed in Section 15.2 of the FSAR. This analysis shows that the negative reactivity rates resulting from the scram with the average response of all the drives as given in the specifications, provided the required protection and MCPR remains greater than the fuel cladding safety limit. The occurrence of scram times longer then those specified should be viewed as an indication of a systemic problem with the rod drives and therefore the surveillance interval is reduced in order to prevent operation of the reactor for long periods of time with a potentially serious problem.

Scram time testing at zero psig reactor coolant pressure is adequate to ensure that the control rod will perform its intended scram function during startup of the plant until scram time testing at 950 psig reactor coolant pressure is performed prior to exceeding 40% rated core thermal power.

The scram discharge volume is required to be OPERABLE so that it will be available when needed to accept discharge water from the control rods during a reactor scram and will isolate the reactor coolant system from the containment when required.

CONTROL RODS (Continued)

The OPERABILITY of all SDV vent and drain valves ensures that the SDV vent and drain valves will close during a scram to contain reactor water discharged to the SDV piping. The SDV has one common drain line and one common vent line. Since the vent and drain lines are provided with two valves in series, the single failure of one valve in the open position will not impair the isolation function of the system. Additionally, the valves are required to open on scram reset to ensure that a path is available for the SDV piping to drain freely at other times.

When one SDV vent or drain valve is inoperable in one or more lines, the valves must be restored to OPERABLE status within 7 days. The allowable outage time is reasonable, given the level of redundancy in the lines and the low probability of a scram occurring while the valve(s) are inoperable. The SDV is still isolable since the redundant valve in the affected line is OPERABLE. During these periods, the single failure criterion may not be preserved, and a higher risk exists to allow reactor water out of the primary system during a scram.

If both valves in a line are inoperable, the line must be isolated to contain the reactor coolant during a scram. When a line is isolated, the potential for an inadvertent scram due to high SDV level is increased. The associated ACTION is modified by a note ("****") that allows periodic draining and venting of the SDV when a line is isolated. During these periods, the line may be unisolated under administrative control. This allows any accumulated water in the line to be drained, to preclude a reactor scram on SDV high level. This is acceptable since the administrative controls ensure the valve can be closed quickly, by a dedicated operator, if a scram occurs with the valve open. The 8 hour allowable outage time to isolate the line is based on the low probability of a scram occurring while the line is not isolated and the unlikelihood of significant CRD seal leakage.

Control rods with inoperable accumulators are declared inoperable and Specification 3.1.3.1 then applies. This prevents a pattern of inoperable accumulators that would result in less reactivity insertion on a scram than has been analyzed even though control rods with inoperable accumulators may still be inserted with normal drive water pressure. The drive water pressure normal operating range is specified in system operating procedures which provide ranges for system alignment and control rod motion (exercising). Operability of the accumulator ensures that there is a means available to insert the control rods even under the most unfavorable depressurization of the reactor. A control rod is considered trippable if it is capable of fully inserting as a result of a scram signal.

THIS PAGE INTENTIONALLY LEFT BLANK

CONTROL RODS (Continued)

Control rod coupling integrity is required to ensure compliance with the analysis of the rod drop accident in the FSAR. The overtravel position feature provides the only positive means of determining that a rod is properly coupled and therefore this check must be performed prior to achieving criticality after completing CORE ALTERATIONS that could have affected the control rod coupling integrity. The subsequent check is performed as a backup to the initial demonstration.

In order to ensure that the control rod patterns can be followed and therefore that other parameters are within their limits, the control rod position indication system must be OPERABLE.

The control rod housing support restricts the outward movement of a control rod to less than 3 inches in the event of a housing failure. The amount of rod reactivity which could be added by this small amount of rod withdrawal is less than a normal withdrawal increment and will not contribute to any damage to the primary coolant system. The support is not required when there is no pressure to act as a driving force to rapidly eject a drive housing.

The required surveillances are adequate to determine that the rods are OPERABLE and not so frequent as to cause excessive wear on the system components.

3/4.1.4 CONTROL ROD PROGRAM CONTROLS

Control rod withdrawal and insertion sequences are established to assure that the maximum insequence individual control rod or control rod segments which are withdrawn at any time during the fuel cycle could not be worth enough to result in a peak fuel enthalpy greater than 280 cal/gm in the event of a control rod drop accident. The specified sequences are characterized by homogeneous, scattered patterns of control rod withdrawal. When THERMAL POWER is greater than 10% of RATED THERMAL POWER, there is no possible rod worth which, if dropped at the design rate of the velocity limiter, could result in a peak enthalpy of 280 cal/gm. Thus requiring the RWM to be OPERABLE when THERMAL POWER is less than or equal to 10% of RATED THERMAL POWER provides adequate control.

The RWM provides automatic supervision to assure that out-of-sequence rods will not be withdrawn or inserted.

The analysis of the rod drop accident is presented in Section 15.4.9 of the FSAR and the techniques of the analysis are presented in a topical report, Reference 1, and two supplements, References 2 and 3. Additional pertinent analysis is also contained in Amendment 17 to the Reference 4 Topical Report.

The RBM is designed to automatically prevent fuel damage in the event of erroneous rod withdrawal from locations of high power density over the range of power operation. Two channels are provided. Tripping one of the channels will block erroneous rod withdrawal to prevent fuel damage. This system backs up the written sequence used by the operator for withdrawal of control rods. RBM OPERABILITY is required when the limiting condition described in Specification 3.1.4.3 exists.

3/4.1.5 STANDBY LIQUID CONTROL SYSTEM

The standby liquid control system provides a backup capability for bringing the reactor from full power to a cold, Xenon-free shutdown, assuming that the withdrawn control rods remain fixed in the rated power pattern. To meet this objective it is necessary to inject a quantity of boron which produces a concen-tration of 660 ppm in the reactor core and other piping systems connected to the reactor vessel. To allow for potential leakage and improper mixing, this con-centration is increased by 25%. The required concentration is achieved by having available a minimum quantity of 3,160 gallons of sodium pentaborate solution containng a minimum of 3,754 lbs of sodium pentaborate having the requisite Boron-10 atom % enrichment of 29% as determined from Reference 5. This quantity of solution is a net amount which is above the pump suction shutoff level setpoint thus allowing for the portion which cannot be injected.

The above quantities calculated at 29% Boron-10 enrichment have been demonstrated by analysis to provide a Boron-10 weight equivalent of 185 lbs in the sodium pentaborate solution. Maintaining this Boron-10 weight in the net tank contents ensures a sufficient quantity of boron to bring the reactor to a cold, Xenon-free shutdown.

The pumping rate of 37.0 gpm provides a negative reactivity insertion rate over the permissible solution volume range, which adequately compensates for the positive reactivity effects due to elimination of steam voids, increased water density from hot to cold, reduced doppler effect in uranium, reduced neutron leakage from boiling to cold, decreased control rod worth as the moderator cools, and xenon decay. The temperature requirement ensures that the sodium pentaborate always remains in solution.

With redundant pumps and explosive injection valves and with a highly reliable control rod scram system, operation of the reactor is permitted to continue for short periods of time with the system inoperable or for longer periods of time with one of the redundant components inoperable.

The SLCS system consists of three separate and independent pumps and explosive valves. Two of the separate and independent pumps and explosive valves are required to meet the minimum requirements of this technical specification and, where applicable, satisfy the single failure criterion. To ensure that SLCS pump discharge pressure does not exceed the SLCS relief valve setpoint during operation following an anticipated transient without scram (ATWS) event, no more than two pumps shall be aligned for automatic operation in OPERATIONAL CONDITIONS 1, 2, and 3. This maintains the equivalent control capacity to satisfy 10 CFR 50.62 (Requirements for reduction of risk from anticipated transients without scram (ATWS). With three pumps aligned for automatic operation, the system is inoperable and ACTION statement (b) applies.

The SLCS must have an equivalent control capacity of 86 gpm of 13% weight sodium pentaborate in order to satisfy 10 CFR 50.62. As part of the ARTS/MELLL program the ATWS analysis was updated to reflect the new rod line. As a result of this it was determined that the Boron 10 enrichment was required to be increased to 29% to prevent exceeding a suppression pool temperature of 190°F. This equivalency requirement is fulfilled by having a system which satisfies the equation given in 4.1.5.b.2.

The upper limit concentration of 13.8% has been established as a reasonable limit to prevent precipitation of sodium pentaborate in the event of a loss of tank heating, which allow the solution to cool. A SLCS Pump flowrate of 37.0 gpm (minimum) and a Sodium Pentaborate Solution concentration of 9% by weight (minimum) will require a Boron-10 enrichment of 49 atom % to be added to the tank. The decreased pump flowrate and increased solution enrichment are acceptable because the results of the ATWS Rule Equation will remain > 1.0.

STANDBY LIQUID CONTROL SYSTEM (Continued)

Surveillance requirements are established on a frequency that assures a high reliability of the system. Once the solution is established, boron concentration will not vary unless more boron or water is added, thus a check on the temperature and volume assures that the solution is available for use.

Replacement of the explosive charges in the valves will assure that these valves will not fail because of deterioration of the charges.

The Standby Liquid Control System also has a post-DBA LOCA safety function to buffer Suppression Pool pH in order to maintain bulk pH above 7.0. The buffering of Suppression Pool pH is necessary to prevent iodine re-evolution to satisfy the methodology for Alternative Source Term. Manual initiation is used, and the minimum amount of total boron required for Suppression Pool pH buffering is 256 lbs. Given that at least 185 lbs of Boron-10 is maintained in the tank, the total boron in the tank will be greater than 256 lbs for the range of enrichments from 29% to 62%.

ACTION Statement (a) applies only to OPERATIONAL CONDITIONS 1 and 2 because a single pump can satisfy both the reactor control function and the post-DBA LOCA function to control Suppression Pool pH since boron injection is not required until 13 hours post-LOCA. ACTION Statement (b) applies to OPERATIONAL CONDITIONS 1, 2 and 3 to address the post-LOCA safety function of the SLC system.

3/4.2.1 AVERAGE PLANAR LINEAR HEAT GENERATION RATE

This specification assures that the peak cladding temperature (PCT) following the postulated design basis Loss-of-Coolant Accident (LOCA) will not exceed the limits specified in 10 CFR 50.46 and that the fuel design analysis limits specified in NEDE-24011-P-A (Reference 2) will not be exceeded.

Mechanical Design Analysis: NRC approved methods (specified in Reference 2) are used to demonstrate that all fuel rods in a lattice operating at the bounding power history, meet the fuel design limits specified in Reference 2. No single fuel rod follows, or is capable of following, this bounding power history. This bounding power history is used as the basis for the fuel design analysis MAPLHGR limit.

LOCA Analysis: A LOCA analysis is performed in accordance with 10CFR50 Appendix K to demonstrate that the permissible planar power (MAPLHGR) limits comply with the ECCS limits specified in 10 CFR 50.46. The analysis is performed for the most limiting break size, break location, and single failure combination for the plant, using the evaluation model described in Reference 9.

The MAPLHGR limit as showm in the CORE OPERATING LIMITS REPORT is the most limiting composite of the fuel mechanical design anaylsis MAPLHGR and the ECCS MAPLHGR limit.

Only the most limiting MAPLHGR values are shown in the CORE OPERATING LIMITS REPORT for multiple lattice fuel. Compliance with the specific lattice MAPLHGR operating limits, which are available in Reference 3, is ensured by use of the process computer.

As a result of no longer utilizing an APRM trip setdown requirement, additional constraints are placed on the MAPLHGR limits to assure adherence to the fuel-mechanical design bases. These constraints are introduced through the MAPFAC(P) and MAPFAC(F) factors as defined in the COLR.

3/4.2.2 (DELETED)

INFORMATION CONTAINED ON

THIS PAGE HAS BEEN

DELETED

LEFT INTENTIONALLY BLANK

3/4.2.3 MINIMUM CRITICAL POWER RATIO

The required operating limit MCPRs at steady-state operating conditions as specified in Specification 3.2.3 are derived from the established fuel cladding integrity MCPR(99.9%), and an analysis of abnormal operational transients. For any abnormal operating transient analysis evaluation with the initial condition of the reactor being at the steady-state operating limit, it is required that less than Ø.1% of fuel rods in the core are susceptible to transition boiling of that the resulting MCPR does not decrease below the operating limit MCPR at any time during the transient assuming instrument trip setting given in Specification 2.2.

To assure that the fuel cladding integrity Safety Limit is not exceeded during any anticipated abnormal operational transient, the most limiting transients have been analyzed to determine which result in the largest reduction in CRITICAL POWER RATIO (CPR). The type of transients evaluated were loss of flow, increase in pressure and power, positive reactivity insertion, and coolant temperature decrease.

The evaluation of a given transient begins with the system initial parameters shown in FSAR Table 15.Ø-2 that are input to a BWR system dynamic behavior transient computer program. The codes used to evaluate transients are discussed in Reference 2.

MCPR(99.9%) is determined to ensure more than 99.9% of the fuel rods in the core are not susceptible to boiling transition using a statistical model that combines all the uncertainties in operating parameters and the procedures used to calculate critical power. The probability of the occurrence of boiling transition is determined using the approved Critical Power correlations. Details of the MCPR(99.9%) calculation are given in Reference 2. Reference 2 also includes a tabulation of the uncertainties and the nominal values of the parameters used in the MCPR99.9% statistical analysis.

The MCPR operating limits are derived from the MCPR(99.9%) value and the transient analysis, and are dependent on the operating core flow and power state (MCPR(F), and MCPR(P), respectively) to ensure adherence to fuel design limits during the worst transient that occurs with moderate frequency (Ref. 6). Flow dependent MCPR limits (MCPR(F)) are determined by steady state thermal hydraulic methods with key physics response inputs benchmarked using the three dimensional BWR simulator code (Ref. 7) to analyze slow flow runout transients.

Power dependent MCPR limits (MCPR(P)) are determined by approved transient analysis (Reference 2). Due to the sensitivity of the transient response to initial core flow levels at power levels below those at which the turbine stop valve closure and turbine control valve fast closure scrams are bypassed, high and low flow MCPR(P), operating limits are provided for operating between 25% RTP and 3Ø% RTP.

The MCPR operating limits specified in the COLR (MCPR(99.9%) value MCPR(F), and MCPR(P) values are the result of the Design Basis Accident (DBA) and transient analysis. The operating limit MCPR is determined by the larger of the MCPR(F), and MCPR(P) limits which are based on the MCPR(99.9%) limit specified in the COLR.

MINIMUM CRITICAL POWER RATIO (Continued)

At THERMAL POWER levels less than or equal to 25% of RATED THERMAL POWER, the reactor will be operating at minimum recirculation pump speed and the moderator void content will be very small. For all designated control rod patterns which may be employed at this point, operating plant experience indicates that the resulting MCPR value is in excess of requirements by a considerable margin. During initial startup testing of the plant, a MCPR evaluation will be made at 25% of RATED THERMAL POWER level with minimum recirculation pump speed. The MCPR margin will thus be demonstrated such that future MCPR evaluation below this power level will be shown to be unnecessary. The daily requirement for calculating MCPR when THERMAL POWER is greater than or equal to 25% of RATED THERMAL POWER is sufficient since power distribution shifts are very slow when there have not been significant power or control rod changes. The requirement for calculating MCPR when a limiting control rod pattern is approached ensures that MCPR will be known following a change in THERMAL POWER or power shape, regardless of magnitude, that could place operation at a thermal limit.

3/4.2.4 LINEAR HEAT GENERATION RATE

This specification assures that the Linear Heat Generation Rate (LHGR) in any rod is less than the design linear heat generation even if fuel pellet densification is postulated.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION

The reactor protection system automatically initiates a reactor scram to:

a. Preserve the integrity of the fuel cladding.

b. Preserve the integrity of the reactor coolant system.

c. Minimize the energy which must be adsorbed following a loss-of-coolant accident, and

d. Prevent inadvertent criticality.

This specification provides the limiting conditions for operation necessary to preserve the ability of the system to perform its intended function even during periods when instrument channels may be out of service because of maintenance. When necessary, one channel may be made inoperable for brief intervals to conduct required surveillance.

The reactor protection system is made up of two independent trip systems. There are usually four channels to monitor each parameter with two channels in each trip system. The outputs of the channels in a trip system are combined in a logic so that either channel will trip that trip system. The tripping of both trip systems will produce a reactor scram. The APRM system is divided into four APRM channels and four 2-Out-Of-4 Voter channels. Each APRM channel provides inputs to each of the four voter channels. The four voter channels are divided into two groups of two each, with each group of two providing inputs to one RPS trip system. The system is designed to allow one APRM channel, but no voter channels, to be bypassed.

The system meets the intent of IEEE-279 for nuclear power plant protection systems. Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30851P-A, "Technical Specification Improvement Analyses for BWR Reactor Protection System" and NEDC-32410P-A, "Nuclear Measurement Analysis and Control Power Range Neutron Monitor (NUMAC PRNM) Retrofit Plus Option III Stability Trip Function." The bases for the trip settings of the RPS are discussed in the bases for Specification 2.2.1.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

The APRM Functions include five Functions accomplished by the four APRM channels (Functions 2.a, 2.b, 2.c, 2.d, and 2.f) and one accomplished by the four 2-Out-Of-4 Voter channels (Function 2.e). Two of the five Functions accomplished by the APRM channels are based on neutron flux only (Functions 2.a and 2.c), one Function is based on neutron flux and recirculation drive flow (Function 2.b) and one is based on equipment status (Function 2.d). The fifth Function accomplished by the APRM channels is the Oscillation Power Range Monitor (OPRM) Upscale trip Function 2.f, which is based on detecting oscillatory characteristics in the neutron flux. The OPRM Upscale Function is also dependent on average neutron flux (Simulated Thermal Power) and recirculation drive flow, which are used to automatically enable the output trip.

The Two-Out-Of-Four Logic Module includes 2-Out-Of-4 Voter hardware and the APRM Interface hardware. The 2-Out-Of-4 Voter Function 2.e votes APRM Functions 2.a, 2.b, 2.c, and 2.d independently of Function 2.f. This voting is accomplished by the 2-Out-Of-4 Voter hardware in the Two-Out-Of-Four Logic Module. The voter includes separate outputs to RPS for the two independently voted sets of Functions, each of which is redundant (four total outputs). The analysis in Reference 2 took credit for this redundancy in the justification of the 12-hour allowed out-of-service time for

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

Action b, so the voter Function 2.e must be declared inoperable if any of its functionality is inoperable. The voter Function 2.e does not need to be declared inoperable due to any failure affecting only the APRM Interface hardware portion of the Two-Out-Of-Four Logic Module.

Three of the four APRM channels and all four of the voter channels are required to be OPERABLE to ensure that no single failure will preclude a scram on a valid signal. To provide adequate coverage of the entire core, consistent with the design bases for the APRM Functions 2.a, 2.b, and 2.c, at least 20 LPRM inputs, with at least three LPRM inputs from each of the four axial levels at which the LPRMs are located, must be operable for each APRM channel. In addition, no more than 9 LPRMs may be bypassed between APRM calibrations (weekly gain adjustments). For the OPRM Upscale Function 2.f, LPRMs are assigned to "cells" of 3 or 4 detectors. A minimum of 23 cells (Reference 9), each with a minimum of 2 OPERABLE LPRMs, must be OPERABLE for each APRM channel for the OPRM Upscale Function 2.f to be OPERABLE in that channel. LPRM gain settings are determined from the local flux profiles measured by the TIP system. This establishes the relative local flux profile for appropriate representative input to the APRM System. The 2000 EFPH frequency is based on operating experience with LPRM sensitivity changes.

References 4, 5 and 6 describe three algorithms for detecting thermal-hydraulic instability related neutron flux oscillations: the period based detection algorithm, the amplitude based algorithm, and the growth rate algorithm. All three are implemented in the OPRM Upscale Function, but the safety analysis takes credit only for the period based detection algorithm. The remaining algorithms provide defense in depth and additional protection against unanticipated oscillations. OPRM Upscale Function OPERABILITY for Technical Specification purposes is based only on the period based detection algorithm.

An OPRM Upscale trip is issued from an APRM channel when the period based detection algorithm in that channel detects oscillatory changes in the neutron flux, indicated by the combined signals of the LPRM detectors in any cell, with period confirmations and relative cell amplitude exceeding specified setpoints. One or more cells in a channel exceeding the trip conditions will result in a channel trip. An OPRM Upscale trip is also issued from the channel if either the growth rate or amplitude based algorithms detect growing oscillatory changes in the neutron flux for one or more cells in that channel.

The OPRM Upscale Function is required to be OPERABLE when the plant is at $\geq$ 25% RATED THERMAL POWER. The 25% RATED THERMAL POWER level is selected to provide margin in the unlikely event that a reactor power increase transient occurring while the plant is operating below 29.5% RATED THERMAL POWER causes a power increase to or beyond the 29.5% RATED THERMAL POWER OPRM Upscale trip auto-enable point without operator action. This OPERABILITY requirement assures that the OPRM Upscale trip automatic-enable function will be OPERABLE when required.

Actions a, b and c define the Action(s) required when RPS channels are discovered to be inoperable. For those Actions, separate entry condition is allowed for each inoperable RPS channel. Separate entry means that the allowable time clock(s) for Actions a, b or c start upon discovery of inoperability for that specific channel. Restoration of an inoperable RPS channel satisfies only the action statements for that particular channel. Action statement(s) for remaining inoperable channel(s) must be met according to their original entry time.

A Note has been provided to modify the Actions when Functional Unit 2.b and 2.c channels are inoperable due to failure of SR 4.3.1.1 and gain adjustments are necessary. The Note allows entry into associated Actions to be delayed for up to 2 hours if the APRM is indicating a lower power value than the calculated power (i.e., the gain adjustment factor (GAF) is high (non-conservative)). The GAF for any channel is defined as the power value determined by the heat balance divided by the APRM reading for that channel. Upon completion of the gain adjustment, or

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

expiration of the allowed time, the channel must be returned to OPERABLE status or the applicable Actions taken. This Note is based on the time required to perform gain adjustments on multiple channels.

Because of the diversity of sensors available to provide trip signals and the redundancy of the RPS design, an allowable out of service time of 12 hours has been shown to be acceptable (NEDC-30851P-A and NEDC-32410P-A) to permit restoration of any inoperable channel to OPERABLE status. However, this out of service time is only acceptable provided that the associated Function's (identified as a "Functional Unit" in Table 3.3.1-1) inoperable channel is in one trip system and the Function still maintains RPS trip capability. Alternatively, an allowable out-of-service time can be determined in accordance with the Risk Informed Completion Time Program.

The requirements of Action a are intended to ensure that appropriate actions are taken if multiple, inoperable, untripped channels within the same trip system for the same Function result in the Function not maintaining RPS trip capability. A Function is considered to be maintaining RPS trip capability when sufficient channels are OPERABLE or in trip (or the associated trip system is in trip), such that both trip systems will generate a trip signal from the given Function on a valid signal. For the typical Function with one-out-of-two taken twice logic, including the IRM Functions and APRM Function 2.e (trip capability associated with APRM Functions 2.a, 2.b, 2.c, 2.d, and 2.f are discussed below), this would require both trip systems to have one channel OPERABLE or in trip (or the associated trip system in trip).

For Function 5 (Main Steam Isolation Valve--Closure), this would require both trip systems to have each channel associated with the MSIVs in three main steam lines (not necessarily the same main steam lines for both trip systems) OPERABLE or in trip (or the associated trip system in trip).

For Function 9 (Turbine Stop Valve-Closure), this would require both trip systems to have three channels, each OPERABLE or in trip (or the associated trip system in trip).

The completion time to satisfy the requirements of Action a is intended to allow the operator time to evaluate and repair any discovered inoperabilities. The 1 hour Completion Time is acceptable because it minimizes risk while allowing time for restoration or tripping of channels. Alternatively, the completion time can be determined in accordance with the Risk Informed Completion Time Program.

With trip capability maintained, i.e., Action a satisfied, Actions b and c as applicable must still be satisfied. If the inoperable channel cannot be restored to OPERABLE status within the allowable out of service time, Action b requires that the channel or the associated trip system must be placed in the tripped condition. Placing the inoperable channel in trip (or the associated trip system in trip) would conservatively compensate for the inoperability, restore capability to accommodate a single failure, and allow operation to continue.

As noted, placing the trip system in trip is not applicable to satisfy Action b for APRM Functions 2.a, 2.b, 2.c, 2.d, or 2.f. Inoperability of one required APRM channel affects both trip systems. For that condition, the Action b requirements can only be satisfied by placing the inoperable APRM channel in trip. Restoring OPERABILITY or placing the inoperable APRM channel in trip are the only actions that will restore capability to accommodate a single APRM channel failure. Inoperability of more than one required APRM channel of the same trip function results in loss of trip capability and the requirement to satisfy Action a.

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

The requirements of Action c must be satisfied when, for any one or more Functions, at least one required channel is inoperable in each trip system. In this condition, provided at least one channel per trip system is OPERABLE, normally the RPS still maintains trip capability for that Function, but cannot accommodate a single failure in either trip system (see additional bases discussion above related to loss of trip capability and the requirements of Action a, and special cases for Functions 2.a, 2.b, 2.c, 2.d, 2.f, 5 and 9).

The requirements of Action c limit the time the RPS scram logic, for any Function, would not accommodate single failure in both trip systems (e.g., one-out-of-one and one-out-of-one arrangement for a typical four channel Function). The reduced reliability of this logic arrangement was not evaluated in NEDC-30851P-A for the 12 hour Completion Time. Within the 6 hour allowance, the associated Function must have all required channels OPERABLE or in trip (or any combination) in one trip system.

Completing the actions required by Action c restores RPS to a reliability level equivalent to that evaluated in NEDC-30851P-A, which justified a 12 hour allowable out of service time as allowed by Action b. To satisfy the requirements of Action c, the trip system in the more degraded state should be placed in trip or, alternatively, all the inoperable channels in that trip system should be placed in trip (e.g., a trip system with two inoperable channels could be in a more degraded state than a trip system with four inoperable channels if the two inoperable channels are in the same Function while the four inoperable channels are all in different Functions). The decision of which trip system is in the more degraded state should be based on prudent judgment and take into account current plant conditions (i.e., what OPERATIONAL CONDITION the plant is in). If this action would result in a scram or RPT, it is permissible to place the other trip system or its inoperable channels in trip.

The 6 hour allowable out of service time is judged acceptable based on the remaining capability to trip, the diversity of the sensors available to provide the trip signals, the low probability of extensive numbers of inoperabilities affecting all diverse Functions, and the low probability of an event requiring the initiation of a scram.

As noted, Action c is not applicable for APRM Functions 2.a, 2.b, 2.c, 2.d, or 2.f. Inoperability of an APRM channel affects both trip systems and is not associated with a specific trip system as are the APRM 2-Out-Of-4 voter and other non-APRM channels for which Action c applies. For an inoperable APRM channel, the requirements of Action b can only be satisfied by tripping the inoperable APRM channel. Restoring OPERABILITY or placing the inoperable APRM channel in trip are the only actions that will restore capability to accommodate a single APRM channel failure.

If it is not desired to place the channel (or trip system) in trip to satisfy the requirements of Action a, Action b or Action c (e.g., as in the case where placing the inoperable channel in trip would result in a full scram), Action d requires that the Action defined by Table 3.3.1-1 for the applicable Function be initiated immediately upon expiration of the allowable out of service time.

Table 3.3.1-1, Function 2.f, references Action 10, which defines the action required if OPRM Upscale trip capability is not maintained. Action 10b is required to address identified equipment failures. Action 10a is to address common mode vendor/industry identified issues that render all four OPRM channels inoperable at once. For this condition, References 2 and 3 justified use of alternate methods to detect and suppress oscillations for a limited period of

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

time, up to 120 days. The alternate methods are procedurally established consistent with the guidelines identified in Reference 7 requiring manual operator action to scram the plant if certain predefined events occur. The 12-hour allowed completion time to implement the alternate methods is based on engineering judgment to allow orderly transition to the alternate methods while limiting the period of time during which no automatic or alternate detect and suppress trip capability is formally in place. The 120-day period during which use of alternate methods is allowed is intended to be an outside limit to allow for the case where design changes or extensive analysis might be required to understand or correct some unanticipated characteristic of the instability detection algorithms or equipment. The evaluation of the use of alternate methods concluded, based on engineering judgment, that the likelihood of an instability event that could not be adequately handled by the alternate methods during the 120-day period was negligibly small. Plant startup may continue while operating within the allowed completion time of Action 10a. The primary purpose of this is to allow an orderly completion, without undue impact on plant operation, of design and verification activities in the event of a required design change to the OPRM Upscale function. This exception is not intended as an alternative to restoring inoperable equipment to OPERABLE status in a timely manner.

Action 10a is not intended and was not evaluated as a routine alternative to returning failed or inoperable equipment to OPERABLE status. Correction of routine equipment failure or inoperability is expected to be accomplished within the completion times allowed for LCO 3.3.1 Action a or Action b, as applicable. Action 10b applies when routine equipment OPERABILITY cannot be restored within the allowed completion times of LCO 3.3.1 Actions a or b, or if a common mode OPRM deficiency cannot be corrected and OPERABILITY of the OPRM Upscale Function restored within the 120-day allowed completion time of Action 10a.

The OPRM Upscale trip output shall be automatically enabled (not-bypassed) when APRM Simulated Thermal Power is $\geq$ 29.5% and recirculation drive flow is $<$ 60% as indicated by APRM measured recirculation drive flow. NOTE: 60% recirculation drive flow is the recirculation drive flow that corresponds to 60% of rated core flow. This is the operating region where actual thermal-hydraulic instability and related neutron flux oscillations may occur. As noted in Table 4.3.1.1-1, Note c, CHANNEL CALIBRATION for the OPRM Upscale trip Function 2.f includes confirming that the auto-enable (not-bypassed) setpoints are correct. Other surveillances ensure that the APRM Simulated Thermal Power properly correlates with THERMAL POWER (Table 4.3.1.1-1, Note d) and that recirculation drive flow properly correlates with core flow (Table 4.3.1.1-1, Note g).

If any OPRM Upscale trip auto-enable setpoint is exceeded and the OPRM Upscale trip is not enabled, i.e., the OPRM Upscale trip is bypassed when APRM Simulated Thermal Power is $\geq$ 29.5% and recirculation drive flow is $<$ 60%, then the affected channel is considered inoperable for the OPRM Upscale Function. Alternatively, the OPRM Upscale trip auto-enable setpoint(s) may be adjusted to place the channel in the enabled condition (not-bypassed). If the OPRM Upscale trip is placed in the enabled condition, the surveillance requirement is met and the channel is considered OPERABLE.

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

As noted in Table 4.3.1.1-1, Note g, CHANNEL CALIBRATION for the APRM Simulated Thermal Power - Upscale Function 2.b and the OPRM Upscale Function 2.f, includes the recirculation drive flow input function. The APRM Simulated Thermal Power - Upscale Function and the OPRM Upscale Function both require a valid drive flow signal. The APRM Simulated Thermal Power - Upscale Function uses drive flow to vary the trip setpoint. The OPRM Upscale Function uses drive flow to automatically enable or bypass the OPRM Upscale trip output to RPS. A CHANNEL CALIBRATION of the APRM recirculation drive flow input function requires both calibrating the drive flow transmitters and establishing a valid drive flow / core flow relationship. The drive flow / core flow relationship is established once per refuel cycle, while operating within 10% of rated core flow and within 10% of RATED THERMAL POWER. Plant operational experience has shown that this flow correlation methodology is consistent with the guidance and intent in Reference 8. Changes throughout the cycle in the drive flow / core flow relationship due to the changing thermal hydraulic operating conditions of the core are accounted for in the margins included in the bases or analyses used to establish the setpoints for the APRM Simulated Thermal Power - Upscale Function and the OPRM Upscale Function.

For the Simulated Thermal Power - Upscale Function (Function 2.b), the CHANNEL CALIBRATION surveillance requirement is modified by two Notes. The first Note requires evaluation of channel performance for the condition where the as-found setting for the channel setpoint is outside its as-found tolerance but conservative with respect to the Allowable Value. Evaluation of channel performance will verify that the channel will continue to behave in accordance with safety analysis assumptions and the channel performance assumptions in the setpoint methodology. The purpose of the assessment is to ensure confidence in the channel performance prior to returning the channel to service. For channels determined to be OPERABLE but degraded, after returning the channel to service the performance of these channels will be evaluated under the plant Corrective Action Program. Entry into the Corrective Action Program will ensure required review and documentation of the condition. The second Note requires that the as-left setting for the channel be within the as-left tolerance of the Trip Setpoint. The as-left and as-found tolerances, as applicable, will be applied to the surveillance procedure setpoint. This will ensure that sufficient margin to the Safety Limit and/or Analytical Limit is maintained. If the as-left channel setting cannot be returned to a setting within the as-left tolerance of the Trip Setpoint, then the channel shall be declared inoperable. The as-left tolerance for this function is calculated using the square-root-sum-of-squares of the reference accuracy and the measurement and test equipment error (including readability). The as-found tolerance for this function is calculated using the square-root-sum-of-squares of the reference accuracy, instrument drift, and the measurement and test equipment error (including readability).

To ensure that the APRMs are accurately indicating the true core average power, the APRMs are adjusted to the reactor power calculated from a heat balance if the heat balance calculated reactor power exceeds the APRM channel output by more than 2% RTP.

This Surveillance does not preclude making APRM channel adjustments, if desired, when the heat balance calculated reactor power is less than the APRM channel output. To provide close agreement between the APRM indicated power and to preserve operating margin, the APRM channels are normally adjusted to within +/- 2% of the heat balance calculated reactor power. However, this agreement is not required for OPERABILITY when APRM output indicates a higher reactor power than the heat balance calculated reactor power.

3/4.3.1 REACTOR PROTECTION SYSTEM INSTRUMENTATION (continued)

As noted in Table 3.3.1-2, Note "*", the redundant outputs from the 2-Out-Of-4 Voter channel are considered part of the same channel, but the OPRM and APRM outputs are considered to be separate channels, so N = 8 to determine the interval between tests for application of Specification 4.3.1.3 (REACTOR PROTECTION SYSTEM RESPONSE TIME). The note further requires that testing of OPRM and APRM outputs shall be alternated.

Each test of an OPRM or APRM output tests each of the redundant outputs from the 2-Out-Of-4 Voter channel for that function, and each of the corresponding relays in the RPS. Consequently, each of the RPS relays is tested every fourth cycle. This testing frequency is twice the frequency justified by References 2 and 3.

Automatic reactor trip upon receipt of a high-high radiation signal from the Main Steam Line Radiation Monitoring System was removed as the result of an analysis performed by General Electric in NEDO-31400A. The NRC approved the results of this analysis as documented in the SER (letter to George J. Beck, BWR Owner's Group from A.C. Thadani, NRC, dated May 15, 1991).

The measurement of response time at the frequencies specified in the Surveillance Frequency Control Program provides assurance that the protective functions associated with each channel are completed within the time limit assumed in the safety analyses. No credit was taken for those channels with response times indicated as not applicable except for the APRM Simulated Thermal Power - Upscale and Neutron Flux - Upscale trip functions and the OPRM Upscale trip function (Table 3.3.1-2, Items 2.b, 2.c, and 2.f). Response time may be demonstrated by any series of sequential, overlapping or total channel test measurement, provided such tests demonstrate the total channel response time as defined. Sensor response time verification may be demonstrated by either (1) inplace, onsite or offsite test measurements, or (2) utilizing replacement sensors with certified response times. Response time testing for the sensors as noted in Table 3.3.1-2 is not required based on the analysis in NEDO-32291-A. Response time testing for the remaining channel components is required as noted. For the digital electronic portions of the APRM functions, performance characteristics that determine response time are checked by a combination of automatic self-test, calibration activities, and response time tests of the 2-Out-Of-4 Voter (Table 3.3.1-2, Item 2.e).

3/4.3.2 ISOLATION ACTUATION INSTRUMENTATION

This specification ensures the effectiveness of the instrumentation used to mitigate the consequences of accidents by prescribing the OPERABILITY trip setpoints and response times for isolation of the reactor systems. When necessary, one channel may be inoperable for brief intervals to conduct required surveillance.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30851P, Supplement 2, "Technical Specification Improvement Analysis for BWR Instrumentation Common to RPS and ECCS Instrumentation" as approved by the NRC and documented in the NRC Safety Evaluation Report (SER) (letter to D.N. Grace from C.E. Rossi dated January 6, 1989) and NEDC-31677P-A, "Technical Specification Improvement Analysis for BWR Isolation Actuation Instrumentation," as approved by the NRC and documented in the NRC SER (letter to S.D. Floyd from C.E. Rossi dated June 18, 1990).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Automatic closure of the MSIVs upon receipt of a high-high radiation signal from the Main Steam Line Radiation Monitoring System was removed as the result of an analysis performed by General Electric in NEDO-31400A. The NRC approved the results of this analysis as documented in the SER (letter to George J. Beck, BWR Owner's Group from A.C. Thadani, NRC, dated May 15, 1991).

Some of the trip settings may have tolerances explicitly stated where both the high and low values are critical and may have a substantial effect on safety. The setpoints of other instrumentation, where only the high or low end of the setting have a direct bearing on safety, are established at a level away from the normal operating range to prevent inadvertent actuation of the systems involved.

Except for the MSIVs, the safety analysis does not address individual sensor response times or the response times of the logic systems to which the sensors are connected. For D.C. operated valves, a 3 second delay is assumed before the valve starts to move. For A.C. operated valves, it is assumed that the A.C. power supply is lost and is restored by startup of the emergency diesel generators. In this event, a time of 13 seconds is assumed before the valve starts to move. In addition to the pipe break, the failure of the D.C. operated valve is assumed; thus the signal delay (sensor response) is concurrent with the 10-second diesel startup and the 3 second load center loading delay. The safety analysis considers an allowable inventory loss in each case which in turn determines the valve speed in conjunction with the 13-second delay. It follows that checking the valve speeds and the 13-second time for emergency power establishment will establish the response time for the isolation functions.

Response time testing for sensors are not required based on the analysis in NEDO-32291-A. Response time testing of the remaining channel components is required as noted in Table 3.3.2-3.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses. Primary containment isolation valves that are actuated by the isolation signals specified in Technical Specification Table 3.3.2-1 are identified in Technical Requirements Manual Table 3.6.3-1.

The opening of a containment isolation valve that was locked or sealed closed to satisfy Technical Specification 3.3.2 Action statements, may be reopened on an intermittent basis under administrative controls. These controls consist of stationing a dedicated individual at the controls of the valve, who is in continuous communication with the control room. In this way, the penetration can be rapidly isolated when a need for primary containment isolation is indicated.

3/4.3.3 EMERGENCY CORE COOLING SYSTEM ACTUATION INSTRUMENTATION

The emergency core cooling system actuation instrumentation is provided to initiate actions to mitigate the consequences of accidents that are beyond the ability of the operator to control. This specification provides the OPERABILITY requirements, trip setpoints and response times that will ensure effectiveness of the systems to provide the design protection. Although the instruments are listed by system, in some cases the same instrument may be used to send the actuation signal to more than one system at the same time.

3/4.3.3 EMERGENCY CORE COOLING SYSTEM ACTUATION INSTRUMENTATION (Continued)

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with NEDC-30936P, Parts 1 and 2, "Technical Specification Improvement Methodology (with Demonstration for BWR ECCS Actuation Instrumentation)," as approved by the NRC and documented in the SER (letter to D. N. Grace from A. C. Thadani dated December 9, 1988 (Part 1) and letter to D. N. Grace from C. E. Rossi dated December 9, 1988 (Part 2)).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Successful operation of the required safety functions of the Emergency Core Cooling Systems (ECCS) is dependent upon the availability of adequate power for energizing various components such as pump motors, motor operated valves, and the associated control components. If the loss of power instrumentation detects that voltage levels are too low, the buses are disconnected from the offsite power sources and connected to the onsite diesel generator (DG) power sources. The loss of power relays in each channel have sufficient overlapping detection characteristics and functionality to permit operation subject to the conditions in Action Statement 37. Bases 3/4.8.1, 3/4.8.2, and 3/4.8.3 provide discussion regarding parametric bounds for determining operability of the offsite sources. Those Bases assume that the loss of power relays are operable. With an inoperable 127Z-11XØX relay, the grid voltage is monitored to 230kV (for the 1Ø1 Safeguard Bus Source) or 525kV (for the 2Ø1 Safeguard Bus Source) to increase the margin for the operation of the 127Z-11XØX relay.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.3.A REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC) INSTRUMENTATION

The RPV contains penetrations below the top of the active fuel (TAF) that have the potential to drain the reactor coolant inventory to below the TAF. If the water level should drop below the TAF, the ability to remove decay heat is reduced, which could lead to elevated cladding temperatures and clad perforation. Safety Limit 2.1.4 requires the RPV water level to be above the top of the active irradiated fuel at all times to prevent such elevated cladding temperatures.

Technical Specifications are required by 1Ø CFR 5Ø.36 to include limiting safety system settings (LSSS) for variables that have significant safety functions. LSSS are defined by the regulation as "Where a LSSS is specified for a variable on which a safety limit has been placed, the setting must be chosen so that automatic protective actions will correct the abnormal situation before a Safety Limit (SL) is exceeded." The Analytical Limit is the limit of the process variable at which a safety action is initiated to ensure that a SL is not exceeded. Any automatic protection action that occurs on reaching the Analytical Limit therefore ensures that the SL is not exceeded. However, in practice, the actual settings for automatic protection channels must be chosen to be more conservative than the Analytical Limit to account for instrument loop uncertainties related to the setting at which the automatic protective action would actually occur. The actual settings for the automatic isolation channels are the same as those established for the same functions in OPERATIONAL CONDITIONS 1, 2, and 3 in Table 3.3.2-2, "ISOLATION ACTUATION INSTRUMENTATION SETPOINTS."

With the unit in OPERATIONAL CONDITION 4 or 5, RPV water inventory control is not required to mitigate any events or accidents evaluated in the safety analyses. RPV water inventory control is required in OPERATIONAL CONDITIONS 4 and 5 to protect Safety Limit 2.1.4 and the fuel cladding barrier to prevent the release of radioactive material should a draining event occur. Under the definition of DRAIN TIME, some penetration flow paths may be excluded from the DRAIN TIME calculation

3/4.3.3.A RPV WATER INVENTORY CONTROL (WIC) INSTRUMENTATION (Continued)

if they will be isolated by valves that will close automatically without offsite power prior to the RPV water level being equal to the TAF when actuated by RPV water level isolation instrumentation.

The purpose of the RPV Water Inventory Control Instrumentation is to support the requirements of LCO 3.5.2, "Reactor Pressure Vessel (RPV) Water Inventory Control (WIC)," and the definition of DRAIN TIME. There are functions that support automatic isolation of Residual Heat Removal (RHR) subsystem and Reactor Water Cleanup (RWCU) system penetration flow path(s) on low RPV water level.

A double-ended guillotine break of the Reactor Coolant System (RCS) is not considered in OPERATIONAL CONDITIONS 4 and 5 due to the reduced RCS pressure, reduced piping stresses, and ductile piping systems. Instead, an event is considered postulated in which an initiating event allows draining of the RPV water inventory through a single penetration flow path with the highest flow rate, or the sum of the drain rates through multiple penetration flow paths susceptible to a common mode failure. It is assumed, based on engineering judgment, that while in OPERATIONAL CONDITIONS 4 and 5, one low pressure ECCS injection/spray subsystem can be manually initiated to maintain adequate reactor vessel water level.

As discussed in References 1, 2, 3, 4, and 5, operating experience has shown RPV water inventory to be significant to public health and safety. Therefore, RPV Water Inventory Control satisfies Criterion 4 of 10 CFR 50.36(c)(2)(ii).

Permissive and interlock setpoints are generally considered as nominal values without regard to measurement accuracy.

The specific Applicable Safety Analyses, LCO, and Applicability discussions are listed below on a Function-by-Function basis.

3/4.3.3.A RPV WATER INVENTORY CONTROL (WIC) INSTRUMENTATION (Continued)

RHR System Isolation - Reactor Vessel Water Level Low - Level 3

The definition of DRAIN TIME allows crediting the closing of penetration flow paths that are capable of being isolated by valves that will close automatically without offsite power prior to the RPV water level being equal to the TAF when actuated by RPV water level isolation instrumentation. The Reactor Vessel Water Level Low - Level 3 Function associated with RHR System isolation may be credited for automatic isolation of penetration flow paths associated with the RHR System.

Reactor Vessel Water Level Low - Level 3 signals are initiated from four level transmitters that sense the difference between the pressure due to a constant column of water (reference leg) and the pressure due to the actual water level (variable leg) in the vessel. While four channels (two channels per trip system) of the Reactor Vessel Water Level Low - Level 3 Function are available, only two channels (all in the same trip system) are required to be OPERABLE.

The Reactor Vessel Water Level Low - Level 3 Allowable Value was chosen to be the same as the Primary Containment Isolation Instrumentation Reactor Vessel Water Level Low - Level 3 Allowable Value (Table 3.3.2-2), since the capability to cool the fuel may be threatened.

The Reactor Vessel Water Level Low - Level 3 Function is only required to be OPERABLE when automatic isolation of the associated penetration flow path is credited in calculating DRAIN TIME. This Function isolates the Group 2 valves.

Reactor Water Cleanup (RWCU) System Isolation - Reactor Vessel Water Level - Low, Low - Level 2

The definition of DRAIN TIME allows crediting the closing of penetration flow paths that are capable of being isolated by valves that will close automatically without offsite power prior to the RPV water level being equal to the TAF when actuated by RPV water level isolation instrumentation. The Reactor Vessel Water Level - Low, Low - Level 2 Function associated with RWCU System isolation may be credited for automatic isolation of penetration flow paths associated with the RWCU System.

3/4.3.3.A RPV WATER INVENTORY CONTROL (WIC) INSTRUMENTATION (Continued)

Reactor Vessel Water Level - Low, Low - Level 2 signals are initiated from four level transmitters that sense the difference between the pressure due to a constant column of water (reference leg) and the pressure due to the actual water level (variable leg) in the vessel. While four channels (two channels per trip system) of the Reactor Vessel Water Level - Low, Low - Level 2 Function are available, only two channels (all in the same trip system) are required to be OPERABLE.

The Reactor Vessel Water Level - Low, Low - Level 2 Allowable Value was chosen to be the same as the Primary Containment Isolation Instrumentation Reactor Vessel Water Level - Low, Low Level 2 Allowable Value (Table 3.3.2-2), since the capability to cool the fuel may be threatened.

The Reactor Vessel Water Level - Low, Low - Level 2 Function is only required to be OPERABLE when automatic isolation of the associated penetration flow path is credited in calculating DRAIN TIME. This Function isolates the Group 3 valves.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Actions

A note has been provided to modify the ACTIONs related to RPV Water Inventory Control instrumentation channels. The ACTIONs for inoperable RPV Water Inventory Control instrumentation channels provide appropriate compensatory measures for each inoperable RPV Water Inventory Control instrumentation channel.

ACTION a. directs taking the appropriate ACTION referenced in Table 3.3.3.A-1. The applicable ACTION referenced in the table is Function dependent.

RHR System Shutdown Cooling Mode Isolation, Reactor Vessel Water Level Low - Level 3, and Reactor Water Cleanup System Isolation, Reactor Vessel Water Level - Low, Low - Level 2 functions are applicable when automatic isolation of the associated penetration flow path is credited in calculating DRAIN TIME. If the instrumentation is inoperable, ACTION 38 directs immediate action to place the channel in trip. With the inoperable channel in the tripped condition, the remaining channel will isolate the penetration flow path on low water level. If both channels are inoperable and placed in trip, the penetration flow path will be isolated. Alternatively, ACTION 38 requires the associated penetration flow path(s) are incapable of automatic isolation and calculation of DRAIN TIME. The calculation cannot credit automatic isolation of the affected penetration flow paths.

3/4.3.4 RECIRCULATION PUMP TRIP ACTUATION INSTRUMENTATION

The anticipated transient without scram (ATWS) recirculation pump trip system provides a means of limiting the consequences of the unlikely occurrence of a failure to scram during an anticipated transient. The response of the plant to this postulated event falls within the envelope of study events in General Electric Company Topical Report NEDO-1Ø349, dated March 1971, NEDO-24222, dated December 1979, and Section 15.8 of the FSAR.

The end-of-cycle recirculation pump trip (EOC-RPT) system is a supplement to the reactor trip. During turbine trip and generator load rejection events, the EOC-RPT will reduce the likelihood of reactor vessel level decreasing to level 2. Each EOC-RPT system trips both recirculation pumps, reducing coolant flow in order to reduce the void collapse in the core during two of the most limiting pressurization events. The two events for which the EOC-RPT protective feature will function are closure of the turbine stop valves and fast closure of the turbine control valves.

A fast closure sensor from each of two turbine control valves provides input to the EOC-RPT system; a fast closure sensor from each of the other two turbine control valves provides input to the second EOC-RPT system. Similarly, a position switch for each of two turbine stop valves provides input to one EOC-RPT system; a position switch from each of the other two stop valves provides input to the other EOC-RPT system. For each EOC-RPT system, the sensor relay contacts are arranged to form a 2-out-of-2 logic for the fast closure of turbine control valves and a 2-out-of-2 logic for the turbine stop valves. The operation of either logic will actuate the EOC-RPT system and trip both recirculation pumps.

3/4.3.4 RECIRCULATION PUMP TRIP ACTUATION INSTRUMENTATION (Continued)

Each EOC-RPT system may be manually bypassed by use of a keyswitch which is administratively controlled. The manual bypasses and the automatic Operating Bypass at less than 29.5% of RATED THERMAL POWER are annunciated in the control room.

The EOC-RPT system response time is the time assumed in the analysis between initiation of valve motion and complete suppression of the electric arc, i.e., 175 ms. Included in this time are: the response time of the sensor, the time allotted for breaker arc suppression, and the response time of the system logic.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been determined in accordance with GENE-770-06-1, "Bases for Changes to Surveillance Test Intervals and Allowed Out-of-Service Times for Selected Instrumentation Technical Specifications," as approved by the NRC and documented in the SER (letter to R.D. Binz, IV, from C.E. Rossi dated July 21, 1992).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.5 REACTOR CORE ISOLATION COOLING SYSTEM ACTUATION INSTRUMENTATION

The reactor core isolation cooling system actuation instrumentation is provided to initiate actions to assure adequate core cooling in the event of reactor isolation from its primary heat sink and the loss of feedwater flow to the reactor vessel. This instrumentation does not provide actuation of any of the emergency core cooling equipment.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage times have been specified in accordance with recommendations made by GE in their letter to the BWR Owner's Group dated August 7, 1989, SUBJECT: "Clarification of Technical Specification changes given in ECCS Actuation Instrumentation Analysis."

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

3/4.3.6 CONTROL ROD BLOCK INSTRUMENTATION

The control rod block functions are provided consistent with the requirements of the specifications in Section 3/4.1.4, Control Rod Program Controls and Section 3/4.2 Power Distribution Limits and Section 3/4.3 Instrumentation. The trip logic is arranged so that a trip in any one of the inputs will result in a control rod block.

Surveillance intervals are determined in accordance with the Surveillance Frequency Control Program and maintenance outage time have been determined in accordance with NEDC-30851P, Supplement 1, "Technical Specification Improvement Analysis for BWR Control Rod Block Instrumentation," as approved by the NRC and documented in the SER (letter to D. N. Grace from C. E. Rossi dated September 22, 1988).

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

Operation with a trip set less conservative than its Trip Setpoint but within its specified Allowable Value is acceptable on the basis that the difference between each Trip Setpoint and the Allowable Value is an allowance for instrument drift specifically allocated for each trip in the safety analyses.

INTENTIONALLY LEFT BLANK

3/4.3.7 MONITORING INSTRUMENTATION

3/4.3.7.1 RADIATION MONITORING INSTRUMENTATION

The OPERABILITY of the radiation monitoring instrumentation ensures that: (1) the radiation levels are continually measured in the areas served by the individual channels, and (2) the alarm or automatic action is initiated when the radiation level trip setpoint is exceeded, and (3) sufficient information is available on selected plant parameters to monitor and assess these variables following an accident. This capability is consistent with 10 CFR Part 50, Appendix A, General Design Criteria 19, 41, 60, 61, 63, and 64.

The surveillance interval for the Main Control Room Normal Fresh Air Supply Radiation Monitor is determined in accordance with the Surveillance Frequency Control Program.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

3/4.3.7.2 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE UFSAR.

3/4.3.7.3 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM.

3/4.3.7.4 REMOTE SHUTDOWN SYSTEM

The OPERABILITY of the remote shutdown system ensures that sufficient capability is available to permit shutdown and maintenance of HOT SHUTDOWN of the unit from locations outside of the control room. This capability is required in the event control room habitability is lost and is consistent with General Design Criterion 19 of 10 CFR Part 50, Appendix A. The Unit 1 RHR transfer switches are included only due to their potential impact on the RHRSW system, which is common to both units.

The systems/functions for which the RSP provides remote instrumentation and controls to accomplish this purpose are as follows:

- Reactor Core Isolation Cooling (RCIC) system to maintain reactor vessel water level.
- Main steam line safety/relief valves (manual actuation) to reduce reactor vessel pressure.
- Nuclear boiler instrumentation to monitor reactor vessel pressure and level.
- Residual Heat Removal (RHR) system for suppression pool cooling and shutdown cooling.
- RHR Service Water system to supply cooling water to the RHR heat exchanger.
- Emergency Service Water (ESW) system to supply cooling water to RCIC and RHR room coolers, RHR motor oil and seal coolers, and the emergency diesel generator.
- Containment and suppression pool system monitoring instrumentation.
- Standby AC power that supplies power to the above systems.

3/4.3.7.5 ACCIDENT MONITORING INSTRUMENTATION

The OPERABILITY of the accident monitoring instrumentation ensures that sufficient information is available on selected plant parameters to monitor and assess important variables following an accident. This capability is consistent with the recommendations of Regulatory Guide 1.97, "Instrumentation for Light Water Cooled Nuclear Power Plants to Assess Plant Conditions During and Following an Accident," December 1975 and NUREG-0737, "Clarification of TMI Action Plan Requirements," November 1980.

Table 3.3.7.5-1, Accident Monitoring Instrumentation, Item 2, requires two OPERABLE channels of Reactor Vessel Water Level monitoring from each of two overlapping instrumentation loops to ensure monitoring of Reactor Vessel Water Level over the range of -350 inches to +60 inches. Each channel is comprised of one OPERABLE Wide Range Level instrument loop (-150 inches to +60 inches) and one OPERABLE Fuel Zone Range instrument loop (-350 inches to -100 inches). Both instrument loops, Wide Range and Fuel Zone Range, are required by Tech. Spec. 3.3.7.5 to provide sufficient overlap to bound the required range as described in UFSAR Section 7.5. Action 80 is applicable if the required number of instrument loops per channel (Wide Range and Fuel Zone Range) is not maintained.

3/4.3.7.5 ACCIDENT MONITORING INSTRUMENTATION (continued)

Table 3.3.7.5-1, Accident Monitoring Instrumentation, Item 13, requires two OPERABLE channels of Neutron Flux monitoring from each of three overlapping instrumentation loops to ensure monitoring of Neutron Flux over the range of 10^{-6}% to 100% full power. Each channel is comprised of one OPERABLE SRM (10^{-9}% to 10^{-3}% power), one OPERABLE IRM (10^{-4}% to 40% power) and one OPERABLE APRM (0% to 125% power). All three instrument loops, SRM, IRM and APRM, are required by Tech. Spec. 3.3.7.5 to provide sufficient overlap to bound the required range as described in UFSAR Section 7.5. Action 80 is applicable if the required number of instrument loops per channel (SRM, IRM, and APRM) is not maintained.

3/4.3.7.6 SOURCE RANGE MONITORS

The source range monitors provide the operator with information of the status of the neutron level in the core at very low power levels during startup and shutdown. At these power levels, reactivity additions shall not be made without this flux level information available to the operator. When the intermediate range monitors are on scale, adequate information is available without the SRMs and they can be retracted.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

3/4.3.7.8 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4.3.7.9 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

(INTENTIONALLY LEFT BLANK)

3/4.3.7.10 (Deleted)

3/4.3.7.11 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM.

3/4.3.7.12 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE ODCM AND THE TRM.

3/4.3.8 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE UFSAR.

3/4.3.9 FEEDWATER/MAIN TURBINE TRIP SYSTEM ACTUATION INSTRUMENTATION

The feedwater/main turbine trip system actuation instrumentation is provided to initiate action of the feedwater system/main turbine trip system in the event of failure of feedwater controller under maximum demand.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

APRM CONFIGURATION

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.4.1 RECIRCULATION SYSTEM

The impact of single recirculation loop operation upon plant safety is assessed and shows that single-loop operation is permitted if the MCPR(99.9%) is increased as noted in the COLR, APRM scram and control rod block setpoints are adjusted as noted in Tables 2.2.1-1 and 3.3.6-2, respectively.

An inoperable jet pump is not, in itself, a sufficient reason to declare a recirculation loop inoperable, but it does, in case of a design-basis-accident, increase the blowdown area and reduce the capability of reflooding the core; thus, the requirement for shutdown of the facility with a jet pump inoperable. Jet pump failure can be detected by monitoring jet pump performance on a prescribed schedule for significant degradation.

Additionally, surveillance on the pump speed of the operating recirculation loop is imposed to exclude the possibility of excessive internals vibration. The surveillance on differential temperatures below 30% RATED THERMAL POWER or 50% rated recirculation loop flow is to mitigate the undue thermal stress on vessel nozzles, recirculation pump and vessel bottom head during the extended operation of the single recirculation loop mode.

Surveillance of recirculation loop flow, total core flow, and diffuser-to-lower plenum differential pressure is designed to detect significant degradation in jet pump performance that precedes jet pump failure. This surveillance is required to be performed only when the loop has forced recirculation flow since surveillance checks and measurements can only be performed during jet pump operation. The jet pump failure of concern is a complete mixer displacement due to jet pump beam failure. Jet pump plugging is also of concern since it adds flow resistance to the recirculation loop. Significant degradation is indicated if the specified criteria confirm unacceptable deviations from established patterns or relationships. Since refueling activities (fuel assembly replacement or shuffle, as well as any modifications to fuel support orifice size or core plate bypass flow) can affect the relationship between core flow, jet pump flow, and recirculation loop flow, these relationships may need to be re-established each cycle. Similarly, initial entry into extended single loop operation may also require establishment of these relationships. During the initial weeks of operation under such conditions, while base-lining new "established patterns," engineering judgment of the daily surveillance results is used to detect significant abnormalities which could indicate a jet pump failure.

The recirculation pump speed operating characteristics (pump flow and loop flow versus pump speed) are determined by the flow resistance from the loop suction through the jet pump nozzles. A change in the relationship indicates a plug, flow restriction, loss in pump hydraulic performance, leakage, or new flow path between the recirculation pump discharge and jet pump nozzle. For this criterion, the pump flow and loop flow versus pump speed relationship must be verified.

3/4.4.1 RECIRCULATION SYSTEM (continued)

Individual jet pumps in a recirculation loop normally do not have the same flow. The unequal flow is due to the drive flow manifold, which does not distribute flow equally to all risers. The flow (or jet pump diffuser to lower plenum differential pressure) pattern or relationship of one jet pump to the loop average is repeatable. An appreciable change in this relationship is an indication that increased (or reduced) resistance has occurred in one of the jet pumps. This may be indicated by an increase in the relative flow for a jet pump that has experienced beam cracks.

The deviations from normal are considered indicative of a potential problem in the recirculation drive flow or jet pump system. Normal flow ranges and established jet pump flow and differential pressure patterns are established by plotting historical data.

Recirculation pump speed mismatch limits are in compliance with the ECCS LOCA analysis design criteria for two recirculation loop operation. The limits will ensure an adequate core flow coastdown from either recirculation loop following a LOCA. In the case where the mismatch limits cannot be maintained during two loop operation, continued operation is permitted in a single recirculation loop mode.

In order to prevent undue stress on the vessel nozzles and bottom head region, the recirculation loop temperatures shall be within 50°F of each other prior to startup of an idle loop. The loop temperature must also be within 50°F of the reactor pressure vessel coolant temperature to prevent thermal shock to the recirculation pump and recirculation nozzles. Sudden equalization of a temperature difference > 145°F between the reactor vessel bottom head coolant and the coolant in the upper region of the reactor vessel by increasing core flow rate would cause undue stress in the reactor vessel bottom head.

3/4.4.2 SAFETY/RELIEF VALVES

The safety valve function of the safety/relief valves operates to prevent the reactor coolant system from being pressurized above the Safety Limit of 1325 psig in accordance with the ASME Code. A total of 12 OPERABLE safety/relief valves is required to limit reactor pressure to within ASME III allowable values for the worst case upset transient.

Demonstration of the safety/relief valve lift settings will occur only during shutdown. The safety/relief valves will be removed and either set pressure tested or replaced with spares which have been previously set pressure tested and stored in accordance with manufacturers recommendations at the frequency specified in the Surveillance Frequency Control Program.

3/4.4.3 REACTOR COOLANT SYSTEM LEAKAGE

3/4.4.3.1 LEAKAGE DETECTION SYSTEMS

BACKGROUND

UFSAR Safety Design Basis (Ref. 1), requires means for detecting and, to the extent practical, identifying the location of the source of Reactor Coolant System (RCS) PRESSURE BOUNDARY LEAKAGE. Regulatory Guide 1.45, Revision 0, (Ref. 2) describes acceptable methods for selecting leakage detection systems.

Limits on leakage from the reactor coolant pressure boundary (RCPB) are required so that appropriate action can be taken before the integrity of the RCPB is impaired (Ref. 2). Leakage detection systems for the RCS are provided to alert the operators when leakage rates above normal background levels are detected and also to supply quantitative measurement of leakage rates. In addition to meeting the OPERABILITY requirements, the monitors are typically set to provide the most sensitive response without causing an excessive number of spurious alarms.

Systems for quantifying the leakage are necessary to provide prompt and quantitative information to the operators to permit them to take immediate corrective action. Leakage from the RCPB inside the drywell is detected by at least one of four (4) independently monitored variables which include drywell sump flow monitoring equipment with the required RCS leakage detection instrumentation (i.e., the drywell floor drain sump flow monitoring system, or, the drywell equipment drain sump monitoring system with the drywell floor drain sump overflowing to the drywell equipment drain sump), drywell gaseous radioactivity, drywell unit cooler condensate flow rate and drywell pressure/temperature levels. The primary means of quantifying leakage in the drywell is the drywell sump monitoring system for UNIDENTIFIED LEAKAGE and the drywell equipment drain tank flow monitoring system for IDENTIFIED LEAKAGE. IDENTIFIED leakage is not germane to this Tech Spec and the associated drywell equipment drain tank flow monitoring system is not included.

The drywell floor drain sump flow monitoring system monitors UNIDENTIFIED LEAKAGE collected in the floor drain sump. UNIDENTIFIED LEAKAGE consists of leakage from RCPB components inside the drywell which are not normally subject to leakage and otherwise routed to the drywell equipment drain sump. The primary containment floor drain sump has transmitters that supply level indication to the main control room via the plant monitoring system. The floor drain sump level transmitters are associated with High/Low level switches that open/close the sump tank drain valves automatically. The level instrument processing unit calculates an average leak rate (gpm) for a given measurement period which resets whenever the sump drain valve closes. The level processing unit provides an alarm to the main control room each time the average leak rate changes by a predetermined value since the last time the alarm was reset. For the drywell floor drain sump flow monitoring system, the setpoint basis is a 1 gpm change in UNIDENTIFIED LEAKAGE.

An alternate to the drywell floor drain sump flow monitoring system for quantifying UNIDENTIFIED LEAKAGE is the drywell equipment drain sump monitoring system, if the drywell floor drain sump is overflowing to the drywell equipment drain sump. In this configuration, the drywell equipment drain sump collects all leakage into the drywell equipment drain sump and the overflow from the drywell floor drain sump. Therefore, if the drywell floor drain sump is overflowing to the drywell equipment drain sump, the drywell equipment drain sump monitoring system can be used to quantify UNIDENTIFIED LEAKAGE. In this condition, all leakage measured by the drywell equipment drain sump monitoring system is assumed to be UNIDENTIFIED LEAKAGE. The leakage determination process, including the transition to and use of the alternate method is described in station procedures. The alternate method would only be used when the drywell floor drain sump flow monitoring system is unavailable.

In addition to the drywell sump monitoring system described above, the discharge of each sump is monitored by an independent flow element. The measured flow rate from the flow element is integrated and recorded. A main control room alarm is also provided to indicate an excessive sump discharge rate measured via the flow element. This system, referred to as the “drywell floor drain flow totalizer”, is not credited for drywell floor drain sump flow monitoring system operability.

BACKGROUND (Continued)

The primary containment atmospheric gaseous radioactivity monitoring system continuously monitors the primary containment atmosphere for gaseous radioactivity levels. A sudden increase of radioactivity, which may be attributed to RCPB steam or reactor water leakage, is annunciated in the main control room.

Condensate from the eight drywell air coolers is routed to the drywell floor drain sump and is monitored by a series of flow transmitters that provide indication and alarms in the main control room. The outputs from the flow transmitters are added together by summing units to provide a total continuous condensate drain flow rate. The high flow alarm setpoint is based on condensate drain flow rate in excess of 1 gpm over the currently identified preset leak rate. The drywell air cooler condensate flow rate monitoring system serves as an added indicator, but not quantifier, of RCS UNIDENTIFIED LEAKAGE (Ref. 4).

The drywell temperature and pressure monitoring systems provide an indirect method for detecting RCPB leakage. A temperature and/or pressure rise in the drywell above normal levels may be indicative of a reactor coolant or steam leakage (Ref. 5).

APPLICABLE SAFETY ANALYSES

A threat of significant compromise to the RCPB exists if the barrier contains a crack that is large enough to propagate rapidly. Leakage rate limits are set low enough to detect the leakage emitted from a single crack in the RCPB (Refs. 6 and 7).

A control room alarm allow the operators to evaluate the significance of the indicated leakage and, if necessary, shut down the reactor for further investigation and corrective action. The allowed leakage rates are well below the rates predicted for critical crack sizes (Ref. 7). Therefore, these actions provide adequate response before a significant break in the RCPB can occur.

RCS leakage detection instrumentation satisfies Criterion 1 of the NRC Policy Statement.

LIMITING CONDITION FOR OPERATION (LCO)

This LCO requires instruments of diverse monitoring principles to be OPERABLE to provide confidence that small amounts of UNIDENTIFIED LEAKAGE are detected in time to allow actions to place the plant in a safe condition, when RCS leakage indicates possible RCPB degradation.

The LCO requires four instruments to be OPERABLE.

The required instrumentation to quantify UNIDENTIFIED LEAKAGE from the RCS consists of either the drywell floor drain sump flow monitoring system, or, the drywell equipment drain sump monitoring system with the drywell floor drain sump overflowing to the drywell equipment drain sump. For either system to be considered operable, the flow monitoring portion of the system must be operable. The identification of an increase in UNIDENTIFIED LEAKAGE will be delayed by the time required for the UNIDENTIFIED LEAKAGE to travel to the drywell floor drain sump and it may take longer than one hour to detect a 1 gpm increase in UNIDENTIFIED LEAKAGE, depending on the origin and magnitude of the leakage. This sensitivity is acceptable for containment sump monitor OPERABILITY.

The reactor coolant contains radioactivity that, when released to the primary containment, can be detected by the gaseous primary containment atmospheric radioactivity monitor. A radioactivity detection system is included for monitoring gaseous activities because of its sensitivity and rapid response to RCS leakage, but it has recognized limitations. Reactor coolant radioactivity levels will be low during initial reactor startup and for a few weeks thereafter, until activated corrosion products have been formed and fission products appear from fuel element cladding contamination or cladding defects. If there are few fuel element cladding defects and low levels of activation products, it may not be possible for the gaseous primary

LIMITING CONDITION FOR OPERATION (LCO) (Continued)

containment atmospheric radioactivity monitor to detect a 1 gpm increase within 1 hour during normal operation. However, the gaseous primary containment atmospheric radioactivity monitor is OPERABLE when it is capable of detecting a 1 gpm increase in UNIDENTIFIED LEAKAGE within 1 hour given an RCS activity equivalent to that assumed in the design calculations for the monitors (Reference 9).

The LCO is satisfied when monitors of diverse measurement means are available. Thus, the drywell floor drain sump monitoring system in combination with a gaseous primary containment atmospheric radioactivity monitor, a primary containment air cooler condensate flow rate monitoring system, and a primary containment pressure and temperature monitoring system provides an acceptable minimum.

APPLICABILITY

In OPERATIONAL CONDITIONS 1, 2, and 3, leakage detection systems are required to be OPERABLE to support LCO 3.4.3.2. This applicability is consistent with that for LCO 3.4.3.2.

ACTIONS

A. With the primary containment atmosphere gaseous monitoring system inoperable, grab samples of the primary containment atmosphere must be taken and analyzed to provide periodic leakage information. [Provided a sample is obtained and analyzed once every 12 hours, the plant may be operated for up to 30 days to allow restoration of the radioactivity monitoring system. The plant may continue operation since other forms of drywell leakage detection are available.]

   The 12 hours interval provides periodic information that is adequate to detect leakage. The 30 day Completion Time for Restoration recognizes other forms of leakage detection are available.

B. With required drywell sump monitoring system inoperable, no other form of sampling can provide the equivalent information to quantify leakage at the required 1 gpm/hour sensitivity. However, the primary containment atmospheric gaseous monitor [and the primary containment air cooler condensate flow rate monitor] will provide indication of changes in leakage.

   With required drywell sump monitoring system inoperable, drywell condensate flow rate monitoring frequency increased from 12 to every 8 hours, and UNIDENTIFIED LEAKAGE and total leakage being determined every 8 hours (Ref: SR 4.4.3.2.1.b) operation may continue for 30 days. To the extent practical, the surveillance frequency change associated with the drywell condensate flow rate monitoring system, makes up for the loss of the drywell floor drain sump monitoring system which had a normal surveillance requirement to monitor leakage every 8 hours. Also note that in this instance, the drywell floor drain tank flow totalizer will be used to comply with SR 4.4.3.2.1.b. The 30 day Completion Time of the required ACTION is acceptable, based on operating experience, considering the multiple forms of leakage detection that are still available.

C. With the required primary containment air cooler condensate flow rate monitoring system inoperable, SR 4.4.3.1.a must be performed every 8 hours to provide periodic information of activity in the primary containment at a more frequent interval than the routine frequency of every 12 hours. The 8 hour interval provides periodic information that is adequate to detect leakage and recognizes that other forms of leakage detection are available. The required ACTION has been clarified to state

ACTIONS (Continued)

that the additional surveillance requirement is not applicable if the required primary containment atmosphere gaseous radioactivity monitoring system is also inoperable. Consistent with SR 4.0.3, surveillances are not required to be performed on inoperable equipment. In this case, ACTION Statement A. and E. requirements apply.

D. With the primary containment pressure and temperature monitoring system inoperable, operation may continue for up to 30 days given the system's indirect capability to detect RCS leakage. However, other more limiting Tech Spec requirements associated with the primary containment pressure/temperature monitoring system will still apply.

E. With both the primary containment atmosphere gaseous radioactivity monitor and the primary containment air cooler condensate flow rate monitor inoperable, the only means of detecting leakage is the drywell floor drain sump monitor and the drywell pressure/temperature instrumentation. This condition does not provide the required diverse means of leakage detection. The required ACTION is to restore either of the inoperable monitors to OPERABLE status within 30 days to regain the intended leakage detection diversity. The 30 day Completion Time ensures that the plant will not be operated in a degraded configuration for a lengthy time period. While the primary containment atmosphere gaseous radioactivity monitor is INOPERABLE, primary containment atmospheric grab samples will be taken and analyzed every 12 hours since ACTION Statement A. requirements also apply.

F. With the drywell floor drain sump monitoring system inoperable and the drywell unit coolers condensate flow rate monitoring system inoperable, one of the two remaining means of detecting leakage is the primary containment atmospheric gaseous radiation monitor. The primary containment atmospheric gaseous radiation monitor typically cannot detect a 1 gpm leak within one hour when RCS activity is low. Indirect methods of monitoring RCS leakage must be implemented. Grab samples of the primary containment atmosphere must be taken and analyzed and monitoring of RCS leakage by administrative means must be performed every 12 hours to provide alternate periodic information.

Administrative means of monitoring RCS leakage include monitoring and trending parameters that may indicate an increase in RCS leakage. There are diverse alternative mechanisms from which appropriate indicators may be selected based on plant conditions. It is not necessary to utilize all of these methods, but a method or methods should be selected considering the current plant conditions and historical or expected sources of UNIDENTIFIED LEAKAGE. The administrative methods are the drywell cooling fan inlet/outlet temperatures, drywell equipment drain sump temperature indicator, drywell equipment drain tank hi temperature indicator, and drywell equipment drain tank flow indicator. These indications, coupled with the atmospheric grab samples, are sufficient to alert the operating staff to an unexpected increase in UNIDENTIFIED LEAKAGE.

In addition to the primary containment atmospheric gaseous radiation monitor and indirect methods of monitoring RCS leakage, the primary containment pressure and temperature monitoring system is also available to alert the operating staff to an unexpected increase in UNIDENTIFIED LEAKAGE.

ACTIONS (Continued)

The 12 hour interval is sufficient to detect increasing RCS leakage. The Required Action provides 7 days to restore another RCS leakage monitor to OPERABLE status to regain the intended leakage detection diversity. The 7-day Completion Time ensures that the plant will not be operated in a degraded configuration for a lengthy time period.

G. If any required ACTION of Conditions A, B, C, D, E or F cannot be met within the associated Completion Time, the plant must be brought to an OPERATIONAL CONDITION in which the LCO does not apply. To achieve this status, the plant must be brought to at least HOT SHUTDOWN within 12 hours and COLD SHUTDOWN within the next 24 hours. The allowed Completion Times are reasonable, based on operating experience, to perform the ACTIONS in an orderly manner and without challenging plant systems.

SURVEILLANCE REQUIREMENTS

SR 4.4.3.1.a
This SR is for the performance of a CHANNEL CHECK of the required primary containment atmospheric monitoring system. The check gives reasonable confidence that the channel is operating properly.

SR 4.4.3.1.b
This SR is for the performance of a CHANNEL FUNCTIONAL TEST of the required RCS leakage detection instrumentation. The test ensures that the monitors can perform their function in the desired manner. The test also verifies the alarm setpoint and relative accuracy of the instrument string. A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

SR 4.4.3.1.c
This SR is for the performance of a CHANNEL CALIBRATION of required leakage detection instrumentation channels. The calibration verifies the accuracy of the instrument string, including the instruments located inside containment.

SR 4.4.3.1.d
This SR provides a routine check of primary containment pressure and temperature for indirect evidence of RCS leakage.

3/4.4.3.2 OPERATIONAL LEAKAGE

The allowable leakage rates from the reactor coolant system have been based on the predicted and experimentally observed behavior of cracks in pipes. The normally expected background leakage due to equipment design and the detection capability of the instrumentation for determining system leakage was also considered. The evidence obtained from experiments suggests that for leakage somewhat greater than that specified for UNIDENTIFIED LEAKAGE the probability is small that the imperfection or crack associated with such leakage would grow rapidly. However, in all cases, if the leakage rates exceed the values specified, the reactor will be shutdown to allow further investigation and corrective action. The limit of 2 gpm increase in UNIDENTIFIED LEAKAGE over a 24-hour period and the monitoring of drywell floor drain sump and drywell equipment drain tank flow rate at least once every eight (8) hours conforms with NRC staff positions specified in NRC Generic Letter 88-01, "NRC Position on IGSCC in BWR Austenitic Stainless Steel Piping," as revised by NRC Safety Evaluation dated March 6, 1990. The ACTION requirement for the 2 gpm increase in UNIDENTIFIED LEAKAGE limit ensures that such leakage is identified or a plant shutdown is initiated to allow further investigation and corrective action. Separating the sources of LEAKAGE (i.e., LEAKAGE from an identified source versus LEAKAGE from an unidentified source) is necessary for prompt identification of potentially adverse conditions, assessment of the safety significance, and corrective action. Once identified, reactor operation may continue dependent upon the impact on total leakage.

PPRESSURE BOUNDARY LEAKAGE is prohibited as the leak itself could cause further reactor coolant pressure boundary deterioration, resulting in higher leakage. If PRESSURE BOUNDARY LEAKAGE exists, the affected component, pipe, or vessel must be isolated from the reactor coolant system by a closed manual valve, closed and de-activated automatic valve, blind flange, or check valve within 4 hours. While in this condition, structural integrity of the system should be considered because the structural integrity of the part of the system within the isolation boundary must be maintained under all licensing basis conditions, including consideration of the potential for further degradation of the isolated location. Normal leakage past the isolation device is acceptable as it will limit reactor coolant system leakage and is included in the IDENTIFIED LEAKAGE or UNIDENTIFIED LEAKAGE. This ACTION is necessary to prevent further deterioration of the reactor coolant pressure boundary. If the ACTION cannot be completed in the required time, then the reactor will be shutdown to allow further investigation and corrective action.

The function of Reactor Coolant System Pressure Isolation Valves (PIVs) is to separate the high pressure Reactor Coolant System from an attached low pressure system. The ACTION requirements for pressure isolation valves are used in conjunction with the system specifications for which PIVs are listed in The Technical Requirements Manual and with primary containment isolation valve requirements to ensure that plant operation is appropriately limited.

The Surveillance Requirements for the RCS pressure isolation valves provide added assurance of valve integrity thereby reducing the probability of gross valve failure and consequent intersystem LOCA. Leakage from the RCS pressure isolation valves is not included in any other allowable operational leakage specified in Section 3.4.3.2.

3/4.4.4 (Deleted) INFORMATION FROM THIS SECTION RELOCATED TO THE TRM

3/4.4.5 SPECIFIC ACTIVITY

The limitations on the specific activity of the primary coolant ensure that the 2-hour thyroid and whole body doses resulting from a main steam line failure outside the containment during steady state operation will not exceed small fractions of the dose guidelines of 10 CFR Part 100. The values for the limits on specific activity represent interim limits based upon a parametric evaluation by the NRC of typical site locations. These values are conservative in that specific site parameters, such as SITE BOUNDARY location and meteorological conditions, were not considered in this evaluation.

The ACTION statement permitting POWER OPERATION to continue for limited time periods with the primary coolant's specific activity greater than 0.2 microcurie per gram DOSE EQUIVALENT I-131, but less than or equal to 4 microcuries per gram DOSE EQUIVALENT I-131, accommodates possible iodine spiking phenomenon which may occur following changes in THERMAL POWER. This action is modified by a Note that permits the use of the provisions of Specification 3.0.4.c. This allowance permits entry into the applicable OPERATIONAL CONDITION (S) while relying on the ACTION requirements. Operation with specific activity levels exceeding 0.2 microcurie per gram DOSE EQUIVALENT I-131 but less than or equal to 4 microcuries per gram DOSE EQUIVALENT I-131 must be restricted since these activity levels increase the 2-hour thyroid dose at the SITE BOUNDARY following a postulated steam line rupture.

Closing the main steam line isolation valves prevents the release of activity to the environs should a steam line rupture occur outside containment. The surveillance requirements provide adequate assurance that excessive specific activity levels in the reactor coolant will be detected in sufficient time to take corrective action.

3/4.4.6 PRESSURE/TEMPERATURE LIMITS

All components in the reactor coolant system are designed to withstand the effects of cyclic loads due to system temperature and pressure changes. These cyclic loads are introduced by normal load transients, reactor trips, and startup and shutdown operations. The various categories of load cycles used for design purposes are provided in Section 3.9 of the FSAR. During startup and shutdown, the rates of temperature and pressure changes are limited so that the maximum specified heatup and cooldown rates are consistent with the design assumptions and satisfy the stress limits for cyclic operation.

PRESSURE/TEMPERATURE LIMITS (Continued)

The operating limit curves specified in the PTLR are derived from the fracture toughness requirements of 10 CFR 50 Appendix G and ASME Code Section XI, Appendix G. The curves are based on the RT_{NDT} and stress intensity factor information for the reactor vessel components. Fracture toughness limits and the basis for compliance are more fully discussed in FSAR Chapter 5, Paragraph 5.3.1.5, "Fracture Toughness."

The reactor vessel materials have been tested to determine their initial RT_{NDT}. The results of these tests are specified in the PTLR. Reactor operation and resultant fast neutron, E greater than 1 MeV, irradiation will cause an increase in the RT_{NDT}. Therefore, an adjusted reference temperature, based upon the fluence, nickel content and copper content of the material in question, can be predicted using the PTLR and the recommendations of Regulatory Guide 1.99, Revision 2, "Radiation Embrittlement of Reactor Vessel Materials." The pressure/temperature limit curves specified in the PTLR include an assumed shift in the RT_{NDT} for the conditions at 57 EFPY.

The pressure-temperature limit lines specified in the PTLR for reactor criticality and for inservice leak and hydrostatic testing have been provided to assure compliance with the minimum temperature requirements of Appendix G to 10 CFR Part 50 for reactor criticality and for inservice leak and hydrostatic testing.

3/4.4.7 MAIN STEAM LINE ISOLATION VALVES

Double isolation valves are provided on each of the main steam lines to minimize the potential leakage paths from the containment in case of a line break. Only one valve in each line is required to maintain the integrity of the containment, however, single failure considerations require that two valves be OPERABLE. The surveillance requirements are based on the operating history of this type valve. The maximum closure time has been selected to contain fission products and to ensure the core is not uncovered following line breaks. The minimum closure time is consistent with the assumptions in the safety analyses to prevent pressure surges.

3/4.4.8 (DELETED)

3/4.4.9 RESIDUAL HEAT REMOVAL

The RHR system is required to remove decay heat and sensible heat in order to maintain the temperature of the reactor coolant. RHR shutdown cooling is comprised of four (4) subsystems which make two (2) loops. Each loop consists of two (2) motor driven pumps, a heat exchanger, and associated piping and valves. Both loops have a common suction from the same recirculation loop. Two (2) redundant, manually controlled shutdown cooling subsystems of the RHR System can provide the required decay heat removal capability. Each pump discharges the reactor coolant, after it has been cooled by circulation through the respective heat exchangers, to the reactor via the associated recirculation loop or to the reactor via the low pressure coolant injection pathway. The RHR heat exchangers transfer heat to the RHR Service Water System. The RHR shutdown cooling mode is manually controlled.

An OPERABLE RHR shutdown cooling subsystem consists of an RHR pump, a heat exchanger, valves, piping, instruments, and controls to ensure an OPERABLE flow path. In HOT SHUTDOWN condition, the requirement to maintain OPERABLE two (2) independent RHR shutdown cooling subsystems means that each subsystem considered OPERABLE must be associated with a different heat exhanger loop, i.e., the "A" RHR heat exchanger with the "A" RHR pump or the "C" RHR pump, and the "B" RHR heat exchanger with the "B" RHR pump or the "D" RHR pump are two (2) independent RHR shutdown cooling subsystems. Only one (1) of the two (2) RHR pumps associated with each RHR heat exchanger loop is

3/4.4.9 RESIDUAL HEAT REMOVAL (Continued)

required to be OPERABLE for that independent subsystem to be OPERABLE. During COLD SHUTDOWN and REFUELING conditions, however, the subsystems not only have a common suction source, but are allowed to have a common heat exchanger and common discharge piping. To meet the LCO of two (2) OPERABLE subsystems, both pumps in one (1) loop or one (1) pump in each of the two (2) loops must be OPERABLE. Since the piping and heat exchangers are passive components, that are assumed not to fail, they are allowed to be common to both subsystems. Additionally, each RHR shutdown cooling subsystem is considered OPERABLE if it can be manually aligned (remote or local) in the shutdown cooling mode for removal of decay heat. Operation (either continuous or intermittent) of one (1) subsystem can maintain and reduce the reactor coolant temperature as required. However, to ensure adequate core flow to allow for accurate average reactor coolant temperature monitoring, nearly continuous operation is required. Management of gas voids is important to RHR Shutdown Cooling System OPERABILITY.

Alternate decay heat removal methods are available to operators. These alternate methods of decay heat removal can be verified available either by calculation (which includes a review of component and system availability to verify that an alternate decay heat removal method is available) or by demonstration, and that a method of coolant mixing be operational. Decay heat removal capability by ambient losses can be considered in evaluating alternate decay heat removal capability.

RHR Shutdown Cooling System piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the RHR shutdown cooling subsystems and may also prevent water hammer, pump cavitation, and pumping of non-condensable gas into the reactor vessel. This surveillance verifies that the RHR Shutdown Cooling System piping is sufficiently filled with water prior to initially placing the system in operation during reactor shutdown. The RHR Shutdown Cooling System is OPERABLE when it is sufficiently filled with water to ensure that it can reliably perform its intended function.

The RHR Shutdown Cooling System is a manually initiated mode of the RHR System whose use is typically preceded by system piping flushes that disturb both the RHR pump suction and discharge piping. RHR Shutdown Cooling System is flushed and manually aligned for service using system operating procedures that ensure the RHR shutdown cooling suction and discharge flow paths are sufficiently filled with water. In the event that RHR Shutdown Cooling is required for emergency service, the system operating procedures that align and start the RHR System in shutdown cooling mode include the flexibility to eliminate piping flushes while maintaining minimum requirements to ensure that the suction and discharge flow paths are sufficiently filled with water. The RHR Shutdown Cooling System surveillance is met through the performance of the operating procedures that initially place the RHR shutdown cooling sub-system in service.

This surveillance requirement is modified by a Note allowing sufficient time (12 hours) to align the RHR System for Shutdown Cooling operation after reactor dome pressure is less than the RHR cut-in permissive set point.

3/4.5.1 ECCS - OPERATING

The core spray system (CSS), together with the LPCI mode of the RHR system, is provided to assure that the core is adequately cooled following a loss-of-coolant accident and provides adequate core cooling capacity for all break sizes up to and including the double-ended reactor recirculation line break, and for smaller breaks following depressurization by the ADS. Management of gas voids is important to ECCS injection/spray subsystem OPERABILITY.

The CSS is a primary source of emergency core cooling after the reactor vessel is depressurized and a source for flooding of the core in case of accidental draining.

The surveillance requirements provide adequate assurance that the CSS will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation through a test loop during reactor operation, a complete functional test requires reactor shutdown.

The low pressure coolant injection (LPCI) mode of the RHR system is provided to assure that the core is adequately cooled following a loss-of-coolant accident. Four subsystems, each with one pump, provide adequate core flooding for all break sizes up to and including the double-ended reactor recirculation line break, and for small breaks following depressurization by the ADS.

The surveillance requirements provide adequate assurance that the LPCI system will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation through a test loop during reactor operation, a complete functional test requires reactor shutdown.

The CCS pump flow of 3,175 gpm and the LPCI pump flow of 10,000 gpm are flow values at nominal grid frequency of 60 Hz. The 10 CFR 50.46 LOCA Analysis of Record (AOR) uses 80 % of the prescribed TS SR flow values (2,500 and 8,000 respectively). The calculated TS SR flow rates at the reduced Emergency Diesel Generator minimum steady-state voltage of 4,160 V and 59.8 Hz, when off site power is not available, demonstrate that the ECCS flow rates used in the LOCA analysis are bounding and satisfy SRs 4.5.1.b.1 and 4.5.1.b.2.

The high pressure coolant injection (HPCI) system is provided to assure that the reactor core is adequately cooled to limit fuel clad temperature in the event of a small break in the reactor coolant system and loss of coolant which does not result in rapid depressurization of the reactor vessel. The HPCI system permits the reactor to be shut down while maintaining sufficient reactor vessel water level inventory until the vessel is depressurized. The HCPI system continues to operate until reactor vessel pressure is below the pressure at which CSS operation or LPCI mode of the RHR system operation maintains core cooling.

The capacity of the system is selected to provide the required core cooling. The HPCI pump is designed to deliver greater than or equal to 5600 gpm at reactor pressures between 1182 and 200 psig and is capable of delivering at least 5000 gpm between 1182 and 1205 psig. In the system's normal alignment, water from the condensate storage tank is used instead of injecting water from the suppression pool into the reactor, but no credit is taken in the safety analyses for the condensate storage tank water.

ECCS - OPERATING (Continued)

With the HPCI system inoperable, adequate core cooling is assured by the OPERABILITY of the redundant and diversified automatic depressurization system and both the CS and LPCI systems. In addition, the reactor core isolation cooling (RCIC) system, a system for which no credit is taken in the safety analysis, will automatically provide makeup at reactor operating pressures on a reactor low water level condition. The HPCI out-of-service period of 14 days is based on the demonstrated OPERABILITY of redundant and diversified low pressure core cooling systems and the RCIC system. The HPCI system, and one LPCI subsystem, and/or one CSS subsystem out-of-service period of 8 hours ensures that sufficient ECCS, comprised of a minimum of one CSS subsystem, three LPCI subsystems, and all of the ADS will be available to 1) provide for safe shutdown of the facility, and 2) mitigate and control accident conditions within the facility. Alternatively, the out-of-service times described above can be determined in accordance with the Risk Informed Completion Time Program. A Note prohibits the application of Specification 3.0.4.b to an inoperable HPCI subsystem. There is an increased risk associated with entering an OPERATIONAL CONDITION or other specified condition in the Applicability with an inoperable HPCI subsystem and the provisions of Specification 3.0.4.b, which allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, should not be applied in this circumstance.

The surveillance requirements provide adequate assurance that the HPCI system will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation through a test loop during reactor operation, a complete functional test with reactor vessel injection requires reactor shutdown.

During plant startup, when HPCI surveillance tests are being performed, the HPCI System is required to be tested within 12 hours after reactor pressure is adequate to perform each surveillance test. For the low reactor pressure surveillance requirement, the intent is to verify HPCI System operability prior to increasing reactor pressure above 215 psig. If operability of the HPCI System is not demonstrated within the 12-hour period, reactor steam dome pressure must be reduced to less than 200 psig within the following 72 hours. For the high reactor pressure surveillance test, the intent is to verify HPCI System operability as soon as possible once plant conditions support the testing. Power ascension can continue during the testing; however, if HPCI is found inoperable or the 12-hour period has elapsed power ascension must be stopped, and reactor steam dome pressure must be reduced to less than 200 psig within the following 72 hours.

The ECCS injection/spray subsystem flow path piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the ECCS injection/spray subsystems and may also prevent a water hammer, pump cavitation, and pumping of noncondensible gas into the reactor vessel.

Selection of ECCS injection/spray subsystem locations susceptible to gas accumulation is based on a review of system design information, including piping and instrumentation drawings, isometric drawings, plan and elevation drawings, and calculations. The design review is supplemented by system walk downs to validate the system high points and to confirm the location and orientation of important components that can become sources of gas or could otherwise cause gas to be trapped or difficult to remove during system maintenance or restoration. Susceptible locations depend on plant and system configuration, such as stand-by versus operating conditions.

The ECCS injection/spray subsystem is OPERABLE when it is sufficiently filled with water. Acceptance criteria are established for the volume of accumulated gas at susceptible locations. If accumulated gas is discovered that exceeds the acceptance criteria for the susceptible location (or the volume of accumulated gas at one or more susceptible locations exceeds an acceptance criteria for gas volume at the suction or discharge of a pump), the Surveillance is not met. Accumulated gas should be eliminated or brought within the acceptance criteria limits.

ECCS - OPERATING (Continued)

ECCS injection/spray subsystem locations susceptible to gas accumulation are monitored and, if gas is found, the gas volume is compared to the acceptance criteria for the location. Susceptible locations in the same system flow path which are subject to the same gas intrusion mechanisms may be verified by monitoring a representative subset of susceptible locations. Monitoring may not be practical for locations that are inaccessible due to radiological or environmental conditions, the plant configuration, or personnel safety. For these locations alternative methods (e.g., operating parameters, remote monitoring) may be used to monitor the susceptible location. Monitoring is not required for susceptible locations where the maximum potential accumulated gas void volume has been evaluated and determined to not challenge system OPERABILITY. The accuracy of the method used for monitoring the susceptible locations and trending of the results should be sufficient to assure system OPERABILITY during the Surveillance interval.

Surveillance 4.5.1.a.1.b is modified by a Note which exempts system vent flow paths opened under administrative control. The administrative control should be proceduralized and include stationing a dedicated individual at the system vent flow path who is in continuous communication with the operators in the control room. This individual will have a method to rapidly close the system vent flow path if directed.

Upon failure of the HPCI system to function properly after a small break loss-of-coolant accident, the automatic depressurization system (ADS) automatically causes selected safety/relief valves to open, depressurizing the reactor so that flow from the low pressure core cooling systems can enter the core in time to limit fuel cladding temperature to less than 2200°F. ADS is conservatively required to be OPERABLE whenever reactor vessel pressure exceeds 100 psig. This pressure is substantially below that for which the low pressure core cooling systems can provide adequate core cooling for events requiring ADS.

SR 4.5.1.c.1 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

ADS automatically controls five selected safety-relief valves. The safety analysis assumes all five are operable. The allowed out-of-service time for one valve for up to fourteen days is determined in a similar manner to other ECCS subsystem out-of-service time allowances. Alternatively, the allowed out-of-service time can be determined in accordance with the Risk Informed Completion Time Program.

Verification that ADS accumulator gas supply header pressure is ≥90 psig ensures adequate gas pressure for reliable ADS operation. The accumulator on each ADS valve provides pneumatic pressure for valve actuation. The design pneumatic supply pressure requirements for the accumulator are such that, following a failure of the pneumatic supply to the accumulator at least two valve actuations can occur with the drywell at 70% of design pressure. The ECCS safety analysis assumes only one actuation to achieve the depressurization required for operation of the low pressure ECCS. This minimum required pressure of ≥90 psig is provided by the PCIG supply.

3/4.5.2 - REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC)

Background:

The RPV contains penetrations below the top of the active fuel (TAF) that have the potential to drain the reactor coolant inventory to below the TAF. If the water level should drop below the TAF, the ability to remove decay heat is reduced, which could lead to elevated cladding temperatures and clad perforation. Safety Limit 2.1.4 requires the RPV water level to be above the top of the active irradiated fuel at all times to prevent such elevated cladding temperatures.

Applicable Safety Analysis:

With the unit in OPERATIONAL CONDITION 4 or 5, RPV water inventory control is not required to mitigate any events or accidents evaluated in the safety analyses. RPV water inventory control is required in OPERATIONAL CONDITIONS 4 and 5 to protect Safety Limit 2.1.4 and the fuel cladding barrier to prevent the release of radioactive material to the environment should an unexpected draining event occur.

A double-ended guillotine break of the Reactor Coolant System (RCS) is not considered in OPERATIONAL CONDITIONS 4 and 5 due to the reduced RCS pressure, reduced piping stresses, and ductile piping systems. Instead, an event is considered in which an initiating event allows draining of the RPV water inventory through a single penetration flow path with the highest flow rate, or the sum of the drain rates through multiple penetration flow paths susceptible to a common mode failure (an event that creates a drain path through multiple vessel penetrations located below top of active fuel, such as loss of normal power or a single human error). It is assumed, based on engineering judgement, that while in OPERATIONAL CONDITIONS 4 and 5, one low pressure ECCS injection/spray subsystem can maintain adequate reactor vessel water level.

As discussed in References 1, 2, 3, 4, and 5, operating experience has shown RPV water inventory to be significant to public health and safety. Therefore, RPV Water Inventory Control satisfies Criterion 4 of 10 CFR 50.36(c)(2)(ii).

Limiting Condition for Operation:

The RPV water level must be controlled in OPERATIONAL CONDITIONS 4 and 5 to ensure that if an unexpected draining event should occur, the reactor coolant water level remains above the top of the active irradiated fuel as required by Safety Limit 2.1.4.

The Limiting Condition for Operation (LCO) requires the DRAIN TIME of RPV water inventory to the TAF to be ≥ 36 hours. A DRAIN TIME of 36 hours is considered reasonable to identify and initiate action to mitigate unexpected draining of reactor coolant. An event that could cause loss of RPV water inventory and result in the RPV water level reaching the TAF in greater than 36 hours does not represent a significant challenge to Safety Limit 2.1.4 and can be managed as part of normal plant operation.

One low pressure ECCS injection/spray subsystem is required to be OPERABLE and capable of being manually aligned and started from the control room to provide defense-in-depth should an unexpected draining event occur. OPERABILITY of the ECCS injection/spray subsystem includes any necessary valves, instrumentation, or controls needed to manually align and start the subsystem from the control room. A low pressure ECCS injection/spray subsystem consists of either one Core Spray System (CSS) subsystem or one Low Pressure Coolant Injection (LPCI) subsystem. Each CSS subsystem consists of two motor driven pumps, piping, and valves to transfer water from the suppression pool or condensate storage tank (CST) to the RPV. Each LPCI subsystem consists of one motor driven pump, piping, and valves to transfer water from the suppression pool to the RPV.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The LCO is modified by a note which allows a required LPCI subsystem to be considered OPERABLE during alignment and operation for decay heat removal if capable of being manually realigned (remote or local) to the LPCI mode and is not otherwise inoperable. Alignment and operation for decay heat removal includes when the required RHR pump is not operating or when the system is realigned from or to the RHR shutdown cooling mode. This allowance is necessary since the RHR System may be required to operate in the shutdown cooling mode to remove decay heat and sensible heat from the reactor. Because of the restrictions on DRAIN TIME, sufficient time will be available following an unexpected draining event to manually align and initiate LPCI subsystem operation to maintain RPV water inventory prior to the RPV water level reaching the TAF.

Applicability:

RPV water inventory control is required in OPERATIONAL CONDITIONS 4 and 5. Requirements on water inventory control are contained in LCO 3.3.3.A, REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC) INSTRUMENTATION, and LCO 3.5.2, REACTOR PRESSURE VESSEL (RPV) WATER INVENTORY CONTROL (WIC). RPV water inventory control is required to protect Safety Limit 2.1.4 which is applicable whenever irradiated fuel is in the reactor vessel.

Actions:

Action a. - If none of the required low pressure ECCS injection/spray subsystems are OPERABLE, one subsystem must be restored to OPERABLE status within 4 hours. In this condition, the LCO controls on DRAIN TIME minimize the possibility that an unexpected draining event could necessitate the use of the ECCS injection/spray subsystem; however, the defense-in-depth provided by the ECCS injection/spray subsystem is lost. The 4-hour allowed outage time for restoring the required low pressure ECCS injection/spray subsystem to OPERABLE status is based on engineering judgment that considers the LCO controls on DRAIN TIME and the low probability of an unexpected draining event that would result in loss of RPV water inventory.

If the inoperable ECCS injection/spray subsystem is not restored to OPERABLE status within 4 hours, action must be initiated immediately to establish a method of water injection capable of operating without offsite electrical power. The method of water injection includes the necessary instrumentation and controls, water sources, and pumps and valves needed to add water to the RPV or refueling cavity should an unexpected draining event occur. The method of water injection may be manually initiated and may consist of one or more systems or subsystems, and must be able to access water inventory capable of maintaining the RPV water level above the TAF for $\geq$ 36 hours. If recirculation of injected water would occur, it may be credited in determining the necessary water volume.

Action b. - Deleted

Action c. - With the DRAIN TIME less than 36 hours but greater than or equal to 8 hours, compensatory measures should be taken to ensure the ability to implement mitigating actions should an unexpected draining event occur. Should a draining event lower the reactor coolant level to below the TAF, there is potential for damage to the reactor fuel cladding and release of radioactive material. Additional actions are taken to ensure that radioactive material will be contained, diluted, and processed prior to being released to the environment.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The secondary containment provides a controlled volume in which fission products can be contained, diluted, and processed prior to release to the environment. Verification of the capability to establish SECONDARY CONTAINMENT INTEGRITY in less than the DRAIN TIME is required. The required verification confirms actions to establish SECONDARY CONTAINMENT INTEGRITY are preplanned and necessary materials are available. SECONDARY CONTAINMENT INTEGRITY is considered established when one Standby Gas Treatment (SGT) subsystem is capable of maintaining a negative pressure in the secondary containment with respect to the environment. Verification that SECONDARY CONTAINMENT INTEGRITY can be established must be performed within 4 hours. The required verification is an administrative activity and does not require manipulation or testing of equipment.

Secondary containment penetration flow paths form a part of SECONDARY CONTAINMENT INTEGRITY. Verification of the capability to isolate each secondary containment penetration flow path in less than the DRAIN TIME is required. The required verification confirms actions to isolate secondary containment penetration flow paths are preplanned and necessary materials are available. Power operated valves are not required to receive automatic isolation signals if they can be closed manually within the required time. Verification that secondary containment penetration flow paths can be isolated must be performed within 4 hours. The required verification is an administrative activity and does not require manipulation or testing of equipment.

One SGT subsystem is capable of maintaining the secondary containment at a negative pressure with respect to the environment and filter gaseous releases. Verification of the capability to place one SGT subsystem in operation in less than the DRAIN TIME is required. The required verification confirms actions to place a SGT subsystem in operation are preplanned and necessary materials are available. Verification that a SGT subsystem can be placed in operation must be performed within 4 hours. The required verification is an administrative activity and does not require manipulation or testing of equipment.

Action d. - With the DRAIN TIME less than 8 hours, mitigating actions are implemented in case an unexpected draining event should occur. Note that if the DRAIN TIME is less than 1 hour, the required Action e. to restore DRAIN TIME to 36 hours or greater is also applicable.

Immediate action to establish an additional method of water injection augmenting the ECCS injection/spray subsystem required by the LCO is required. The additional method of water injection includes the necessary instrumentation and controls, water sources, and pumps and valves needed to add water to the RPV or refueling cavity should an unexpected draining event occur. The note states that either the ECCS injection/spray subsystem or the additional method of water injection must be capable of operating without offsite electrical power. The additional method of water injection may be manually initiated and may consist of one or more systems or subsystems. The additional method of water injection must be able to access water inventory capable of being injected to maintain the RPV water level above the TAF for $\geq$ 36 hours. The additional method of water injection and the ECCS injection/spray subsystem may share all or part of the same water sources. If recirculation of injected water would occur, it may be credited in determining the required water volume.

Should a draining event lower the reactor coolant level to below the TAF, there is potential for damage to the reactor fuel cladding and release of radioactive material. Additional actions are taken to ensure that radioactive material will be contained, diluted, and processed prior to being released to the environment.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The secondary containment provides a control volume into which fission products can be contained, diluted, and processed prior to release to the environment. Actions to immediately establish SECONDARY CONTAINMENT INTEGRITY are required. With SECONDARY CONTAINMENT INTEGRITY established, one SGT subsystem is capable of maintaining a negative pressure in the secondary containment with respect to the environment.

The secondary containment penetrations form a part of SECONDARY CONTAINMENT INTEGRITY. Actions to immediately verify that each secondary containment penetration flow path is isolated or to verify that it can be automatically or manually isolated from the control room are required.

One SGT subsystem is capable of maintaining the secondary containment at a negative pressure with respect to the environment and filter gaseous releases. Actions to immediately verify that at least one SGT subsystem is capable of being placed in operation are required. The required verification is an administrative activity and does not require manipulation or testing of equipment.

Action e. - If the ACTIONs and associated allowed outage times are not met or if the DRAIN TIME is less than 1 hour, actions must be initiated immediately to restore the DRAIN TIME to ≥ 36 hours. In this condition, there may be insufficient time to respond to an unexpected draining event to prevent the RPV water inventory from reaching the TAF. Note that ACTIONs are also applicable when DRAIN TIME is less than 1 hour.

Surveillance Requirements:

Surveillance Requirement (SR) 4.5.2.1 verifies that the DRAIN TIME of RPV water inventory to the TAF is ≥ 36 hours. The period of 36 hours is considered reasonable to identify and initiate action to mitigate draining of reactor coolant. Loss of RPV water inventory that would result in the RPV water level reaching the TAF in greater than 36 hours does not represent a significant challenge to Safety Limit 2.1.4 and can be managed as part of normal plant operation.

The definition of DRAIN TIME states that realistic cross-sectional areas and drain rates are used in the calculation. A realistic drain rate may be determined using a single, step-wise, or integrated calculation considering the changing RPV water level during a draining event. For a control rod RPV penetration flow path with the control rod drive mechanism removed and not replaced with a blank flange, the realistic cross-sectional area is based on the control rod blade seated in the control rod guide tube. If the control rod blade will be raised from the penetration to adjust or verify seating of the blade, the exposed cross-sectional area of the RPV penetration flow path is used.

The definition of DRAIN TIME excludes from the calculation those penetration flow paths connected to an intact closed system, or isolated by manual or automatic valves that are closed and administratively controlled, blank flanges, or other devices that prevent flow of reactor coolant through the penetration flow paths. A blank flange or other bolted device must be connected with a sufficient number of bolts to prevent draining. Normal or expected leakage from closed systems or past isolation devices is permitted. Determination that a system is intact and closed or isolated must consider the status of branch lines.

The Residual Heat Removal (RHR) Shutdown Cooling System is only considered an intact closed system when misalignment issues (Reference 6) have been precluded by functional valve interlocks or by isolation devices, such that redirection of RPV water out of an RHR subsystem is precluded. Further, the RHR Shutdown Cooling System is only considered an intact closed system if its controls have not been transferred to Remote Shutdown, which disables the interlocks and isolation signals.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

The exclusion of a single penetration flow path, or multiple penetration flow paths susceptible to a common mode failure, from the determination of DRAIN TIME should consider the effects of temporary alterations in support of maintenance (rigging, scaffolding, temporary shielding, piping plugs, freeze seals, etc.). If reasonable controls are implemented to prevent such temporary alterations from causing a draining event from a closed system or between the RPV and the isolation device, the effect of the temporary alterations on DRAIN TIME need not be considered. Reasonable controls include, but are not limited to, controls consistent with the guidance in NUMARC 93-01, "Industry Guideline for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," Revision 4, NUMARC 91-06, "Guidelines for Industry Actions to Assess Shutdown Management," or commitments to NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants."

TS 4.0.1 requires SRs to be met between performances. Therefore, any changes in plant conditions that would change the DRAIN TIME requires that a new DRAIN TIME be determined.

SRs 4.5.2.2 and 4.5.2.3 - The minimum water level of 16 feet required for the suppression pool is periodically verified to ensure that the suppression pool will provide adequate net positive suction head (NPSH) for the CSS subsystem or LPCI subsystem pumps, recirculation volume, and vortex prevention. With the suppression pool water level less than the required limit, the required ECCS injection/spray subsystem is inoperable unless aligned to an OPERABLE CST.

The required CSS subsystem is OPERABLE if it can take suction from the CST, and the CST water level is sufficient to provide the required NPSH for the CSS pumps. Therefore, a verification that either the suppression pool water level is greater than or equal to 16 feet 0 inches or that a CSS subsystem is aligned to take suction from the CST and the CST contains greater than or equal to 135,000 available gallons of water, equivalent to a level of 29 feet 0 inches, ensures that the CSS subsystem can supply the required makeup water to the RPV.

SR 4.5.2.4 - The flow path piping has the potential to develop voids and pockets of entrained air. Maintaining the pump discharge lines of the required ECCS injection/spray subsystems full of water ensures that the ECCS subsystem will perform properly. This may also prevent a water hammer following an ECCS actuation. One acceptable method of ensuring that the lines are full is to vent at the high points.

SR 4.5.2.5 - DELETED

SR 4.5.2.6 - Verifying that the required ECCS injection/spray subsystem can be manually aligned, and the pump started and operated for at least 10 minutes demonstrates that the subsystem is available to mitigate a draining event. This surveillance requirement is modified by two footnotes. The first states that testing the ECCS injection/spray subsystem may be done through the test return line to avoid overfilling the refueling cavity. The second states that credit for meeting the surveillance requirement may be taken for normal system operation that satisfies the surveillance requirement, such as using the RHR mode of LPCI for greater than or equal to 10 minutes. The minimum operating time of 10 minutes was based on engineering judgement.

SR 4.5.2.7 and 4.5.2.8 exclude automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SRs do not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the applicable SR has been met within its required Frequency.

SR 4.5.2.7 - Verifying that each valve credited for automatically isolating a penetration flow path actuates to the isolation position on an actual or simulated RPV water level isolation signal is required to prevent RPV water inventory from dropping below the TAF should an unexpected draining event occur.

RPV WATER INVENTORY CONTROL (WIC) (Continued)

SR 4.5.2.8 - This surveillance verifies that a required CSS subsystem or LPCI subsystem can be manually aligned and started from the control room, including any necessary valve alignment, instrumentation, or controls, to transfer water from the suppression pool or CST to the RPV.

The Surveillance Frequencies in the above SRs are controlled under the Surveillance Frequency Controlled Program.

3/4.5.3 SUPPRESSION CHAMBER

The suppression chamber is required to be OPERABLE as part of the ECCS to ensure that a sufficient supply of water is available to the HPCI, CS and LPCI systems in the event of a LOCA. This limit on suppression chamber minimum water volume ensures that sufficient water is available to permit recirculation cooling flow to the core. The OPERABILITY of the suppression chamber in OPERATIONAL CONDITION 1, 2, or 3 is also required by Specification 3.6.2.1.

3/4.6.1 PRIMARY CONTAINMENT

3/4.6.1.1 PRIMARY CONTAINMENT INTEGRITY

PRIMARY CONTAINMENT INTEGRITY ensures that the release of radioactive materials from the containment atmosphere will be restricted to those leakage paths and associated leak rates assumed in the safety analyses. This restriction, in conjunction with the leakage rate limitation, will limit the SITE BOUNDARY radiation doses to within the limits of 10 CFR Part 100 during accident conditions.

3/4.6.1.2 PRIMARY CONTAINMENT LEAKAGE

The limitations on primary containment leakage rates ensure that the total containment leakage volume will not exceed the value calculated in the safety analyses at the design basis LOCA maximum peak containment pressure of 44 psig, Pa. As an added conservatism, the measured overall integrated leakage rate (Type A Test) is further limited to less than or equal to 0.75 La during performance of the periodic tests to account for possible degradation of the containment leakage barriers between leakage tests.

Operating experience with the main steam line isolation valves has indicated that degradation has occasionally occurred in the leak tightness of the valves; therefore the special requirement for testing these valves.

The surveillance testing for measuring leakage rates is consistent with the Primary Containment Leakage Rate Testing Program.

Limerick has an approved license amendment to implement 10 CFR 50.69, "Risk-Informed Categorization and Treatment of Structures, Systems and Components for Nuclear Power Reactors", and may voluntarily comply with the treatment requirements of 10 CFR 50.69 as an alternative to compliance with the Type B and Type C leakage testing requirements of 10 CFR 50, Appendix J for Risk-Informed Safety Classification (RISC) RISC-3 or RISC-4 penetrations and valves meeting the following criteria:

A. Containment penetrations that are either 1-inch nominal size or less, or continuously pressurized.
B. Containment isolation valves that meet one or more of the following criteria.
   1. The valve is required to be open under accident conditions to prevent or mitigate core damage events;
   2. The valve is normally closed and in a physically closed, water-filled system;
   3. The valve is in a physically closed system whose piping pressure rating exceeds the containment design pressure rating and is not connected to the reactor coolant pressure boundary; or
   4. The valve is 1-inch nominal size or less.

RISC-3 penetrations and valves that meet the criteria above may be removed from the scope of the Primary Containment Leakage Rate Testing Program, as implemented by Technical Specifications 3.6.1, 4.6.1 and 6.8.4.g. Alternative Treatment will be implemented in accordance with the requirements of 10 CFR 50.69(d).

3/4.6.1.3 PRIMARY CONTAINMENT AIR LOCK

The limitations on closure and leak rate for the primary containment air lock are required to meet the restrictions on PRIMARY CONTAINMENT INTEGRITY and the Primary Containment Leakage Rate Testing Program. Only one closed door in the air lock is required to maintain the integrity of the containment.

3/4.6.1.4 MSIV LEAKAGE ALTERNATE DRAIN PATHWAY

Calculated doses resulting from the maximum leakage allowances for the main steamline isolation valves in the postulated LOCA situations will not exceed the criteria of 10 CFR Part 100 guidelines, provided the main steam line system from the isolation valves up to and including the turbine condenser remains intact. Operating experience has indicated that degradation has occasionally occurred in the leak tightness of the MSIVs such that the specified leakage requirements have not always been continuously maintained. The requirement for the MSIV Leakage Alternate Drain Pathway serves to reduce the offsite dose.

3/4.6.1.5 PRIMARY CONTAINMENT STRUCTURAL INTEGRITY

This limitation ensures that the structural integrity of the containment will be maintained comparable to the original design standards for the life of the unit. Structural integrity is required to ensure that the containment will withstand the maximum calculated pressure in the event of a LOCA. A visual inspection in accordance with the Primary Containment Leakage Rate Testing Program is sufficient to demonstrate this capability.

3/4.6.1.6 DRYWELL AND SUPPRESSION CHAMBER INTERNAL PRESSURE

The limitations on drywell and suppression chamber internal pressure ensure that the calculated containment peak pressure does not exceed the design pressure of 55 psig during LOCA conditions or that the external pressure differential does not exceed the design maximum external pressure differential of 5.0 psid. The limit of - 1.0 to + 2.0 psig for initial containment pressure will limit the total pressure to $\leq$ 44 psig which is less than the design pressure and is consistent with the safety analysis.

3/4.6.1.7 DRYWELL AVERAGE AIR TEMPERATURE

The limitation on drywell average air temperature ensures that the containment peak air temperature does not exceed the design temperature of 340°F during steam line break conditions and is consistent with the safety analysis.

3/4.6.1.8 DRYWELL AND SUPPRESSION CHAMBER PURGE SYSTEM

The drywell and suppression chamber purge supply and exhaust isolation valves are required to be closed during plant operation except as required for inerting, deinerting, pressure control, ALARA or air quality considerations for personnel entry, or Surveillances that require the valves to be open. Limiting the use of the drywell and suppression chamber purge system to specific criteria is imposed to protect the integrity of the SGTS filters. Analysis indicates that should a LOCA occur while this pathway is being utilized, the associated pressure surge through the (18 or 24") purge lines will adversely affect the integrity of SGTS. This condition is not imposed on the 1 and 2 inch valves used for pressure control since a surge through these lines does not threaten the operability of SGTS.

Surveillance requirement 4.6.1.8 ensures that the primary containment purge valves are closed as required or, if open, open for an allowable reason. If a purge valve is open in violation of this SR, the valve is considered inoperable. The SR is modified by a Note stating that primary containment purge valves are only required to be closed in OPERATIONAL CONDITIONS 1, 2 and 3. The SR is also modified by a Note stating that the SR is not required to be met when the purge valves are open for the stated reasons. The Note states that these valves may be opened for inerting, deinerting, pressure control, ALARA or air quality considerations for personnel entry, or Surveillances that require the valves to be open. The 18 or 24 inch purge valves are capable of closing in the environment following a LOCA. Therefore, these valves are allowed to be open for limited periods of time.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.6.2 DEPRESSURIZATION SYSTEMS

The specifications of this section ensure that the primary containment pressure will not exceed the design pressure of 55 psig during primary system blowdown from full operating pressure. Management of gas voids is important to Suppression Pool Cooling/Spray Subsystem OPERABILITY.

The suppression chamber water provides the heat sink for the reactor coolant system energy release following a postulated rupture of the system. The suppression chamber water volume must absorb the associated decay and structural sensible heat released during reactor coolant system blowdown from rated conditions. Since all of the gases in the drywell are purged into the suppression chamber air space during a loss-of-coolant accident, the pressure of the suppression chamber air space must not exceed 55 psig. The design volume of the suppression chamber, water and air, was obtained by considering that the total volume of reactor coolant is discharged to the suppression chamber and that the drywell volume is purged to the suppression chamber.

Using the minimum or maximum water volumes given in this specification, suppression pool pressure during the design basis accident is below the design pressure. Maximum water volume of 134,600 ft^3 results in a downcomer submergence of 12'3" and the minimum volume of 122,120 ft^3 results in a submergence approximately 2'3" less. The majority of the Bodega tests were run with a submerged length of 4 feet and with complete condensation. Thus, with respect to the downcomer submergence, this specification is adequate. The maximum temperature at the end of the blowdown tested during the Humboldt Bay and Bodega Bay tests was 170°F and this is conservatively taken to be the limit for complete condensation of the reactor coolant, although condensation would occur for temperature above 170°F.

Should it be necessary to make the suppression chamber inoperable, this shall only be done as specified in Specification 3.5.3.

Under full power operating conditions, blowdown through safety/relief valves assuming an initial suppression chamber water temperature of 95°F results in a bulk water temperature of approximately 140°F immediately following blowdown which is below the 190°F bulk temperature limit used for complete condensation via T-quencher devices. At this temperature and atmospheric pressure, the available NPSH exceeds that required by both the RHR and core spray pumps, thus there is no dependency on containment overpressure during the accident injection phase. If both RHR loops are used for containment cooling, there is no dependency on containment overpressure for post-LOCA operations.

3/4.6.2 DEPRESSURIZATION SYSTEMS (Continued)

RHR Suppression Pool Cooling/Spray subsystem piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the RHR suppression pool subsystems and may also prevent water hammer and pump cavitation.

Selection of RHR Suppression Pool Cooling/Spray subsystem locations susceptible to gas accumulation is based on a review of system design information, including piping and instrumentation drawings, isometric drawings, plan and elevation drawings, and calculations. The design review is supplemented by system walk downs to validate the system high points and to confirm the location and orientation of important components that can become sources of gas or could otherwise cause gas to be trapped or difficult to remove during system maintenance or restoration. Susceptible locations depend on plant and system configuration, such as stand-by versus operating conditions.

The RHR Suppression Pool Cooling/Spray subsystem is OPERABLE when it is sufficiently filled with water. Acceptance criteria are established for the volume of accumulated gas at susceptible locations. If accumulated gas is discovered that exceeds the acceptance criteria for the susceptible location (or the volume of accumulated gas at one or more susceptible locations exceeds an acceptance criteria for gas volume at the suction or discharge of a pump), the Surveillance is not met. Accumulated gas should be eliminated or brought within the acceptance criteria limits.

RHR Suppression Pool Cooling/Spray subsystem locations susceptible to gas accumulation are monitored and, if gas is found, the gas volume is compared to the acceptance criteria for the location. Susceptible locations in the same system flow path which are subject to the same gas intrusion mechanisms may be verified by monitoring a representative subset of susceptible locations. Monitoring may not be practical for locations that are inaccessible due to radiological or environmental conditions, the plant configuration, or personnel safety. For these locations alternative methods (e.g., operating parameters, remote monitoring) may be used to monitor the susceptible location. Monitoring is not required for susceptible locations where the maximum potential accumulated gas void volume has been evaluated and determined to not challenge system OPERABILITY. The accuracy of the method used for monitoring the susceptible locations and trending of the results should be sufficient to assure system OPERABILITY during the Surveillance interval.

One of the surveillance requirements for the suppression pool cooling (SPC) mode of the RHR system is to demonstrate that each RHR pump develops a flow rate ^{3}10,000 gpm while operating in the SPC mode with flow through the heat exchanger and its associated closed bypass valve, ensuring that pump performance has not degraded during the cycle and that the flow path is operable. This test confirms one point on the pump design curve and is indicative of overall performance. Such inservice inspections confirm component operability, trend performance and detect incipient failures by indicating abnormal performance. The RHR heat exchanger bypass valve is used for adjusting flow through the heat exchanger, and is not designed to be a tight shut-off valve. With the bypass valve closed, a portion of the total flow still travels through the bypass, which

3/4.6.2 DEPRESSURIZATION SYSTEMS (Continued)

can affect overall heat transfer. However, no heat transfer performance requirement of the heat exchanger is intended by the current Technical Specification surveillance requirement. This is confirmed by the lack of any flow requirement for the RHRSW system in Technical Specifications Section 3/4.7.1. Verifying an RHR flowrate through the heat exchanger does not demonstrate heat removal capability in the absence of a requirement for RHRSW flow. LGS does perform heat transfer testing of the RHR heat exchangers as part of its response to Generic Letter 89-13, which verified the commitment to meet the requirements of GDC 46.

Experimental data indicate that excessive steam condensing loads can be avoided if the peak local temperature of the suppression pool is maintained below 200°F during any period of relief valve operation for T-quencher devices. Specifications have been placed on the envelope of reactor operating conditions so that the reactor can be depressurized in a timely manner to avoid the regime of potentially high suppression chamber loadings.

Because of the large volume and thermal capacity of the suppression pool, the volume and temperature normally changes very slowly and monitoring these parameters daily is sufficient to establish any temperature trends. By requiring the suppression pool temperature to be frequently recorded during periods of significant heat addition, the temperature trends will be closely followed so that appropriate action can be taken.

In addition to the limits on temperature of the suppression chamber pool water, operating procedures define the action to be taken in the event a safety-relief valve inadvertently opens or sticks open. As a minimum this action shall include: (1) use of all available means to close the valve, (2) initiate suppression pool water cooling, (3) initiate reactor shutdown, and (4) if other safety-relief valves are used to depressurize the reactor, their discharge shall be separated from that of the stuck-open safety/relief valve to assure mixing and uniformity of energy insertion to the pool.

During a LOCA, potential leak paths between the drywell and suppression chamber airspace could result in excessive containment pressures, since the steam flow into the airspace would bypass the heat sink capabilities of the chamber. Potential sources of bypass leakage are the suppression chamber-to-drywell vacuum breakers (VBs), penetrations in the diaphragm floor, and cracks in the diaphragm floor and/or liner plate and downcomers located in the suppression chamber airspace. The containment pressure response to the postulated bypass leakage can be mitigated by manually actuating the suppression chamber sprays. An analysis was performed for a design bypass leakage area of $A/\sqrt{k}$ equal to 0.0500 ft^2 to verify that the operator has sufficient time to initiate the sprays prior to exceeding the containment design pressure of 55 psig. The limit of 10% of the design value of 0.0500 ft^2 ensures that the design basis for the steam bypass analysis is met

THIS PAGE INTENTIONALLY LEFT BLANK

DEPRESSURIZATION SYSTEMS (Continued)

The drywell-to-suppression chamber bypass test at a differential pressure of at least 4.0 psi verifies the overall bypass leakage area for simulated LOCA conditions is less than the specified limit. For those outages where the drywell-to-suppression chamber bypass leakage test in not conducted, the VB leakage test verifies that the VB leakage area is less than the bypass limit, with a 76% margin to the bypass limit to accommodate the remaining potential leakage area through the passive structural components. Previous drywell-to-suppression chamber bypass test data indicates that the bypass leakage through the passive structural components will be much less than the 76% margin. The VB leakage limit, combined with the negligible passive structural leakage area, ensures that the drywell-to-suppression chamber bypass leakage limit is met for those outages for which the drywell-to-suppression chamber bypass test is not scheduled.

3/4.6.3 PRIMARY CONTAINMENT ISOLATION VALVES

The OPERABILITY of the primary containment isolation valves ensures that the containment atmosphere will be isolated from the outside environment in the event of a release of radioactive material to the containment atmosphere or pressurization of the containment and is consistent with the requirements of GDC 54 through 57 of Appendix A of 10 CFR Part 50. Containment isolation within the time limits specified for those isolation valves designed to close automatically ensures that the release of radioactive material to the environment will be consistent with the assumptions used in the analyses for a LOCA.

The scram discharge volume vent and drain valves serve a dual function, one of which is primary containment isolation. Since the other safety functions of the scram discharge volume vent and drain valves would not be available if the normal PCIV actions were taken, actions are provided to direct the user to the scram discharge volume vent and drain operability requirements contained in Specification 3.1.3.1. However, since the scram discharge volume vent and drain valves are PCIVs, the Surveillance Requirements of Specification 4.6.3 still apply to these valves.

The opening of a containment isolation valve that was locked or sealed closed to satisfy Technical Specification 3.6.3 Action statements, may be reopened on an intermittent basis under administrative controls. These controls consist of stationing a dedicated individual at the controls of the valve, who is in continuous communication with the control room. In this way, the penetration can be rapidly isolated when a need for primary containment isolation is indicated.

Primary containment isolation valves governed by this Technical Specification are identified in Table 3.6.3-1 of the TRM.

This Surveillance Requirement requires a demonstration that a representative sample of reactor instrument line excess flow check valves (EFCVs) is OPERABLE by verifying that the valve actuates to the isolation position on a simulated instrument line break signal. The representative sample consists of an approximately equal number of EFCVs, such that each EFCV is tested in accordance with the Surveillance Frequency Control Program. In addition, the EFCVs in the sample are representative of the various plant configurations, models, sizes, and operating environments. This ensures that any potentially common problem with a specific type or application of EFCV is detected at the earliest possible time. This Surveillance Requirement provides assurance that the instrumentation line EFCVs will perform so that predicted radiological consequences will not be exceeded during a postulated instrument line break event. Furthermore, any EFCV failures will be evaluated to determine if additional testing in the test interval is warranted to ensure overall reliability is maintained. Operating experience has demonstrated that these components are highly reliable and that failures to isolate are very infrequent. Therefore, testing of a representative sample was concluded to be acceptable from a reliability standpoint. For some EFCVs, this Surveillance can be performed with the reactor at power.

3/4.6.4 VACUUM RELIEF

Vacuum relief valves are provided to equalize the pressure between the suppression chamber and drywell. This system will maintain the structural integrity of the primary containment under conditions of large differential pressures.

The vacuum breakers between the suppression chamber and the drywell must not be inoperable in the open position since this would allow bypassing of the suppression pool in case of an accident. Two pairs of valves are required to protect containment structural integrity. There are four pairs of valves (three to provide minimum redundancy) so that operation may continue for up to 72 hours or in accordance with the Risk Informed Completion Time Program with no more than two pairs of vacuum breakers inoperable in the closed position.

Each vacuum breaker valve's position indication system is of great enough sensitivity to ensure that the maximum steam bypass leakage coefficient of

$$\frac{A}{\sqrt{k}} = 0.05 \text{ ft}^2$$

for the vacuum relief system (assuming one valve fully open) will not be exceeded.

3/4.6.5 SECONDARY CONTAINMENT

Secondary containment is designed to minimize any ground level release of radioactive material which may result from an accident. The Reactor Enclosure and associated structures provide secondary containment during normal operation when the drywell is sealed and in service. At other times the drywell may be open and, when required, secondary containment integrity is specified.

Establishing and maintaining a vacuum in the reactor enclosure secondary containment with the standby gas treatment system in accordance with the Surveillance Frequency Control Program, along with the surveillance of the doors, hatches, dampers and valves, is adequate to ensure that there are no violations of the integrity of the secondary containment.

The OPERABILITY of the reactor enclosure recirculation system and the standby gas treatment systems ensures that sufficient iodine removal capability will be available in the event of a LOCA. The reduction in containment iodine inventory reduces the resulting SITE BOUNDARY and Control Room radiation doses associated with containment leakage. The operation of these systems and resultant iodine removal capacity are consistent with the assumptions used in the LOCA analysis. Provisions have been made to continuously purge the filter plenums with instrument air when the filters are not in use to prevent buildup of moisture on the adsorbers and the HEPA filters.

As a result of the Alternative Source Term (AST) project, secondary containment integrity of the refueling area is not required during certain conditions when handling irradiated fuel or during CORE ALTERATIONS and alignment of the Standby Gas Treatment System to the refueling area is not required. The control room dose analysis for the Fuel Handling Accident (FHA) is based on unfiltered releases from the South Stack and therefore, does not require the Standby Gas Treatment System to be aligned to the refueling area.

However, when handling RECENTLY IRRADIATED FUEL, secondary containment integrity of the refueling area is required and alignment of the Standby Gas Treatment System to the refueling area is required. The AST fuel handling analysis does not include an accident involving RECENTLY IRRADIATED FUEL or an accident involving draining the reactor vessel.

The Standby Gas Treatment System is required to be OPERABLE when handling irradiated fuel, handling RECENTLY IRRADIATED FUEL and during CORE ALTERATIONS. Fuel Handling Accident releases from the North Stack must be filtered through the Standby Gas Treatment System to maintain control room doses within regulatory limits. The OPERABILITY of the Standby Gas Treatment System assures that releases, if made through the North Stack, are filtered prior to release.

SECONDARY CONTAINMENT (Continued)

Surveillances 4.6.5.1.1.a and 4.6.5.1.2.a are each modified by a footnote (*) which states the surveillance is not required to be met for up to 4 hours if an analysis demonstrates that one standby gas treatment subsystem remains capable of establishing the required secondary containment vacuum. Use of the footnote is expected to be infrequent but may be necessitated by situations in which secondary containment vacuum may be less than the required containment vacuum, such as, but not limited to, wind gusts or failure or change of operating normal ventilation subsystems. These conditions do not indicate any change in the leak tightness of the secondary containment boundary. The analysis should consider the actual conditions (equipment configuration, temperature, atmospheric pressure, wind conditions, measured secondary containment vacuum, etc.) to determine whether, if an accident requiring secondary containment to be OPERABLE were to occur, one train of standby gas treatment could establish the assumed secondary containment vacuum within the time assumed in the accident analysis. If so, the surveillance may be considered met for a period up to 4 hours. The 4-hour limit is based on the expected short duration of the situations when the footnote would be applied.

Surveillances 4.6.5.1.1.b.2 and 4.6.5.1.2.b.2 require verifying that one secondary containment personnel access door in each access opening is closed which provides adequate assurance that exfiltration from the secondary containment will not occur. An access opening contains at least one inner and one outer door. The intent is to not breach the secondary containment, which is achieved by maintaining the inner or outer personnel access door closed. Surveillances 4.6.5.1.1.b.2 and 4.6.5.1.2.b.2 provide an allowance for brief, inadvertent, simultaneous openings of redundant secondary containment personnel access doors for normal entry and exit conditions.

SR 4.6.5.3.d.2 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

Although the safety analyses assumes that the reactor enclosure secondary containment draw down time will take 930 seconds, these surveillance requirements specify a draw down time of 916 seconds. This 14 second difference is due to the diesel generator starting and sequence loading delays which is not part of this surveillance requirement.

The reactor enclosure secondary containment draw down time analyses assumes a starting point of 0.25 inch of vacuum water gauge and worst case SGTS dirty filter flow rate of 2800 cfm. The surveillance requirements satisfy this assumption by starting the drawdown from ambient conditions and connecting the adjacent reactor enclosure and refueling area to the SGTS to split the exhaust flow between the three zones and verifying a minimum flow rate of 2800 cfm from the test zone. This simulates the worst case flow alignment and verifies adequate flow is available to drawdown the test zone within the required time. The Technical Specification Surveillance Requirement 4.6.5.3.b.3 is intended to be a multi-zone air balance verification without isolating any test zone.

The SGTS is common to Unit 1 and 2 and consists of two independent subsystems. The power supplies for the common portions of the subsystems are from Unit 1 safeguard busses, therefore the inoperability of these Unit 1 supplies are addressed in the SGTS ACTION statements in order to ensure adequate onsite power sources to SGTS for its Unit 2 function during a loss of offsite power event. The allowable out of service times are consistent with those in the Unit 1 Technical Specifications for SGTS and AC electrical power supply out of service condition combinations.

SECONDARY CONTAINMENT (Continued)

The SGTS fans are sized for three zones and therefore, when aligned to a single zone or two zones, will have excess capacity to more quickly drawdown the affected zones. There is no maximum flow limit to individual zones or pairs of zones and the air balance and drawdown time are verified when all three zones are connected to the SGTS.

The three zone air balance verification and drawdown test will be done after any major system alteration, which is any modification which will have an effect on the SGTS flowrate such that the ability of the SGTS to drawdown the reactor enclosure to greater than or equal to 0.25 inch of vacuum water gage in less than or equal to 916 seconds could be affected.

The field tests for bypass leakage across the SGTS charcoal adsorber and HEPA filter banks are performed at a flow rate of 5764 ± 10% cfm. The laboratory analysis performed on the SGTS carbon samples will be tested at a velocity of 66 fpm based on the system residence time.

The SGTS filter train pressure drop is a function of air flow rate and filter conditions. Surveillance testing is performed using either the SGTS or drywell purge fans to provide operating convenience.

Each reactor enclosure secondary containment zone and refueling area secondary containment zone is tested independently to verify the design leak tightness. A design leak tightness of 2500 cfm or less for each reactor enclosure and 764 cfm or less for the refueling area at a 0.25 inch of vacuum water gage will ensure that containment integrity is maintained at an acceptable level if all zones are connected to the SGTS at the same time.

SR 4.6.5.4.d.2 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

The Reactor Enclosure Secondary Containment Automatic Isolation Valves and Refueling Area Secondary Containment Automatic Isolation Valves can be found in the UFSAR.

The post-LOCA offsite dose analysis assumes a reactor enclosure secondary containment post-draw down leakage rate of 2500 cfm and certain post-accident X/Q values. While the post-accident X/Q values represent a statistical interpretation of historical meteorological data, the highest ground level wind speed which can be associated with these values is 7 mph (Pasquill-Gifford stability Class G for a ground level release). Therefore, the surveillance requirement assures that the reactor enclosure secondary containment is verified under meteorological conditions consistent with the assumptions utilized in the design basis analysis. Reactor Enclosure Secondary Containment leakage tests that are successfully performed at wind speeds in excess of 7 mph would also satisfy the leak rate surveillance requirements, since it shows compliance with more conservative test conditions.

3/4.6.6 PRIMARY CONTAINMENT ATMOSPHERE CONTROL

The primary containment atmospheric mixing system is provided to ensure adequate mixing of the containment atmosphere to prevent localized accumulations of hydrogen and oxygen from exceeding the lower flammability limit during post-LOCA conditions.

All nuclear reactors must be designed to withstand events that generate hydrogen either due to the zirconium metal water reaction in the core or due to radiolysis. The primary method to control hydrogen is to inert the primary containment. With the primary containment inert, that is, oxygen concentration <4.0 volume percent (v/o), a combustible mixture cannot be present in the primary containment for any hydrogen concentration. The capability to inert the primary containment and maintain oxygen <4.0 v/o works together with Drywell Hydrogen Mixing System to provide redundant and diverse methods to mitigate events that produce hydrogen.

If oxygen concentration is ≥ 4.0 v/o at any time while operating in OPERATIONAL CONDITION 1 or 2, oxygen concentration must be restored to < 4.0 v/o within 72 hours. The 72 hour Completion Time is allowed when oxygen concentration is ≥ 4.0 v/o because of the low probability and long duration of an event that would generate significant amounts of hydrogen occurring during this period.

The provision of Specification 3.0.4.c is applicable. This allowance permits entry into the applicable OPERATIONAL CONDITION(S) while relying on the Actions. This allowance is acceptable because inerting the primary containment prevents containment access without an appropriate breathing apparatus. Therefore, the primary containment is inerted as late as possible in the plant startup, after entering OPERATIONAL CONDITIONS 1 and 2, and deinerted as soon as possible in the plant shutdown. It is acceptable to intentionally enter the Action prior to a shutdown in order to begin deinerting the primary containment prior to exiting the Applicability.

If oxygen concentration cannot be restored to within the limit within the required Completion Time, the plant must be brought to a OPERATIONAL CONDITION in which the LCO does not apply. To achieve this status, power must be reduced to HOT SHUTDOWN within 12 hours. The 12 hour Completion Time is reasonable, based on operating experience, to reduce reactor power from full power conditions in an orderly manner and without challenging plant systems.

3/4.7.1 SERVICE WATER SYSTEMS - COMMON SYSTEMS

The OPERABILITY of the service water systems ensures that sufficient cooling capacity is available for continued operation of safety-related equipment during normal and accident conditions. The redundant cooling capacity of these systems, assuming a single failure, is consistent with the assumptions used in the accident conditions within acceptable limits.

The RHRSW and ESW systems are common to Units 1 and 2 and consist of two independent subsystems each with two pumps. One pump per subsystem (loop) is powered from a Unit 1 safeguard bus and the other pump is powered from a Unit 2 safeguard bus. In order to ensure adequate onsite power sources to the systems during a loss of offsite power event, the inoperability of these supplies are restricted in system ACTION statements.

RHRSW is a manually operated system used for core and containment heat removal. Each of two RHRSW subsystems has one heat exchanger per unit. Each RHRSW pump provides adequate cooling for one RHR heat exchanger. By limiting operation with less than three OPERABLE RHRSW pumps with OPERABLE Diesel Generators, each unit is ensured adequate heat removal capability for the design scenario of LOCA/LOOP on one unit and simultaneous safe shutdown of the other unit.

Each ESW pump provides adequate flow to the cooling loads in its associated loop. With only two divisions of power required for LOCA mitigation of one unit and one division of power required for safe shutdown of the other unit, one ESW pump provides sufficient capacity to fulfill design requirements. ESW pumps are automatically started upon start of the associated Diesel Generators. Therefore, the allowable out of service times for OPERABLE ESW pumps and their associated Diesel Generators is limited to ensure adequate cooling during a loss of offsite power event. Alternatively, the allowable out-of-service times can be determined in accordance with the Risk Informed Completion Time Program.

SR 4.7.1.2.b.1 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

3/4.7.2.1 CONTROL ROOM EMERGENCY FRESH AIR SUPPLY SYSTEM - COMMON SYSTEM

The OPERABILITY of the control room emergency fresh air supply system ensures that the control room will remain habitable for occupants during and following an uncontrolled release of radioactivity, hazardous chemicals, or smoke. Constant purge of the system at 1 cfm is sufficient to reduce the buildup of moisture on the adsorbers and HEPA filters. The OPERABILITY of this system in conjunction with control room design provisions is based on limiting the radiation exposure to personnel occupying the control room to 5 rem or less Total Effective Dose Equivalent. This limitation is consistent with the requirements of 10 CFR Part 50.67, Accident Source Term.

Each CREFAS subsystem is considered OPERABLE when the individual components necessary to limit Control Room Envelope occupant exposure are OPERABLE. A subsystem is considered OPERABLE when its associated:

a. CREFAS fan is OPERABLE, and

b. HEPA filter and charcoal adsorbers are capable of performing their filtration functions, and

c. Heater, ductwork, dampers, controls, and power are OPERABLE, and air circulation to the occupied areas can be maintained. Air circulation is a support system function provided by one control room AC supply fan and one control room AC return air fan, and

d. CRE boundary is OPERABLE.

Since the Control Room Emergency Fresh Air Supply System is not credited for filtration in OPERATIONAL CONDITIONS 4 and 5, applicability to 4 and 5 is only required to support the Chlorine and Toxic Gas design basis isolation requirements.

The CREFAS is common to Units 1 and 2 and consists of two independent subsystems. The power supplies for the system are from Unit 1 Safeguard busses, therefore, the inoperability of these Unit 1 supplies are addressed in the CREFAS ACTION statements in order to ensure adequate onsite power sources to CREFAS during a loss of offsite power event. The allowable out of service

3/4.7.2.1 CONTROL ROOM EMERGENCY FRESH AIR SUPPLY SYSTEM - COMMON SYSTEM (Continued)

times are consistent with those in the Unit 1 Technical Specifications for CREFAS and AC electrical power supply out of service condition combinations.

The Control Room Envelope (CRE) is the area within the confines of the CRE boundary that contains the spaces that control room occupants inhabit to control the unit during normal and accident conditions. This area encompasses the control room, and other noncritical areas including adjacent support offices, toilet and utility rooms. The CRE is protected during normal operation, natural events, and accident conditions. The CRE boundary is the combination of walls, floor, ceiling, ducting, valves, doors, penetrations and equipment that physically form the CRE. The OPERABILITY of the CRE boundary must be maintained to ensure that the inleakage of unfiltered air into the CRE will not exceed the inleakage assumed in the licensing basis analysis of design basis accident (DBA) consequences to CRE occupants. The CRE and its boundary are defined in the Control Room Envelope Habitability Program.

In addition, the CREFAS System provides protection from radiation, smoke and hazardous chemicals to the CRE occupants. The analysis of hazardous chemical releases demonstrates that the toxicity limits are not exceeded in the CRE following a hazardous chemical release (Ref. 1). The evaluation of a smoke challenge demonstrates that it will not result in the inability of the CRE occupants to control the reactor either from the control room or from the remote shutdown panels (Ref. 2).

In order for the CREFAS subsystems to be considered OPERABLE, the CRE boundary must be maintained such that the CRE occupant dose from a large radioactive release does not exceed the calculated dose in the licensing basis consequence analyses for DBAs, and that CRE occupants are protected from hazardous chemicals and smoke.

The LCO is modified by a Note allowing the CRE boundary to be opened intermittently under administrative controls. This Note only applies to openings in the CRE boundary that can be rapidly restored to the design condition, such as doors, hatches, floor plugs, and access panels. For entry and exit through doors, the administrative control of the opening is performed by the person(s) entering or exiting the area. For other openings, these controls should be proceduralized and consist of stationing a dedicated individual at the opening who is in continuous communication with the operators in the CRE. This individual will have a method to rapidly close the opening and to restore the CRE boundary to a condition equivalent to the design condition when a need for CRE isolation is indicated.

If the unfiltered inleakage of potentially contaminated air past the CRE boundary and into the CRE can result in CRE occupant radiological dose greater than the calculated dose of the licensing basis analyses of DBA consequences (allowed to be up to 5 rem TEDE), or inadequate protection of CRE occupants from hazardous chemicals or smoke, the CRE boundary is inoperable. Actions must be taken to restore an OPERABLE CRE boundary within 90 days.

3/4.7.2.1 CONTROL ROOM EMERGENCY FRESH AIR SUPPLY SYSTEM - COMMON SYSTEM (Continued)

During the period that the CRE boundary is considered inoperable, action must be initiated immediately to implement mitigating actions to lessen the effect on CRE occupants from the potential hazards of a radiological or chemical event or a challenge from smoke. Actions must be taken within 24 hours to verify that in the event of a DBA, the mitigating actions will ensure that CRE occupant radiological exposures will not exceed the calculated dose of the licensing basis analyses of DBA consequences, and that CRE occupants are protected from hazardous chemicals and smoke. These mitigating actions (i.e., actions that are taken to offset the consequences of the inoperable CRE boundary) should be preplanned for implementation upon entry into the condition, regardless of whether entry is intentional or unintentional. The 24 hour Completion Time is reasonable based on the low probability of a DBA occurring during this time period, and the use of mitigating actions. The 90 day Completion Time is reasonable based on the determination that the mitigating actions will ensure protection of CRE occupants within analyzed limits while limiting the probability that CRE occupants will have to implement protective measures that may adversely affect their ability to control the reactor and maintain it in a safe shutdown condition in the event of a DBA. In addition, the 90 day Completion Time is a reasonable time to diagnose, plan and possibly repair, and test most problems with the CRE boundary.

SR 4.7.2.2 verifies the OPERABILITY of the CRE boundary by testing for unfiltered air inleakage past the CRE boundary and into the CRE. The details of the testing are specified in the Control Room Envelope Habitability Program.

The CRE is considered habitable when the radiological dose to CRE occupants calculated in the licensing basis analyses of DBA consequences is no more than 5 rem Total Effective Dose Equivalent and the CRE occupants are protected from hazardous chemicals and smoke. SR 4.7.2.2 verifies that the unfiltered air inleakage into the CRE is no greater than the flow rate assumed in the licensing basis analyses of DBA consequences. When unfiltered air inleakage is greater than the assumed flow rate, Required Action 3.7.2.a.2 must be entered. Required Action 3.7.2.a.2.c allows time to restore the CRE boundary to OPERABLE status provided mitigating actions can ensure that the CRE remains within the licensing basis habitability limits for the occupants following an accident. Compensatory measures are discussed in Regulatory Guide 1.196, Section C.2.7.3, (Ref. 3) which endorses, with exceptions, NEI 99-03, Section 8.4 and Appendix F (Ref. 4). These compensatory measures may also be used as mitigating actions as required by Required Action 3.7.2.a.2.b. Temporary analytical methods may also be used as compensatory measures to restore OPERABILITY (Ref. 5). Options for restoring the CRE boundary to OPERABLE status include changing the licensing basis DBA consequence analysis, repairing the CRE boundary, or a combination of these actions. Depending upon the nature of the problem and the corrective action, a full scope inleakage test may not be necessary to establish that the CRE boundary has been restored to OPERABLE status.

3/4.7.2.2 CONTROL ROOM AIR CONDITIONING (AC) SYSTEM - COMMON SYSTEM

Each MCR AC subsystem is considered operable when the individual components necessary to maintain the control room temperature are functional. Each subsystem includes a supply fan, a return air fan, associated ductwork, dampers, centrifugal water chiller, a chilled water circulating pump, MCR cooling coil, controls, power, piping, and valves. One control room supply fan and one control room return air fan and their associated ductwork, CREFAS subsystem function by providing a flow path to and from the control room whenever CREFAS is operating.

If both chillers or subsystems become inoperative and main control room temperature remains less than 90°F WBGT, 72-hours is permitted to restore one chiller/subsystem provided control room temperature is monitored once per 4 hours to ensure that temperature is monitored that occupants and equipment in the control room are not adversely affected. This repair time duration is reasonable considering that the control room temperature is being maintained within allowable limits and the low probability of an event occurring requiring control room isolation.

The main control room purge mod of operation, and any other viable supplemental cooling options (portable cooling, fans, opening doors, etc.) can be utilized if both chillers or subsystems are inoperative. A concurrent design basis event is not postulated while in the complete loss of cooling LCO to support supplemental cooling, as required, in order to maintain main control room temperature less than 90°F WBGT. This is based upon the low probability of a concurrent event occurring while in the 72-hour LCO that requires MCR isolation.

Temporary DWCW to CECW crosstie jumpers can also be utilized as a viable supplemental cooling option, but it requires a HELB door between the Turbine Enclosure and Control Enclosure to be breached (blocked open) while only in the 72-hour complete loss of cooling LCO. It is permitted to breach the subject HELB door for supplemental cooling jumper use although it impacts several multi-train TS systems and creates a loss of function situation which is not permitted under TS 3.0.9 if a HELB occurred. CREFAS, SGT, and EDGs (required for DBA accident mitigation) all constitute loss of function situations.

The safety related SSCs protected by the breached HELB door to solely facilitate utilizing the CECW to DWCW- crosstie cooling jumpers are not required to be declared inoperable while in the complete loss of CECW cooling 72-hour LCO.

The justification for this request was (1) the low probability of HELB occurring while in the LCO and (2) the ability to realistic detect a turbine enclosure high energy line leak far prior to a break occurring. The caveat for breaching the HELB door for this supplemental cooling provision is to confirm that a main steam line or feedwater high energy line leak is nonexistent. With this basis, safety related equipment in Control Enclosure room 619 would not be exposed to any post HELB environmental conditions that could compromise equipment functionality while only in the 72-hour complete loss of cooling dual unit LCO. Notwithstanding the above justification, if a postulated HELB occurred with the HELB door breached, while in the LCO, the ability to mitigate the consequences of a HELB are still maintained and plant safe shutdown can be achieved by using a preexisting fire safe shutdown strategy.

A list of impacted Tech. Spec. SSCs protected by the breached HELB door are provided below:

- Unit 1 and 2 SGT TS 3.6.5.3, 3.0.3 dual unit shutdown
- Unit 1 and 2 CREFAS TS 3.7.2.1, 3.0.3 dual unit shutdown
- Unit 1 RERS TS 3.6.5.4, 12-hour shutdown
- Unit 1 EDG Power TS 3.8.1.1 (3 inoperable EDGs), 2-hour action
- Unit 2 2B RERS, TS 3.6.5.4 7 day LCO
- Unit 2 EDG Power TS 3.8.1.1 (2 inoperable EDGs), 72-hour LCO

3/4.7.2.2 CONTROL ROOM AIR CONDITIONING (AC) SYSTEM - COMMON SYSTEM (Continued)

The MCR AC periodic surveillance requirement verifies that the system is Capable of removing the control room design basis heat loads.

- When handling RECENTLY IRRADIATED FUEL, a fuel handling accident is postulated and therefore it is appropriate to suspend movement of RECENTLY IRRADIATED FUEL.

3/4.7.3 REACTOR CORE ISOLATION COOLING SYSTEM

The reactor core isolation cooling (RCIC) system is provided to assure adequate core cooling in the event of reactor isolation from its primary heat sink and the loss of feedwater flow to the reactor vessel without requiring actuation of any of the emergency core cooling system equipment. The RCIC system is conservatively required to be OPERABLE whenever reactor pressure ex-ceeds 150 psig. This pressure is substantially below that for which low pressure core cooling systems can provide adequate core cooling. Management of gas voids is important to RCIC System OPERABILITY.

The RCIC system specifications are applicable during OPERATIONAL CONDITIONS 1, 2, and 3 when reactor vessel pressure exceeds 150 psig because RCIC is the primary non-ECCS source of emergency core cooling when the reactor is pressurized.

With the RCIC system inoperable, adequate core cooling is assured by the OPERABILITY of the HPCI system and justifies the specified 14 day out-of-service period. Alternatively, out-of-service time can be determined in accordance with the Risk Informed Completion Time Program. A Note prohibits the application of Specification 3.0.4.b to an inoperable RCIC system. There is an increased risk associated with entering an OPERATIONAL CONDITION or other specified condition in the Applicability with an inoperable RCIC subsystem and the provisions of Specification 3.0.4.b, which allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, should not be applied in this circumstance.

The surveillance requirements provide adequate assurance that RCIC will be OPERABLE when required. Although all active components are testable and full flow can be demonstrated by recirculation during reactor operation, a complete functional test requires reactor shutdown.

During plant startup, when RCIC surveillance tests are being performed, the RCIC System is required to be tested within 12 hours after reactor pressure is adequate to perform each surveillance test. For the low reactor pressure surveillance requirement, the intent is to verify RCIC System operability prior to increasing reactor pressure above 165 psig. If operability of the RCIC System is not demonstrated within the 12-hour period, reactor steam dome pressure must be reduced to less than 150 psig within the following 72 hours. For the high reactor pressure surveillance test, the intent is to verify RCIC System operability as soon as possible once plant conditions support the testing. Power ascension can continue during the testing; however, if RCIC is found inoperable or the 12-hour period has elapsed power ascension must be stopped, and reactor steam dome pressure must be reduced to less than 150 psig within the following 72 hours.

3/4.7.3 REACTOR CORE ISOLATION COOLING SYSTEM (Continued)

The RCIC System flow path piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the required RCIC System and may also prevent water hammer, pump cavitation, and pumping of noncondensible gas into the reactor vessel.

Selection of RCIC System locations susceptible to gas accumulation is based on a review of system design information, including piping and instrumentation drawings, isometric drawings, plan and elevation drawings, and calculations. The design review is supplemented by system walk downs to validate the system high points and to confirm the location and orientation of important components that can become sources of gas or could otherwise cause gas to be trapped or difficult to remove during system maintenance or restoration. Susceptible locations depend on plant and system configuration, such as stand-by versus operating conditions.

The RCIC System is OPERABLE when it is sufficiently filled with water. Acceptance criteria are established for the volume of accumulated gas at susceptible locations. If accumulated gas is discovered that exceeds the acceptance criteria for the susceptible location (or the volume of accumulated gas at one or more susceptible locations exceeds an acceptance criteria for gas volume at the suction or discharge of a pump), the Surveillance is not met. Accumulated gas should be eliminated or brought within the acceptance criteria limits.

RCIC System locations susceptible to gas accumulation are monitored and, if gas is found, the gas volume is compared to the acceptance criteria for the location. Susceptible locations in the same system flow path which are subject to the same gas intrusion mechanisms may be verified by monitoring a representative subset of susceptible locations. Monitoring may not be practical for locations that are inaccessible due to radiological or environmental conditions, the plant configuration, or personnel safety. For these locations alternative methods (e.g., operating parameters, remote monitoring) may be used to monitor the susceptible location. Monitoring is not required for susceptible locations where the maximum potential accumulated gas void volume has been evaluated and determined to not challenge system OPERABILITY. The accuracy of the method used for monitoring the susceptible locations and trending of the results should be sufficient to assure system OPERABILITY during the Surveillance interval.

Surveillance 4.7.3.a.2 is modified by a Note which exempts system vent flow paths opened under administrative control. The administrative control should be proceduralized and include stationing a dedicated individual at the system vent flow path who is in continuous communication with the operators in the control room. This individual will have a method to rapidly close the system vent flow path if directed.

SR 4.7.3.c.1 excludes automatic dampers and valves that are locked, sealed, or otherwise secured in the actuated position. The SR does not apply to dampers or valves that are locked, sealed, or otherwise secured in the actuated position since the affected dampers or valves were verified to be in the actuated position prior to being locked, sealed, or otherwise secured. Placing an automatic valve or damper in a locked, sealed, or otherwise secured position requires an assessment of the operability of the system or any supported systems, including whether it is necessary for the valve or damper to be repositioned to the non-actuated position to support the accident analysis. Restoration of an automatic valve or damper to the non-actuated position requires verification that the SR has been met within its required Frequency.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.7.4 DELETED

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.7.5 SEALED SOURCE CONTAMINATION

The limitations on removable contamination for sources requiring leak testing, including alpha emitters, is based on 10 CFR 70.39(c) limits for plutonium. This limitation will ensure that leakage from byproduct, source, and special nuclear material sources will not exceed allowable intake values. Sealed sources are classified into three groups according to their use, with surveillance requirements commensurate with the probability of damage to a source in that group. Those sources which are frequently handled are required to be tested more often than those which are not. Sealed sources which are continuously enclosed within a shielded mechanism, i.e,, sealed sources within radiation monitoring devices, are considered to be stored and need not be tested unless they are removed from the shielded mechanism.

SEALED SOURCE CONTAMINATION (Continued)

The testing frequency for start-up sources and fission detectors is based upon physical limitations in leak testing. For example, the Californium 252 start-up neutron source must be leak tested by the manufacturer remotely in a hot cell facility. Due to the physical design of this source, a six month frequency for contamination testing provides reasonable assurance that the radioactive material is properly contained.

3/4.7.6 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4.7.7 (Deleted) - INFORMATION FROM THIS SECTION RELOCATED TO THE TRM.

3/4 7.8 MAIN TURBINE BYPASS SYSTEM

The required OPERABILITY of the main turbine bypass system is consistent with the assumptions of the feedwater controller failure analysis in the cycle specific
transient analysis.

The main turbine bypass system is required to be OPERABLE to limit peak pressure in the main steam lines and to maintain reactor pressure within acceptable limits during events that cause rapid pressurization such that the Safety Limit MCPR is not exceeded. With the main turbine bypass system inoperable, continued operation is based on the cycle specific transient analysis which has been performed for the feedwater controller failure, maximum demand with bypass failure.

3/4 7.9 TURBINE ENLCOSURE MAIN STEAM LINE TUNNEL TEMPERATURE

Should a temperature greater than the limit be detected, operators will determine if there is a leak from the Main Steam Line pressure boundary. Evidence of a Main Steam leak includes, but is not limited to:

- An unexpected sudden rise in tunnel temperature,
- An unexpected increase in radiation monitor readings,
- An unexpected rise in TE sump levels,
- An unexpected decrease in plant electrical output, or
- Visual and sound indications.

If a Main Steam Line pressure boundary leak is detected, a plant shutdown is required. Pressure boundary leakage includes ASME SSC(s). Leakage past gaskets, packing, and seals is not pressure boundary leakage.

3/4.8.1, 3/4.8.2, and 3/4.8.3 A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS

The OPERABILITY of the A.C. and D.C. power sources and associated distribution systems during operation ensures that sufficient power will be available to supply the safety-related equipment required for (1) the safe shutdown of the facility and (2) the mitigation and control of accident conditions within the facility. The minimum specified independent and redundant A.C. and D.C. power sources and distribution systems satisfy the requirements of General Design Criterion 17 of Appendix A to 10 CFR Part 50.

An offsite power source consists of all breakers, transformers, switches, interrupting devices, cabling, and controls required to transmit power from the offsite transmission network to the onsite Class 1E emergency bus or buses. The determination of the OPERABILITY of an offsite source of power is dependent upon grid and plant factors that, when taken together, describe the design basis calculation requirements for voltage regulation. The combination of these factors ensures that the offsite source(s), which provide power to the plant emergency buses, will be fully capable of supporting the equipment required to achieve and maintain safe shutdown during postulated accidents and transients.

The plant factors consist of the status of the Startup Transformer (#10 and #20) load tap changers (LTCs), the status of the Safeguard Transformer (#101 and #201) load tap changers (LTCs), and the alignment of emergency buses on the Safeguard Buses (101-Bus and 201-Bus). For an offsite source to be considered operable, both of its respective LTCs (#10 AND #101 for the source to the 101-Bus, #20 AND #201 for the source to the 201-Bus) must be in service, and in automatic. For the third offsite source (from 66 kV System) to be considered operable, the connected Safeguard Transformer (#101 or #201) LTC must be in service and in automatic. There is a dependency between the alignment of the emergency buses and the allowable post contingency voltage drop percentage.

The grid factors consist of actual grid voltage levels (real time) and the post trip contingency voltage drop percentage value.

The minimum offsite source voltage levels are established by the voltage regulation calculation. The transmission system operator (TSO) will notify LGS when an agreed upon limit is approached.

The post trip contingency percentage voltage drop is a calculated value determined by the TSO that would occur as a result of the tripping of one of the Limerick generators. The TSO will notify LGS when an agreed upon limit is exceeded. The voltage regulation calculation establishes the acceptable percentage voltage drop based upon plant configuration; the acceptable value is dependent upon plant configuration.

Due to the 20 Source being derived from the tertiary of the 4A and 4B transformer, its operability is influenced by both the 230 kV system and the 500 kV system. The 10 Source operability is only influenced by the 230 kV system.

3/4.8.1, 3/4.8.2, and 3/4.8.3 A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS

The anticipated post trip contingency voltage drop for the 66 kV Source (Transformer 80) is calculated to be less than the 230 kV and 500 kV systems. This is attributed to the electrical distance between the output of the Limerick generators and the input to the 80 transformer. Additionally, the Unit Auxiliary Buses do not transfer to the 80 transformer; this provides margin to the calculated post trip contingency voltage drop limit.

There are various means of hardening the 10 and 20 Sources to obtain additional margin to the post trip contingency voltage drop limits. These means include, but are not limited to, source alignment of the 4 kV buses, preventing transfer of 13 kV buses, limiting transfer of selected 13 kV loads, and operation with 13 kV buses on the offsite sources. The specific post trip contingency voltage drop percentage limits for these alignments are identified in the voltage regulation calculation, and controlled via plant procedures. There are also additional restrictions that can be applied to these limits in the event that an LTC is taken to manual, or if the bus alignment is outside the Two Source rule set.

LGS unit post trip contingency voltage drop percentage calculations are performed by the PJM Energy Management System (EMS). The PJM EMS consists of a primary and backup system. LGS will be notified if the real time contingency analysis capability of PJM is lost. Upon receipt of this notification, LGS is to request PJM to provide an assessment of the current condition of the grid based on the tools that PJM has available. The determination of the operability of the offsite sources would consider the assessment provided by PJM and whether the current condition of the grid is bounded by the grid studies previously performed for LGS.

Based on specific design analysis, variations to any of these parameters can be determined, usually at the sacrifice of another parameter, based on plant conditions. Specifics regarding these variations must be controlled by plant procedures or by operability determinations, backed by specific design calculations.

The ACTION requirements specified for the levels of degradation of the power sources provide restriction upon continued facility operation commensurate with the level of degradation. The OPERABILITY of the power sources are consistent with the initial condition assumptions of the safety analyses and are based upon maintaining at least two of the onsite A.C. and the corresponding D.C. power sources and associated distribution systems OPERABLE during accident conditions coincident with an assumed loss-of-offsite power and single failure of the other onsite A.C. or D.C. source. At least two onsite A.C. and their corresponding D.C. power sources and distribution systems providing power for at least two ECCS divisions (1 Core Spray loop, 1 LPCI pump and 1 RHR pump in suppression pool cooling) are required for design basis accident mitigation as discussed in UFSAR Table 6.3-3.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

Onsite A.C. operability requirements for common systems such as CREFAS, SGTS, RHRSW and ESW are addressed in the appropriate system specification action statements.

A.C. Sources

As required by Specification 3.8.1.1, Action e, when one or more diesel generators are inoperable, there is an additional ACTION requirement to verify that all remaining required systems, subsystems, trains, components, and devices, that depend on the OPERABLE diesel generators as a source of emergency power, are also OPERABLE. The LPCI mode of the RHR system is considered a four train system, of which only two trains are required. The verification for LPCI is not required until two diesel generators are inoperable. This requirement is intended to provide assurance that a loss-of-offsite power event will not result in a complete loss of safety function of critical systems during the period when one or more of the diesel generators are inoperable. The term verify as used in this context means to administratively check by examining logs or other information to determine if certain components are out-of-service for maintenance or other reasons. It does not mean to perform the surveillance requirements needed to demonstrate the OPERABILITY of the component.

Specification 3.8.1.1, Action j, prohibits the application of Specification 3.0.4.b to an inoperable diesel generator. There is an increased risk associated with entering an OPERATIONAL CONDITION or other specified condition in the Applicability with an inoperable diesel generator subsystem and the provisions of Specification 3.0.4.b, which allow entry into an OPERATIONAL CONDITION or other specified condition in the Applicability with the Limiting Condition for Operation not met after performance of a risk assessment addressing inoperable systems and components, should not be applied in this circumstance.

If it can be determined that the cause of the inoperable EDG does not exist on the remaining operable EDG(s), based on a common-mode evaluation, then the EDG start test (SR 4.8.1.1.2.a.4) does not have to be performed. If it cannot otherwise be determined that the cause of the initial inoperable EDG does not exist on the remaining EDG(s), then satisfactory performance of the start test suffices to provide assurance of continued operability of the remaining EDG(s). If the cause of the initial inoperability exists on the remaining operable EDG(s), the EDG(s) shall be declared inoperable upon discovery and the appropriate action statement for multiple inoperable EDGs shall be entered. In the event the inoperable EDG is restored to operable status prior to completing the EDG start test (SR 4.8.1.1.2.a.4) or common-mode failure evaluation as required in Specification 3.8.1.1, the plant corrective action program shall continue to evaluate the common-mode failure possibility. However, this continued evaluation is not subject to the time constraint imposed by the action statement. The provisions contained in the inoperable EDG action requirements that avoid unnecessary EDG testing are based on Generic Letter 93-05, “Line-Item Technical Specifications Improvement to Reduce Surveillance Requirements for Testing During Power Operation,” dated September 27, 1993.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

The time, voltage, and frequency acceptance criteria specified for the EDG single largest post-accident load rejection test (SR 4.8.1.1.2.e.2) are derived from Regulatory Guide 1.9, Rev. 2, December 1979, recommendations. The test is acceptable if the EDG speed does not exceed the nominal (synchronous) speed plus 75% of the difference between nominal speed and the overspeed trip setpoint, or 115% of nominal, whichever is lower. This computes to be 66.5 Hz for the LGS EDGs. The RHR pump motor represents the single largest post-accident load. The 1.8 seconds specified is equal to 60% of the 3-second load sequence interval associated with sequencing the next load following the RHR pumps in response to an undervoltage on the electrical bus concurrent with a LOCA. This provides assurance that EDG frequency does not exceed predetermined limits and that frequency stability is sufficient to support proper load sequencing following a rejection of the largest single load.

D.C. Sources

With one division with one or two battery chargers inoperable (e.g., the voltage limit of 4.8.2.1.a.2 is not maintained), the ACTIONS provide a tiered response that focuses on returning the battery to the fully charged state and restoring a fully qualified charger to OPERABLE status in a reasonable time period. Action a.1 requires that the battery terminal voltage be restored to greater than or equal to the minimum established float voltage within 2 hours. This time provides for returning the inoperable charger to OPERABLE status or providing an alternate means of restoring battery terminal voltage to greater than or equal to the minimum established float voltage. Restoring the battery terminal voltage to greater than or equal to the minimum established float voltage provides good assurance that, within 18 hours, the battery will be restored to its fully charged condition (Action a.2) from any discharge that might have occurred due to the charger inoperability.

A discharged battery having terminal voltage of at least the minimum established float voltage indicates that the battery is on the exponential charging current portion (the second part) of its recharge cycle. The time to return a battery to its fully charged state under this condition is simply a function of the amount of the previous discharge and the recharge characteristic of the battery. Thus there is good assurance of fully recharging the battery within 18 hours, avoiding a premature shutdown with its own attendant risk.

If established battery terminal float voltage cannot be restored to greater than or equal to the minimum established float voltage within 2 hours, and the charger is not operating in the current-limiting mode, a faulty charger is indicated. A faulty charger that is incapable of maintaining established battery terminal float voltage does not provide assurance that it can revert to and operate properly in the current limit mode that is necessary during the recovery period following a battery discharge event that the DC system is designed for.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

If the charger is operating in the current limit mode after 2 hours that is an indication that the battery is partially discharged and its capacity margins will be reduced. The time to return the battery to its fully charged condition in this case is a function of the battery charger capacity, the amount of loads on the associated DC system, the amount of the previous discharge, and the recharge characteristic of the battery. The charge time can be extensive, and there is not adequate assurance that it can be recharged within 18 hours (Action a.2).

Action a.2 requires that the battery float current be verified for Divisions 1 and 2 as $\leq$ 2 amps, and for Divisions 3 and 4 as $\leq$ 1 amp. This indicates that, if the battery had been discharged as the result of the inoperable battery charger, it has now been fully recharged. If at the expiration of the initial 18 hour period the battery float current is not within limits this indicates there may be additional battery problems.

Action a.3 limits the restoration time for the inoperable battery charger to 7 days or in accordance with the Risk Informed Completion Time Program. This action is applicable if an alternate means of restoring battery terminal voltage to greater than or equal to the minimum established float voltage has been used (e.g., balance of plant non-Class 1E battery charger). The 7 days reflects a reasonable time to effect restoration of the qualified battery charger to OPERABLE status. Alternatively, the allowable out-of-service time can be determined in accordance with the Risk Informed Completion Time Program.

With one or more cells in one or more batteries in one division < 2.07 V, the battery cell is degraded. Per Action b.1, within 2 hours, verification of the required battery charger OPERABILITY is made by monitoring the battery terminal voltage (4.8.2.1.a.2) and of the overall battery state of charge by monitoring the battery float charge current (4.8.2.1.a.1). This assures that there is still sufficient battery capacity to perform the intended function. Therefore, with one or more cells in one or more batteries < 2.07 V, continued operation is permitted for a limited period up to 24 hours.

Division 1 or 2 with float current > 2 amps, or Division 3 or 4 with float current > 1 amp, indicates that a partial discharge of the battery capacity has occurred. This may be due to a temporary loss of a battery charger or possibly due to one or more battery cells in a low voltage condition reflecting some loss of capacity. Per Action b.2, within 2 hours verification of the required battery charger OPERABILITY is made by monitoring the battery terminal voltage.

Since Actions b.1 and b.2 only specify "perform," a failure of 4.8.2.1.a.1 or 4.8.2.1.a.2 acceptance criteria does not result in this Action not being met. However, if one of the Surveillance Requirements is failed the appropriate Action(s), depending on the cause of the failures, is also entered.

If the Action b.2 condition is due to one or more cells in a low voltage condition but still greater than 2.07 V and float voltage is found to be satisfactory, this is not indication of a substantially discharged battery and 18 hours is a reasonable time prior to declaring the battery inoperable.

With one or more batteries in one division with one or more cells electrolyte level above the top of the plates, but below the minimum established design limits, (i.e., greater than the minimum level indication mark), the battery still retains sufficient capacity to perform the intended function. Per Action b.3, within 31 days the minimum established design limits for electrolyte level must be re-established.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

With electrolyte level below the top of the plates there is a potential for dryout and plate degradation. Action b.3 addresses this potential (as well as provisions in Specification 6.8.4.h, "Battery Monitoring and Maintenance Program"). Within 8 hours level is required to be restored to above the top of the plates. The Action requirement to verify that there is no leakage by visual inspection and the Specification 6.8.4.h item to initiate action to equalize and test in accordance with manufacturer's recommendation are taken from Annex D of IEEE Standard 450-1995. They are performed following the restoration of the electrolyte level to above the top of the plates. Based on the results of the manufacturer's recommended testing the battery may have to be declared inoperable and the affected cell(s) replaced.

Per Action b.4, with one or more batteries in one division with pilot cell temperature less than the minimum established design limits, 12 hours is allowed to restore the temperature to within limits. A low electrolyte temperature limits the current and power available. Since the battery is sized with margin, while battery capacity is degraded, sufficient capacity exists to perform the intended function and the affected battery is not required to be considered inoperable solely as a result of the pilot cell temperature not met.

Per Action b.5, with one or more batteries in more than one division with battery parameters not within limits there is not sufficient assurance that battery capacity has not been affected to the degree that the batteries can still perform their required function, given that multiple divisions are involved. With multiple divisions involved, this potential could result in a total loss of function on multiple systems that rely upon the batteries. The longer restoration times specified for battery parameters on one division not within limits are therefore not appropriate, and the parameters must be restored to within limits on all but one division within 2 hours.

When any battery parameter is outside the allowances of Actions b.1, b.2, b.3, b.4, or b.5, sufficient capacity to supply the maximum expected load requirement is not ensured and a 2 hour restoration time is appropriate. Additionally, discovering one or more batteries in one division with one or more battery cells float voltage less than 2.07 V and float current greater than limits indicates that the battery capacity may not be sufficient to perform the intended functions. The battery must therefore be restored within 2 hours.

When any batteries and/or battery chargers in two divisions of the required D.C. electrical sources are inoperable, or when two or more of the required A.C. and/or D.C. distribution system divisions are not energized resulting in a loss of function, the unit must be brought to an OPERATIONAL CONDITION in which the LCO does not apply. To achieve this status, the plant must be brought to at least HOT SHUTDOWN within 12 hours and to COLD SHUTDOWN within 36 hours. The allowed times are reasonable, based on operating experience, to reach the required plant conditions from full power conditions in an orderly manner and without challenging plant systems.

The OPERABILITY of the minimum specified A.C. and D.C. power sources and associated distribution systems during shutdown and refueling ensures that (1) the facility can be maintained in the shutdown or refueling condition for extended time periods and (2) sufficient instrumentation and control capability is available for monitoring and maintaining the unit status.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

The surveillance requirements for demonstrating the OPERABILITY of the diesel generators are in accordance with the recommendations of Regulatory Guide 1.9, "Selection of Diesel Generator Set Capacity for Standby Power Supplies, March 10, 1971, Regulatory Guide 1.137 "Fuel-Oil Systems for Standby Diesel Generators," Revision 1, October 1979 and Regulatory Guide 1.108, "Periodic Testing of Diesel Generator Units Used as Onsite Electric Power Systems at Nuclear Power Plants," Revision 1, August 1977 except for paragraphs C.2.a(3), C.2.b, C.2.c(1), C.2.c(2), C.2.d(3) and C.2.d(4), and the periodic testing will be performed in accordance with the Surveillance Frequency Control Program. The exceptions to Regulatory Guide 1.108 allow for gradual loading of diesel generators during testing and decreased surveillance test frequencies (in response to Generic Letter 84-15). The single largest post-accident load on each diesel generator is the RHR pump.

The Surveillance Requirement for removal of accumulated water from the fuel oil storage tanks is for preventive maintenance. The presence of water does not necessarily represent failure of the Surveillance Requirement, provided the accumulated water is removed during performance of the Surveillance. Accumulated water in the fuel oil storage tanks constitutes a collection of water at a level that can be consistently and reliably measured. The minimum level at which accumulated water can be consistently and reliably measured in the fuel oil storage tank sump is 0.25 inches. Microbiological fouling is a major cause of fuel oil degradation. There are numerous bacteria that can grow in fuel oil and cause fouling, but all must have a water environment in order to survive. Removal of accumulated water from the fuel storage tanks once every (31) days eliminates the necessary environment for bacterial survival. This is the most effective means of controlling microbiological fouling. In addition, it eliminates the potential for water entrainment in the fuel oil during DG operation. Water may come from any of several sources, including condensation, ground water, rain water, contaminated fuel oil, and from breakdown of the fuel oil by bacteria. Frequent checking for and removal of accumulated water minimizes fouling and provides data regarding the watertight integrity of the fuel oil system. The Surveillance Frequencies are established by Regulatory Guide 1.137.

The surveillance requirements for demonstrating the OPERABILITY of the units batteries are in accordance with the recommendations of IEEE Standard 450-1995, "IEEE Recommended Practice for Maintenance, Testing, and Replacement of Vented Lead-Acid Batteries for Stationary Applications."

Verifying battery float current while on float charge (4.8.2.1.a.1) is used to determine the state of charge of the battery. Float charge is the condition in which the charger is supplying the continuous charge required to overcome the internal losses of a battery and maintain the battery in a charged state. The float current requirements are based on the float current indicative of a charged battery. Use of float current to determine the state of charge of the battery is consistent with IEEE-450-1995.

This Surveillance Requirement states the float current requirement is not required to be met when battery terminal voltage is less than the minimum established float voltage of 4.8.2.1.a.2. When this float voltage is not maintained the Actions of LCO 3.8.2.1, Action b., are being taken, which provide the necessary and appropriate verifications of the battery condition. Furthermore, the float current limits are established based on the float voltage range and is not directly applicable when this voltage is not maintained.

THIS PAGE INTENTIONALLY LEFT BLANK

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

Verifying, per 4.8.2.1.a.2, battery terminal voltage while on float charge for the batteries helps to ensure the effectiveness of the battery chargers, which support the ability of the batteries to perform their intended function. Float charge is the condition in which the charger is supplying the continuous charge required to overcome the internal losses of a battery and maintain the battery in a fully charged state while supplying the continuous steady state loads of the associated DC subsystem. On float charge, battery cells will receive adequate current to optimally charge the battery. The voltage requirements are based on the minimum float voltage established by the battery manufacturer (2.20 Vpc, average, or 132 V at the battery terminals). This voltage maintains the battery plates in a condition that supports maintaining the grid life (expected to be approximately 20 years).

Surveillance Requirements 4.8.2.1.b.1 and 4.8.2.1.c require verification that the cell float voltages are equal to or greater than 2.07 V.

The limit specified in 4.8.2.1.b.2 for electrolyte level ensures that the plates suffer no physical damage and maintains adequate electron transfer capability.

Surveillance Requirement 4.8.2.1.b.3 verifies that the pilot cell temperature is greater than or equal to the minimum established design limit (i.e., 60 degrees Fahrenheit). Pilot cell electrolyte temperature is maintained above this temperature to assure the battery can provide the required current and voltage to meet the design requirements. Temperatures lower than assumed in battery sizing calculations act to inhibit or reduce battery capacity.

Surveillance Requirement 4.8.2.1.d.1 verifies the design capacity of the battery chargers. According to Regulatory Guide 1.32, the battery charger supply is recommended to be based on the largest combined demands of the various steady state loads and the charging capacity to restore the battery from the design minimum charge state to the fully charged state, irrespective of the status of the unit during these demand occurrences. The minimum required amperes and duration ensures that these requirements can be satisfied.

Surveillance Requirement 4.8.2.1.d.1 requires that each battery charger be capable of supplying the amps listed for the specified charger at the minimum established float voltage for 4 hours. The ampere requirements are based on the output rating of the chargers. The voltage requirements are based on the charger voltage level after a response to a loss of AC power. This time period is sufficient for the charger temperature to have stabilized and to have been maintained for at least 2 hours.

A battery service test, per 4.8.2.1.d.2, is a special test of the battery's capability, as found, to satisfy the design requirements (battery duty cycle) of the DC electrical power system. The discharge rate and test length corresponds to the design duty cycle requirements as specified in the UFSAR.

A.C. SOURCES, D.C. SOURCES, and ONSITE POWER DISTRIBUTION SYSTEMS (Continued)

A battery performance discharge test (4.8.2.1.e and f) is a test of constant current capacity of a battery, normally done in the as found condition, after having been in service, to detect any change in the capacity determined by the acceptance test. The test is intended to determine overall battery degradation due to age and usage. Degradation (as used in 4.8.2.1.f) is indicated when the battery capacity drops more than 10% from its capacity on the previous performance test, or is below 90% of the manufacturer's rating.

Either the battery performance discharge test or the modified performance discharge test is acceptable for satisfying 4.8.2.1.e and 4.8.2.1.f; however, only the modified performance discharge test may be used to satisfy the battery service test requirements of 4.8.2.1.d.2.

3/4.8.4 ELECTRICAL EQUIPMENT PROTECTIVE DEVICES

The RPS Electric Power Monitoring System is provided to isolate the RPS bus from the RPS/UPS inverter or an alternate power supply in the event of overvoltage, undervoltage, or underfrequency. This system protects the loads connected to the RPS bus from unacceptable voltage and frequency conditions. The essential equipment powered from the RPS buses includes the RPS logic, scram solenoids, and valve isolation logic.

The Allowable Values are derived from equipment design limits, corrected for calibration and instrument errors. The trip setpoints are then determined, accounting for the remaining instrument errors (e.g., drift). The trip setpoints derived in this manner provide adequate protection and include allowances for instrumentation uncertainties, calibration tolerances, and instrument drift.

The Allowable Values for the instrument settings are based on the RPS providing power within the design ratings of the associated RPS components (e.g., RPS logic, scram solenoids). The most limiting voltage requirement and associated line losses determine the settings of the electric power monitoring instrument channels.

THIS PAGE INTENTIONALLY LEFT BLANK

3/4.9 REFUELING OPERATIONS

BASES

3/4.9.1 REACTOR MODE SWITCH

Locking the OPERABLE reactor mode switch in the Refuel position, as specified, ensures that the restrictions on control rod withdrawal and refueling platform movement during the refueling operations are properly activated. These conditions reinforce the refueling procedures and reduce the probability of inadvertent criticality, damage to reactor internals or fuel assemblies, and exposure of personnel to excessive radioactivity.

The effect of these requirements is to lock the Reactor Mode Switch in the Refuel position during refueling operations, which is defined at Limerick by our refueling procedures and only occurs during OPCON 5. Additionally, in OPCON 3 and 4 when the one rod out interlock is required to be OPERABLE to withdraw a single control rod with the Mode Switch in the Refuel Position.

A successful test of the required contact(s) of a channel relay may be performed by the verification of the change of state of a single contact of the relay. This clarifies what is an acceptable CHANNEL FUNCTIONAL TEST of a relay. This is acceptable because all of the other required contacts of the relay are verified by other Technical Specification and non-Technical Specifications tests as determined by the Surveillance Frequency Control Program.

3/4.9.2 INSTRUMENTATION

The OPERABILITY of at least two source range monitors ensures that redundant monitoring capability is available to detect changes in the reactivity condition of the core. The minimum count rate is not required when sixteen or fewer fuel assemblies are in the core. During a typical core reloading, two, three or four irradiated fuel assemblies will be loaded adjacent to each SRM to produce greater than the minimum required count rate. Loading sequences are selected to provide for a continuous multiplying medium to be established between the required operable SRMs and the location of the core alteration. This enhances the ability of the SRMs to respond to the loading of each fuel assembly. During a core un-loading, the last fuel to be removed is that fuel adjacent to the SRMs.

3/4.9.3 CONTROL ROD POSITION

The requirement that all control rods be inserted during other CORE ALTERATIONS ensures that fuel will not be loaded into a cell without a control rod.

3/4.9.4 DECAY TIME

The minimum requirement for reactor subcriticality prior to fuel movement ensures that sufficient time has elapsed to allow the radioactive decay of the short lived fission products. This decay time is consistent with the assumptions used in the accident analyses.

3/4.9.5 COMMUNICATIONS

The requirement for communications capability ensures that refueling station personnel can be promptly informed of significant changes in the facility status or core reactivity condition during movement of fuel within the reactor pressure vessel.

3/4.9.6 REFUELING PLATFORM

The OPERABILITY requirements ensure that (1) the refueling platform will be used for handling control rods and fuel assemblies within the reactor pressure vessel, (2) each hoist has sufficient load capacity for handling fuel assemblies and control rods, (3) the core internals and pressure vessel are protected from excessive lifting force in the event they are inadvertently engaged during lifting operations, and (4) inadvertent criticality will not occur due to fuel being loaded into a unrodded cell.

Inadvertent criticality is prevented by the refueling interlocks that block unacceptable operations (e.g., loading fuel into a cell with a control rod withdrawn or withdrawal of a rod from the core while the grapple is over the core and loaded with fuel). The hoist loaded values identified in Sections 4.9.6.1b and 4.9.6.1c support the refueling interlock logic by ensuring that the hoist fuel loaded switches function with a load lighter than the weight of a single fuel assembly in water. Load values represent fuel (load) on the grapple. The values of 485 +/- 50 pounds and 550 + 0, -115 pounds are both less than the weight of a single fuel assembly in water attached to the grapple. These load values ensure that as soon as a fuel assembly is grappled and lifted, the refueling interlocks (control rod block and bridge motion interlock) are enforced as required. The hoist load weighing system is compensated for mast weight to ensure that lifting of components other than fuel assemblies (e.g., blade guides) do not cause inadvertent control rod blocks or bridge motion stops.

3/4.9.7 CRANE TRAVEL - SPENT FUEL STORAGE POOL

The restriction on movement of loads in excess of the nominal weight of a fuel assembly and associated lifting device over other fuel assemblies in the storage pool ensures that in the event this load is dropped 1) the activity release will be limited to that contained in a single fuel assembly, and 2) any possible distortion of fuel in the storage racks will not result in a critical array. This assumption is consistent with the activity release assumed in the safety analyses.

3/4.9.8 and 3/4.9.9 WATER LEVEL - REACTOR VESSEL and WATER LEVEL - SPENT FUEL STORAGE POOL

The restrictions on minimum water level ensure that sufficient water depth is available to remove 99% of the assumed 10% iodine gap activity released from the rupture of an irradiated fuel assembly. This minimum water depth is consistent with the assumptions of the accident analysis.

3/4.9.10 CONTROL ROD REMOVAL

These specifications ensure that maintenance or repair of control rods or control rod drives will be performed under conditions that limit the probability of inadvertent criticality. The requirements for simultaneous removal of more than one control rod are more stringent since the SHUTDOWN MARGIN specification provides for the core to remain subcritical with only one control rod fully withdrawn.

3/4.9.11 RESIDUAL HEAT REMOVAL AND COOLANT CIRCULATION

Irradiated fuel in the shutdown reactor core generates heat during the decay of fission products and increases the temperature of the reactor coolant. This decay heat must be removed by the RHR system to maintain adequate reactor coolant temperature.

RHR shutdown cooling is comprised of four (4) subsystems which make two (2) loops. Each loop consists of two (2) motor driven pumps, a heat exchanger, and associated piping and valves. Both loops have a common suction from the same recirculation loop. Two (2) redundant, manually controlled shutdown cooling subsystems of the RHR system provide decay heat removal. Each pump discharges the reactor coolant, after circulation through the respective heat exchanger, to the reactor via the associated recirculation loop. The RHR heat exchangers transfer heat to the RHR Service Water System.

An OPERABLE RHR shutdown cooling subsystem consists of one (1) OPERABLE RHR pump, one (1) heat exchanger, and the associated piping and valves. The requirement for having one (1) RHR shutdown cooling subsystem OPERABLE ensures that 1) sufficient cooling capacity is available to remove decay heat and maintain the water in the reactor pressure vessel below 140°F, and 2) sufficient coolant circulation would be available through the reactor core to assure accurate temperature indication. Management of gas voids is important to RHR Shutdown Cooling Subsystem OPERABILITY.

The requirement to have two (2) RHR shutdown cooling subsystems OPERABLE when there is less than 22 feet of water above the reactor vessel flange ensures that a single failure of the operating loop will not result in a complete loss of residual heat removal capability. With the reactor vessel head removed and 22 feet of water above the reactor vessel flange, a large heat sink is available for core cooling. Thus, in the event of a failure of the operating RHR subsystem, adequate time is provided to initiate alternate methods capable of decay heat removal or emergency procedures to cool the core.

To meet the LCO of the two (2) subsystems OPERABLE when there is less than 22 feet of water above the reactor vessel flange, both pumps in one (1) loop or one (1) pump in each of the two (2) loops must be OPERABLE. The two (2) subsystems have a common suction source and are allowed to have a common heat exchanger and common discharge piping. Additionally, each shutdown cooling subsystem can provide the required decay heat removal capability; however, ensuring operability of the other shutdown cooling subsystem provides redundancy.

The required cooling capacity of an alternate method of decay heat removal should be ensured by verifying its capability to maintain or reduce reactor coolant temperature either by calculation (which includes a review of component and system availability to verify that an alternate decay heat removal method is available) or by demonstration. Decay heat removal capability by ambient losses can be considered in evaluating alternate decay heat removal capability.

3/4.9.11 RESIDUAL HEAT REMOVAL AND COOLANT CIRCULATION (Continued)

RHR Shutdown Cooling System piping and components have the potential to develop voids and pockets of entrained gases. Preventing and managing gas intrusion and accumulation is necessary for proper operation of the RHR shutdown cooling subsystems and may also prevent water hammer, pump cavitation, and pumping of non-condensible gas into the reactor vessel. This surveillance verifies that the RHR Shutdown Cooling System piping is sufficiently filled with water prior to placing the system in operation when in OPCON 5. The RHR Shutdown Cooling System is OPERABLE when it is sufficiently filled with water to ensure that it can reliably perform its intended function.

The RHR Shutdown Cooling System is a manually initiated mode of the RHR System that is aligned for service using system operating procedures that ensure the RHR shutdown cooling suction and discharge flow paths are sufficiently filled with water. An RHR Shutdown Cooling sub-system that is already in operation at the time of entry into the APPLICABILITY is OPERABLE. For an idle RHR Shutdown Cooling subsystem, the surveillance is met through the performance of the operating procedures that place the RHR Shutdown Cooling subsystem in service.

With the required decay heat removal subsystem(s) inoperable and the required alternate method(s) of decay heat removal not available in accordance with Action "a", additional actions are required to minimize any potential fission product release to the environment. This includes ensuring Refueling Floor Secondary Containment is OPERABLE; one (1) Standby Gas Treatment subsystem is OPERABLE; and Secondary Containment isolation capability (i.e., one (1) Secondary Containment isolation valve and associated instrumentation are OPERABLE or other acceptable administrative controls to assure isolation capability) in each associated penetration not isolated that is assumed to be isolated to mitigate radioactive releases. This may be performed as an administrative check, by examining logs or other information to determine whether the components are out of service for maintenance or other reasons. It is not necessary to perform the Surveillances needed to demonstrate the OPERABILITY of the components. If, however, any required component is inoperable, then it must be restored to OPERABLE status. In this case, the surveillance may need to be performed to restore the component to OPERABLE status. Actions must continue until all required components are OPERABLE.

If no RHR subsystem is in operation, an alternate method of coolant circulation is required to be established within one (1) hour. The Completion Time is modified such that one (1) hour is applicable separately for each occurrence involving a loss of coolant circulation.

3/4.10.1 PRIMARY CONTAINMENT INTEGRITY

The requirement for PRIMARY CONTAINMENT INTEGRITY is not applicable during the period when open vessel tests are being performed during the low power PHYSICS TESTS.

3/4.10.2 ROD WORTH MINIMIZER

In order to perform the tests required in the technical specifications it is necessary to bypass the sequence restraints on control rod movement. The additional surveillance requirements ensure that the specifications on heat generation rates and shutdown margin requirements are not exceeded during the period when these tests are being performed and that individual rod worths do not exceed the values assumed in the safety analysis.

3/4.10.3 SHUTDOWN MARGIN DEMONSTRATIONS

Performance of shutdown margin demonstrations with the vessel head removed requires additional restrictions in order to ensure that criticality does not occur. These additional restrictions are specified in this LCO.

3/4.10.4 RECIRCULATION LOOPS

This special test exception permits reactor criticality under no flow conditions and is required to perform certain startup and PHYSICS TESTS while at low THERMAL POWER levels.

3/4.10.5 OXYGEN CONCENTRATION

Relief from the oxygen concentration specifications is necessary in order to provide access to the primary containment during the initial startup and testing phase of operation. Without this access the startup and test program could be restricted and delayed.

3/4.10.6 TRAINING STARTUPS

This special test exception permits training startups to be performed with the reactor vessel depressurized at low THERMAL POWER and temperature while controlling RCS temperature with one RHR subsystem aligned in the shutdown cooling mode in order to minimize contaminated water discharge to the radioactive waste disposal system.

3/4.10.7 SPECIAL INSTRUMENTATION - INITIAL CORE LOADING

This special test exception permits relief from the requirements for a minimum count rate while loading the first 16 fuel bundles to allow sufficient source-to-detector coupling such that minimum count rate can be achieved on an SRM. This is acceptable because of the significant margin to criticality while loading the initial 16 fuel bundles.

3/4.10.8 INSERVICE LEAK AND HYDROSTATIC TESTING

This special test exception permits certain reactor coolant pressure tests to be performed in OPERATIONAL CONDITION 4 when the metallurgical characteristics of the reactor pressure vessel (RPV) or plant temperature control capabilities during these tests require the pressure testing at temperatures greater than 200°F (normally corresponding to OPERATIONAL CONDITION 3). The additionally imposed OPERATIONAL CONDITION 3 requirements for SECONDARY CONTAINMENT INTEGRITY provide conservatism in response to an operational event.

Invoking the requirement for Refueling Area Secondary Containment Integrity along with the requirement for Reactor Enclosure Secondary Containment Integrity applies the requirements for Reactor Enclosure Secondary Containment Integrity to an extended area encompassing Zones 2 and 3. Core alterations and fuel handling are prohibited in this secondary containment configuration. Drawdown and inleakage testing performed for the combined zone system alignment shall be considered adequate to demonstrate integrity of the combined zones.

Inservice hydrostatic testing and inservice leak pressure tests required by Section XI of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code are performed prior to the reactor going critical after a refueling outage. The minimum temperatures (at the required pressures) allowed for these tests are determined from the RPV pressure and temperature (P/T) limits required by LCO 3.4.6, Reactor Coolant System Pressure/Temperature Limits. These limits are conservatively based on the fracture toughness of the reactor vessel, taking into account anticipated vessel neutron fluence. With increased reactor fluence over time, the minimum allowable vessel temperature increases at a given pressure.

3/4.11.1.4 LIQUID HOLDUP TANKS

The tanks listed in this specification include all those outdoor radwaste tanks that are not surrounded by liners, dikes, or walls capable of holding the tank contents and that do not have tank overflows and surrounding area drains connected to the liquid radwaste treatment system.

Restricting the quantity of radioactive material contained in the specified tanks provides assurance that in the event of an uncontrolled release of the tanks' contents, the resulting concentrations would be less than 10 times the limits of 10 CFR Part 20, Appendix B, Table 2, Column 2, at the nearest potable water supply and the nearest surface water supply in an UNRESTRICTED AREA.

3/4.11.2.6 MAIN CONDENSER

Restricting the gross radioactivity rate of noble gases from the main condenser provides reasonable assurance that the total body exposure to an individual at the exclusion area boundary will not exceed a small fraction of the limits of 10 CFR Part 100 in the event this effluent is inadvertently discharged directly to the environment without treatment. This specification implements the requirements of General Design Criteria 60 and 64 of Appendix A to 10 CFR Part 50.
